The year 1938 witnessed the worst measles epidemic in recent times. The number of cases reported was more than two and a half times that of 1937 and twice the average of that of the preceding five years. Deaths from measles were three times that of 1936 and 1937. The epidemic was widespread over the whole continent with the exception of the New England and Pacific Coasts, which remained fairly free.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 14, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)

Medico-Legal

INSANITY AND DESERTION

Mr. Justice Langton decided on October 11 in Rushbrook *v.* Rushbrook[1] that a petition for divorce based on desertion cannot succeed if the respondent has been certified insane during the three years immediately before it is filed. The Matrimonial Causes Act, 1937, makes desertion continuously for three years before the petition a ground for divorce, but in addition to separation the respondent must also have what is called the *animus deserendi*—the intention to desert. If the respondent loses volition even for a single day he loses this *animus* and the period of desertion is interrupted. Mrs. Rushbrook was described as a case of dementia praecox, but the husband brought evidence that she had been at all times able to exercise a rational judgment upon the question of her relations with her husband. He asked the court to infer that she had a continuing *animus deserendi.* The learned judge, however, pointed to the judgment of the Master of the Rolls in Williams *v.* Williams,[2] from which he understood that it is not possible to make any inferences at all concerning the intention of a certified lunatic. This woman was under certificate for at least one year of the period necessary for the success of the petition, and the presumption that she had then no *animus* could not be rebutted by medical or other evidence.

A LEGAL ANOMALY

What a confusing state of the law! If a certified patient on leave from a mental hospital is sued for assault, negligence, or trespass, the certificate is not a final answer to the allegation; his mental condition is a matter of fact to be established by evidence. If a patient under certificate in a mental hospital attacks another patient and kills him he is put on trial, and may be found by a jury fit to plead; the relevant fact is his actual mental condition, not the existence of the certificate. A lunatic under certificate can during a lucid interval make a valid will. Why should there, in the Divorce Court alone, be an irrebuttable presumption that he is irresponsible? Every psychiatrist knows that many patients under certificate are perfectly capable of forming or maintaining an intention with reference to their marriages. Even if this were not so it is unfair that when a spouse has been a wilful deserter for a substantial period his insanity should count, against the other spouse, as a change of mind. This position must cause unjust and unnecessary hardship in many cases.

NEGLIGENCE OF A DENTAL CORPORATION

In December, 1937,[3] a lady visited the premises of the Co-operative Dental Association, Ltd., of Balloon Street, Manchester, to have an aching tooth extracted. She was advised to have all her teeth removed, and this was done. The anaesthetist then advised the dentist to tell her friends that she should be taken home as soon as possible and given medical attention. She died from pulmonary tuberculosis, although at the time of the extraction no one had any idea that she was already tuberculous. Her death was not connected with the extraction. When the association claimed their fees from her husband he refused to pay, and alleged that the dentist had been negligent in proceeding to complete the extraction in view of the patient's symptoms. The association sued the husband in the county court, but the learned judge found that the dentist had been negligent, and that the negligence of the association had continued in providing dentures at a time when the patient's mouth had been quite unfit to receive them. He therefore gave judgment for the husband with costs.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The TELEGRAPHIC ADDRESSES are.

EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*

SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Doctúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Income Tax

Naval Service—Lump-sum Gratuity

"S. P." is serving as a temporary surgeon lieutenant R.N., and is due to complete his five-year short service commission next February. If he then leaves the service the £1,000 gratuity payable will be untaxed. Will he have to pay tax thereon if he remains in the Service?

⁂ The decisions in the leading cases of lump-sum payments—Cowan *v.* Seymour and Hunter *v.* Dewhurst—lay stress on the fact that non-liability arose from the cessation of the employment. It would seem to follow that in the continuance of the employment there would not be grounds legally to remove the gratuity from the general liability that attaches to payments received for services rendered. At the same time it would clearly be inequitable for the Government to levy a tax otherwise not due because an officer had remained at his post in time of war. We suggest that our correspondent should communicate with the Admiralty Income Tax Assessor (or the Board of Inland Revenue at Somerset House), putting the facts before them and asking for their special consideration. We should be interested to learn the result. Failing other means, would it be possible to allow the present commission to lapse at the end of the five years, and rejoin a few days later?

LETTERS, NOTES, ETC.

Booklets on First Aid

The Boys' Brigade Ambulance Handbook and Manual of First Aid, by Dr. R. Leslie Ridge, and published by authority of the Brigade Executive, is a well-illustrated and compact volume of 199 pages (6d.). It deals with the usual matters included in first-aid books, and the use of thick type makes reference easy—an important point. The photographs illustrating the various types of bandage are particularly good. The clearly written section on fractured spine is accompanied by an *x*-ray picture of fracture of the cervical spine, but this particular fracture is not dealt with in the text, an omission which might be remedied in the next edition, as the mode of transport of such a case differs from that of a case of fracture of the lumbar vertebrae. The book is written in clear and unambiguous English, and should be of value to all concerned in the teaching of first aid. For those attending first-aid lectures Dr. E. S. Brawn has compiled his *Questions and Model Answers on First Aid* (George Gill and Sons; 6d.). Another help to the first-aider is *The Lecture Pocket Book* by Dr. Kenneth Black (George Gill and Sons; 1s.)—this consists of four useful coloured plates illustrating the anatomy of the body and of hints on treatment of haemorrhage and fractures.

THE ANATOMICAL AND PHYSIOLOGICAL BASIS OF PHYSICAL TRAINING[*]

BY

H. A. HARRIS, M.D., D.Sc.

Professor of Anatomy, Cambridge University

In view of the recent interest shown by the State in problems of physical education it may be profitable to consider certain anatomical and physiological facts which so far have not been given the prominence and forethought they demand. I propose to consider certain anatomical features and growth changes in the spine, the upper limb girdle, and the lower limb girdle, together with certain physiological principles in relation to posture. Agility, strength, and dexterity are useful servants but dangerous masters. Any collection of skeletons in a museum shows a high percentage of aged females and a higher percentage of adventurous inquisitive young males.

The Spine

As Ward (1876) said: "The vertebral column is a remarkable piece of mechanism. Strong enough to support several hundredweight, yet pliant and elastic: furnished with levers and muscles, by which it is bent in every direction, yet lodging an organ susceptible to injury from the slightest pressure: formed, for lightness, of a loose and reticular tissue, yet capable of sustaining, without fracture, shocks, strains, and contortions of considerable violence: this column certainly combines the most opposite qualities, and performs functions apparently incompatible."

In the infant each vertebra consists of three bony parts, a centrum and two lateral masses, separated by the neurocentral articulation, which consists of a plate of cartilage faced on both sides by a thin layer of calcified cartilage (Harris, 1933). The presence of three tissues so different in physical properties as bone, cartilage, and the intervening calcified cartilage is in itself a source of mechanical weakness in each vertebra. Active growth in size of the vertebra takes place at the neurocentral articulation (Fig. 1). The cartilage plates grow in thickness, cartilage is calcified and replaced by bone: the three constituent parts of the vertebra are carried further apart. The cartilage plates are true epiphysial plates, and are therefore subject to all those injuries and diseases which take place in the fast-growing epiphysial plates of the long bones. Bony union of the centrum and lateral masses to form the definitive vertebra by calcification and ossification of the neurocentral articulation is completed by 6 years of age.

In later childhood the spine consists of individual bony vertebrae, covered above and below by cartilage plates, and separated from one another by intervening fibrocartilages. At puberty certain changes take place. Annular epiphyses of bone appear in the cartilage plates above and below each vertebra, so that the vertebra now consists of bone, epiphysial bone, epiphysial cartilage, and calcified cartilage (Figs. 2 and 3). This increase in the heterogeneity of the tissue elements in the spine accounts for its special susceptibility to deformity and disease in puberty and adolescence. Kyphosis, lordosis, and, in particular, scoliosis appear. The vertebra with its superior and inferior epiphysial bony annuli is not consolidated by cessation of growth, calcification, and ossification of the epiphysial cartilages and final union of the annular epiphyses until about 23 to 24 years, when all growth has ceased in the long bones.

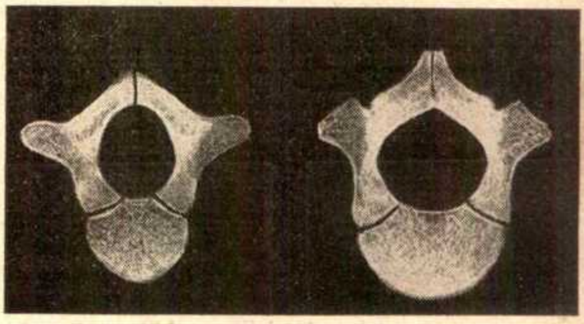

FIG. 1.—Radiograph of typical thoracic and lumbar vertebrae in the lamb to show the cartilaginous neurocentral articulation between the centrum and the right and left lateral masses. The spinal canal is larger than in the adult sheep.

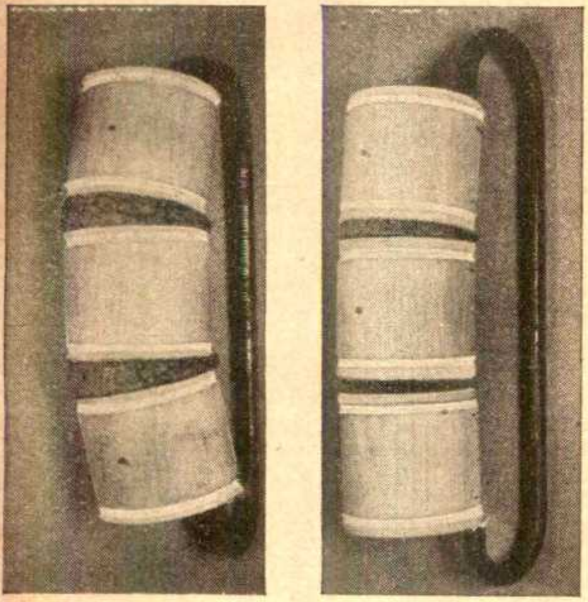
The growth in length of the spine as a whole is most rapid in the first two years of life, when it increases from eight inches to sixteen and a half inches. Growth is then fairly regular and does not show the spurts which are registered so frequently in the lower limb. The adult spine in the male approximates closely to twenty-eight and a half inches and in the female to twenty-four and a half inches. Growth in the spine is not truly proportional, but takes place at varying rates in different parts, particularly during the first seven years of life. Roughly speaking, at birth the cervical, lumbar, and sacral parts of the spine each contribute one-fifth of the total length, the dorsal or thoracic region occupying two-fifths. From birth to adult life the spine increases in length by three and a half times, but whereas the cervical region increases threefold the lumbar region increases fourfold, so that the greatest growth is in this region and is associated with the great growth in the lower limb—the skin, musculature, and joints of which are largely supplied by lumbar nerves.

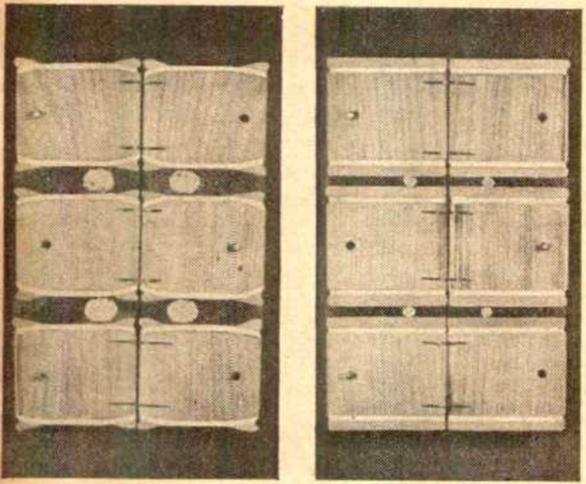
---

[*] Read in opening a discussion in the Section of Anatomy and Anthropology at the Annual Meeting of the British Medical Association, Aberdeen, 1939.



Man Sheep

FIG. 2.—Model of the lumbar vertebrae in man and sheep in the position of extension to show the relative proportions of the fibrocartilaginous disks, the vertebrae, and the bony epiphysial annuli or plates which lie above and below each vertebra with an intervening plaque of growth cartilage.



Man Sheep

FIG. 3.—The same models in section to show the increased thickness of the fibrocartilaginous disk and the reduction of the plate-like epiphysis of the sheep to an annulus in man. The nucleus pulposus is nearer the posterior surface of the vertebra and may be dislocated posteriorly.

The growth in transverse dimensions of the spine is determined essentially by the growth in the spinal cord. At 6 years of age the spinal canal is larger than in the adult and the spinal cord is almost adult in cross-section. This precocity in growth of the spinal cord determines the time of onset of calcification and ossification in the neurocentral synchondrosis. Moreover, the epiphysial rings above and below each vertebra are an index of the attempt so to modify and control the growth of the spine that spine length shall be almost constantly twenty-eight and a half inches in the male and twenty-four and a half inches in the female, in accord with a spinal cord length of eighteen inches and sixteen and a half inches respectively. This relative lack of variation in spine length in the two sexes accounts for the trade in ready-made shirts, coats, and corsets, of given length but varying girths. Throughout puberty and adolescence the spine does its utmost to reach its normal length, irrespective of stature.

The Intervertebral Disks

The intervertebral disks are more complicated in structure than the vertebrae themselves. The nucleus pulposus at the centre is essentially a remnant of the primitive notochord. This is surrounded by the annulus lamellosus, which consists of concentric lamellae of fibrous tissue, some of the fibres circular, some spiral. Above and below this element are two cartilage plates bounding the adjacent vertebrae. Some fibres are inserted into the cartilage plate, some into bone, and some into the anterior and posterior common longitudinal ligament. George Murray Humphry (1858) described the nucleus pulposus as a "fluid ball girt by surrounding bands of fibrous tissue . . . which the adjoining vertebrae rotated in their movements on one another." This ball-bearing function of the nucleus pulposus is of the utmost importance, for the disks as a whole are more susceptible to age changes and to injuries than the bony vertebrae themselves.

The growth of the intervertebral disks is extremely interesting. At birth the nucleus pulposus is small and the disk is relatively narrow. The lamellae of fibrous tissue develop after birth and are distinct entities at 6 months, when the child is first able to hold up its head. With age the fibrous rings grow at the expense of the adjoining cartilage plates. At birth approximately one-third of the total length of the spine is due to the disks, which are practically half as deep as the individual vertebrae. At 7 years of age and on to adult life the disks account for one-fifth of the total length, so that they are roughly one-quarter the depth of the vertebrae. But the thickness varies considerably in different parts of the spine. Between the shoulders, in the upper thoracic region, the disks are thin, in accord with the reduced movements of flexion and extension in the vertebrae of a region subjected to the pull of the large muscles of the head and neck and upper limb. The disk between the second and third cervical vertebrae is thinnest of all. In the lower dorsal region the disks gradually increase in thickness, reaching their maximum in the lumbar region. This is due partly to the range of movement between the neighbouring vertebrae and partly to the large area of the contiguous surfaces which naturally tends to restrict the range of movement.

From birth to adolescence the total depth of the disks increases from 0.3 in. to 0.7 in. in the cervical region, from 0.65 in. to 1.45 in. in the dorsal region, and from 0.42 in. to 1.7 in. in the lumbar region. Thus the outstanding feature of the spine in man is the great size of the lumbar vertebrae and still more the thickness of the lumbar disks. In all quadrupeds the epiphyses of the vertebrae are relatively thick plates instead of rings, and the disks are relatively thin. Only in man and the great apes are the plates reduced to rings and the lumbar disks increased so much in thickness. The range of movement and the large cross-sectional area in the lumbar and lower cervical spine are associated with the attempt to assume and maintain the erect attitude. Man alone has massive lumbar vertebrae, thick lumbar disks, annular epiphyses, huge buttocks, massive quadriceps, and long lower limbs. Even the gorilla, chimpanzee, and orang have failed to grow buttocks. It is only within recent years, as the result of the earlier isolated studies of Schmorl (1931) in Dresden, that the frequency of lesions in the intervertebral disks has been appreciated. More than 80 per cent. of these lesions are in the lumbar region, according to a recent report from the Mayo Clinic (Walsh and Love, 1939).

Most of the exercises found in the handbooks of physical training, if employed without due care and supervision, may tend to abuse these recently acquired and peculiarly human features of the spine. Toe-touching and trunk-twisting are fraught with danger, particularly at such ages and in such types of build as are characterized by relatively long legs and short arms. Mobility of the spine, like the back view of the torso, is largely an individual characteristic. The rough-and-tumble of ball games is less dangerous than squad drill or organized "jerks."

The Upper Limb

The shoulder-blade in childhood consists of two bony elements—the scapula and coracoid—separated by a band of actively growing cartilage. Thus the shoulder-joint comprises on the one hand the head of the humerus and on the other the glenoid cavity, consisting of two elements separated by an intervening band of cartilage, the scapula occupying two-thirds and the coracoid one-third. This cartilage is a growth cartilage and allows the glenoid cavity to grow in accord with the head of the humerus. In all the main joints of the body Nature attempts to provide facilities for growth by arranging that a convex surface on one bone shall articulate with a concave surface on another two or three bones, these bones being separated by a growth cartilage. Like all growth cartilages, the intra-articular ones are separated from the adjoining bone by a narrow band of calcified cartilage. It follows that the shoulder-joint of the growing child is much more complicated than that of the adult, in that the glenoid contains two bones, coracoid and scapula, and the articular cartilage overlies growth cartilage, calcified cartilage, and bone.

During puberty the growth cartilage ceases to grow, calcifies, and ossifies. It is at this age, when the scapula and coracoid are becoming firmly knit, that the muscles of the neck and upper limb display active growth. The development of the neck and chest is rapid, as is that of the biceps and triceps. The boy begins to "throw his weight about" in more senses than one.

Union of the epiphyses takes place at the elbow earlier than at the wrist and shoulder. Thus fairly heavy muscular work involving the elbow-joint, such as bench work, is more easily faced by the adolescent than heavy muscular work involving the wrist and shoulder, such as coal-mining, quarrying, and heaving. Any undue load on the musculature of the upper limb, such as frequent and persistent throwing of the cricket ball, or carrying a heavy hod of bricks up a ladder, is to be deprecated; for not only is there danger to the upper limb itself, particularly the shoulder-joint, but there is danger to the upper thoracic and cervical spine, to which are attached the muscles involving violent movements, such as the trapezius, and the muscles involving fixation, such as the rhomboids. Abuse of the upper limb muscles is a threat to the slender upper thoracic spinal column and the enclosed spinal cord.

Pelvis and Lower Limb

The sacro-iliac joint is formed by the auricular surface of the ilium and that of the sacrum. The sacral surface is complex, and consists of the bony costal elements of the first three sacral vertebrae, separated by fibrous tissue and cartilage. The ossification centre for the first and second sacral "ribs" is present before birth and that for the third "rib" appears soon after birth. At puberty a thin epiphysial bony plate appears in the cartilage on the auricular surface of the sacrum. This bony plate unites relatively late in adolescence and is associated with the late date of union of the first and second sacral vertebrae. Thus the sacro-iliac joint is definitely one in which the age changes and the number of separate elements involved are such as to call for the greatest care in its use. The common practice in secondary schools for girls to spend hours in jumping over a high rope is to be deprecated. Lastly, since the sacro-iliac joint is devoid of a cavity lined by synovial membrane it is, like almost all the vertebral joints, one which can be injured or diseased without pain becoming a cardinal symptom. The fact that pain may be absent in joints which are injured or diseased should be continually present in the minds of physical training instructors.

The hip-joint in the child displays the general rule that a joint will be formed if possible between more than two skeletal elements. The convex spherical head of the femur articulates with four other elements consisting of ilium, ischium, pubis, and the triradiate cartilage which separates the three constituent bones. In all animal forms the triradiate cartilage is a true growth cartilage and is separated from the neighbouring bones by thin strips of calcified cartilage. About puberty the growth cartilage ceases to proliferate, calcifies, and ossifies. The ossification is often patchy, and so accounts for the irregular features displayed radiologically in the cartilage by the so-called os acetabuli. Thus, from puberty to adolescence the hip-joint is even more complicated than the shoulder-joint. The bearing surface in the acetabulum, by reason of the growth at the triradiate cartilage, gives rise to many of the deformities and diseases of the pelvis. The hip-joint is often considered only in terms of the head of the femur. The hip-bone is forgotten.

Mention should be made of the cartilage at the conjoined ischio-pubic ramus, over which is attached the crura of the penis. Union of the two rami by calcification and ossification of the cartilage usually takes place at about 8 to 10 years of age. This area of union is liable to disease, and is particularly liable to injury by falls on the edge of a chair, rail, fence, gymnastic apparatus, or by jumping on to a bicycle. Such injury or disease is difficult to diagnose, and may eventually appear as an abscess in the adductor muscles or an osteomyelitis following an osteochondritis. Injury of any part of the pelvis may lead to bony union of the sacro-iliac joint on one or both sides.

The first thoracic nerve and ulnar nerve in association with cervical rib, and the fourth and fifth lumbar nerves in association with sacralization of the fifth lumbar vertebra, and several other anatomical anomalies, call for special care. Space does not permit a detailed account, but one may say that the ulnar nerve and the lower two lumbar nerves are always living dangerously.

Need for Caution in Physical Training

I do not wish to be regarded as an opponent of all forms of physical training, but the anatomical and physiological basis of such training is a subject which calls for cautious research on the part of all concerned. As Cathcart *et al.* (1935) state, no certain index of physical fitness, industrial or other, has yet been discovered. It is essential that we should ask if the boys and girls of this country are to be submitted to as expensive and unproductive a course in physical training as that to which they have been subjected in Latin and French. Many children in Wales have learnt to speak Welsh and English at home by 3 years of age without tears and without specialist teachers. Countless children have learnt to play, to work, and eventually to support themselves and a family without being subjected to lifting, throwing, hitting, gripping, swinging, bending, and twisting by numbers in regimental formation. To be born in a comfortable nest, den, or house, to have adequate food and unorganized free play—these are Nature's own essentials for physical training.

The ideal of *mens sana in corpore sano* is essentially a demand for two distinct attributes of mind and body that are not necessarily closely related. Between intelligence and common physical measurements such as height and weight there is but a low correlation, which decreases still further during adolescence. There is practically no correlation between mental intelligence tests and the physical measurements most commonly studied in children. There is a positive correlation between the mental test scores and the precocity of puberty in school children. On the other hand, slow rate of development is a peculiarly valuable human feature: apples which ripen most slowly last longest.

No two children progress towards maturity at the same pace, yet natural forces have a way of reducing the differences to some extent as maturity is approached. It is an impossible and unnecessary task to make all children conform to a standard rate of growth, to attain a standard developmental pattern or a standard physical performance test in terms of age.

Chronological age in itself is a snare, for the most developed of a group of 9-year-old children will often be more mature than the most immature of a group of 12-year-olds. Attempts at substituting skeletal age in terms of ossification of the carpus and hand, or mental age in terms of intelligence tests, are equally dangerous. Children are parts of the group in which they live, but they are also individuals who have a right to develop at their own pace.

Posture and Attitude

"Posture" is not a question of physical exercises, physical jerks, or training of the muscles. Posture is essentially the *nervous* (not *muscular*) mechanism which "keeps the world right side up for the organism by keeping the organism right side up to the external world" (Sherrington, 1906), as a result of the co-ordination of visual and labyrinthine stimuli with stimuli from the proprioceptive nerve endings in muscles, tendons, and joints. The midbrain contains the important group of centres concerned in the acquirement and maintenance of equilibrium and posture.

> "Posture is the solid foundation upon which perception is built, and it is of such pre-eminently vital importance to the animal that it is subserved almost entirely, even in Man, by a dyscritic (protopathic) mechanism. Posture is a relatively static condition, maintained indefinitely so long as circumstances remain relatively unaltered: so far it demands a plastic pose, subserved by tonic impulses and muscular contractions. Posture on the verge of change assumes a dynamic aspect and becomes an *attitude*, in which the distribution of tone in various muscles is in a sense precurrent—prepared for active movement" (Parsons, 1927).

Even attitude, posture on the verge of change, is subserved almost entirely by a protopathic mechanism.

Much of the physical drill is directed towards the acquirement of an attitude rather than the maintenance of a pose. The soldier on parade too often exhibits attitude—not posture. The maintenance of attitude involves continuous conscious endeavour. The maintenance of a natural posture is automatic and involves the minimum of mental and physical fatigue. A natural "posture" does not lead to fainting; a forced "attitude" may, as is so well known on parade or at morning prayers. If one watches a group of children playing "blind man's buff" one may see and analyse the various elements concerned in the maintenance of posture. The "righting reflexes" can be classified as:

1. Labyrinthine reflexes tending to restore the position of the head to the normal.
2. Reflexes arising in the muscles of the body wall so that, if the trunk be bent to the right, muscle tonus is increased on the left as a preparation for restoration of the trunk and head to the erect position.
3. Reflexes arising in the muscles of the neck as a result of the reflexes initiated in the labyrinth with a view to rapid restoration of the position of the head on the neck, irrespective of the position of the trunk and limbs.
4. Reflexes arising in the muscles of the trunk and limbs as a preparation for the necessary movement to maintain balance and equilibration.
5. Reflexes arising in the retinae with a view to acting on the muscles of the neck, trunk, and limbs in such a way as to retain the visual field so far as possible in its normal orientation.
6. Reflexes arising in the skin of the soles of the feet.

The extent to which the visual mechanism is concerned is clearly seen in the different movements, particularly of the upper limbs, in the blindfolded and the normal child. The effect is still more exaggerated if the ground surface becomes more rough and irregular, or if the blindfolded one is spun a few times, and even more so if the child is blind in one eye, deaf in one ear, crippled in trunk or limb, wry-necked, or suffering from cold feet. The maintenance of posture is controlled in most mammals by the midbrain. In fact, it is entirely so in the guinea-pig and rabbit. The visual cortex of the cerebrum is concerned with the ocular "righting" reflex to an increased degree as one passes from cat, dog, and monkey to man. One may regard the maintenance of posture as fundamentally a protopathic mechanism which in man has become augmented by an epicritic mechanism dependent upon the ocular reflexes and the power of binocular vision localized in the visual cortex.

In assessing alike the stance and the poise of children it is important to remember that the widely accepted appreciation of military "smartness" has no anatomical or physiological basis. Military drill is designed to make a group of different individuals look alike and act alike synchronously. It is the worship of uniform and of uniformity. Physical training should involve something distinct from regimentation. It should aim at the cultivation of the maximum efficiency consonant with the neuromuscular equipment of the individual.

The feats of daring, of physical and mental endurance, the lonely watches and the forced marches, whether at the Equator or the Poles, on the Himalayas or in the Arabian Desert, have been a product of the spirit of the British race, not of the gymnasium or the barrack square. Drake, Cook, Scott, Lawrence, and Somerville are not the product of any system of physical education or sport. Among the golden words of the English language are those in Captain Scott's farewell letter to his wife:

> " Make the boy interested in natural history if you can; it is better than games: they encourage it at some schools. I know you will keep him in the open air.
>
> " Above all, he must guard and you must guard him against indolence. Make him a strenuous man."

Bodily Habitus, Constitution, and Health

In the Report on the Primary School (Harris, 1931), when discussing the four physical types—hypersthenic, sthenic, hyposthenic, and asthenic—it was emphasized that any one type of bodily habitus and visceral topography cannot be radically altered. Concentration should be directed towards making each child efficient within his group. In view of recent attempts to classify children in terms of psychological characters in relation to bodily habitus a word of warning is necessary. There is much nonsense talked about " constitutionalism." Prejudices, beliefs, sentiments, and that authoritarianism which is the pitfall of the educationist play a large part in the prevailing fashionable beliefs. The canons of statistical sampling are rarely satisfied, and it is essential that much of the fashionable talk about the pyknic child or the asthenic child, particularly in relation to his mental and emotional qualities, should be recognized as the result of amateurism and unwarranted speculation. In a recent survey of 500 asthmatic and 500 rheumatic children in one of the large hospitals (Young, 1933) no distinct difference in anthropometric measurements or body build was found.

Mankind has always been dominated by a belief in the mental significance of particular physical features. Chaucer, Shakespeare, and Dickens have impressed upon us an association of this type. Modern playwrights, novelists, and, above all, the cinema, exaggerate it. At present there is no scientific evidence that any of the accepted criteria of the relation of mental qualities to physical traits are sound. Goring (1913) effectively destroyed the belief that the possessor of the " high brow " was more intelligent than he of the " low brow." Pearson (1906) has proved that " it is impossible to use head size as a basis for judgment as to intelligence." He proved that eye colour and hair colour are as closely related to intelligence as are head diameters.

The intelligence tests of Binet, the study of skeletal development by *x* rays, the measurement of height and weight of the body, and of the head in particular, have yielded nothing more definite than that little correlation exists between mental and physical status. On the other hand, the various attempts to correlate the type of body build with temperament have been somewhat more successful. Draper (1930) in America is of the opinion that certain types of body build are associated with a predisposition to certain diseases. Kretschmer (1925) in Germany connects body build with temperamental disposition. It is probable that Alfred Adler's (1938) theory of " organ inferiority," based upon a demonstrable physical deficiency, is the only field in which definite correlation has been proved between physique and temperament.

In short, apart from disease of the central nervous system and grave physical defects, the prevailing notions as to the relation of *mens sana* and *corpus sanum* have been grossly exaggerated. Malnutrition, poverty, dirt, and even a succession of acute or chronic diseases do not seem able, of themselves, to subdue the master organ of the body, the brain, to any considerable extent. On the other hand it is obvious that malnutrition, poverty, dirt, disease, and war do wipe out individuals, families, and races. The effect on the race or the breed should not be confused with the effect on the brain of the individual.

The psychological effects of class gymnastics have not been considered any more than the psychological effects of grooming, dress, and personal adornment. The present problem is anatomical and physiological. Growth, development, posture, like health, depend to a large extent on the freedom for the individual to join in any play, game, or sport, to exert himself according to his powers, and to know when he has had enough. Food, fun, and frolic are of more importance than drill and discipline.

Summary

The pattern of growth in the spine, upper limb, and lower limb is described.

The difference in the structure of the spine in man from that of quadrupeds is discussed in its relation to the assumption of the erect attitude in man.

Posture is considered as a nervous mechanism, and emphasis is laid on the importance of the " righting reflexes."

The fixity of bodily build or habitus in an individual is emphasized.

Food, play, and free unorganized games in early childhood are discussed in their connexion with healthy growth and physical training.

SULPHAPYRIDINE (M & B 693) AND PNEUMOCOCCAL INFECTIONS*

BY

H. L. MARRIOTT, M.D., F.R.C.P.
Assistant Physician, Middlesex Hospital

The purpose of this paper is to review briefly the main facts relating to sulphapyridine, and particularly to deal with its use in combating pneumococcal infections. Although only eighteen months have elapsed since Lionel Whitby[1] first published his discovery of the value of sulphapyridine, yet in this short time a large number of papers concerning it have been published in many countries. It is now established that sulphapyridine is a most effective agent against infections by pneumococci of all types.[1-6] In its action against the pneumococcus it represents an outstanding medical advance, for it is superior to specific antiserum and unapproached at present by any other sulphonamide compound. The chief evidence for these statements has been provided by the case series[7-26] summarized in Table I, reporting results in lobar pneumonia from various parts of the world. It has uniformly been found that the average gross mortality of cases treated with sulphapyridine is about 5 to 8 per cent., as compared with 20 to 30 per cent. in the former experience of the hospitals concerned or in control series.

TABLE I.—*Mortality of Cases of Lobar Pneumonia Treated with Sulphapyridine*

	Total of Treated Cases	Deaths
Africa :		
Agranat *et al.*[7]	98	8
Anderson and Dowdeswell[8]	50	1
Canada :		
Graham *et al.*[9]	50	3
Meakins and Hanson[10]	30	1
Denmark :		
Alsted[11]	28	1
Eldahl[12]	54	4
Hjorth[13]	28	0
Lundsteen and Mogensen[14]	39	2
Finland :		
Saltzman[15]	100	6
Great Britain :		
Anderson *et al.*[16]	70	6
Banks[17]	30	0
Dyke and Reid[18]	8	0
Evans and Gaisford[19-21]	627	34
Marriott[22]	25	0
Norway :		
Römcke and Vogt[23]	254	11
U.S.A. :		
Janney-Smith and Needles[24]	50	4
Pepper *et al.*[25 90 91]	400	28
Williams and Morgan[26]	50	1
Totals	1,991	110

Average mortality, 5.5 per cent.

These series contain patients of all ages, but no series entirely composed of children is included. In the series of Agranat *et al.* I have excluded their native miner groups as being not comparable with the other series. In these miners so excluded there were only two deaths in 172 cases.

In regard to infections by organisms other than the pneumococcus, the value of sulphapyridine relative to other sulphonamide compounds awaits final definition. Present opinion[1-6 27] suggests that: (1) it is about equal, or slightly superior, to sulphanilamide against haemolytic streptococci, meningococci,[28-33] Friedländer's bacillus, *Clostridium welchii,* and *B. coli*[34]; (2) it is the most effective of the sulphonamides against the gonococcus[35-44]; (3) it is the least ineffective against *Staphylococcus aureus*[22 45-47] and *Streptococcus viridans*[4 22 48]; (4) it may be of value against *B. typhosus,*[49] *B. pestis,*[50] and *B. influenzae.*[51] At the present time sulphapyridine is undoubtedly the drug of choice for empirical use in any fever of uncertain causation probably due to bacterial infection.[27]

Pharmacology of Sulphapyridine

Sulphapyridine is chemically 2-sulphanilyl-aminopyridine. It is a white powder, almost insoluble in water. It is, however, fairly rapidly absorbed[52-54]; the maximum blood concentration from a single dose is usually reached in about four hours. Thereafter the concentration slowly falls to zero in approximately forty-eight hours. In the blood the free form of the drug is slowly converted to the conjugated or acetylated form; the former is said to be therapeutically active, and the latter, which is even more insoluble, is said to be inactive. In twelve hours about half the sulphapyridine from a single dose is acetylated. The rate of acetylation appears to vary in different persons; it has been suggested that it may bear relation to the metabolic rate.[55] The kidneys are almost the sole channels of sulphapyridine excretion, and the free and acetylated forms are found in the urine in various amounts.[56] In the body fluids, such as cerebrospinal fluid, pleural fluid, or pus, the concentration of sulphapyridine is usually between 50 per cent. and 100 per cent. that of the blood at the same moment.[5 9 30 54 56] The ready distribution of sulphapyridine between the blood and the body fluids renders intrathecal or intrapleural administration unnecessary.

How sulphapyridine produces its remarkable effects is still unknown.[57 58] Both *in vitro* and *in vivo* there is a lag period of six hours during which organisms multiply in spite of contact with the drug. Then the organisms increasingly die off[1 2 57] from what appears to be direct action of the drug upon them.[1 2 59 60] It may be that the effect of the drug is the production of bacteriostasis, from starvation of the organisms due to inhibition of their enzymes,[57 67] and that the body does the actual killing of the invaders.[61-65] However, there does not seem as a rule to be any evidence of exceptional stimulation of the body's defence mechanisms,[57] nor indeed of interference with them.[66]

Pneumococcal Infections of the Respiratory System

As before stated, the outstanding value of sulphapyridine against the pneumococcus was first convincingly demonstrated clinically in relation to lobar pneumonia. This demonstration was achieved by Evans and Gaisford[19] following upon Whitby's discovery of the potency of sulphapyridine in the treatment of pnenumococcal infections in mice.[1] The well-defined clinical course of lobar pneumonia renders recognition of the beneficial effect of the drug easy. Many confirmatory series[7-26] and striking individual cases[59 69-74] have been published. The principal points now established concerning the sulphapyridine treatment of lobar pneumonia are:

1. The average reduction in gross mortality is such that three patients out of four who would formerly have died may now live.

2. Sulphapyridine is particularly valuable in severe cases with bacteriaemia.

3. The drug is as effective in the elderly as in the young. In persons of 50 and upwards gross mortality in the past[20 23 75 76] has usually been accepted as approaching in percentage figures the figures of the subjects' ages. In Table II are extracted from the main case series,[7-26] which give the requisite data, the mortality of all patients aged 50 or more treated with sulphapyridine. The average mortality is seen to be 16.6 per cent.

---

* Partly based on a paper prepared for the Annual Meeting of the Danish Medical Society to have been held on September 24, 1939, at Aarhus.

TABLE II.—*Mortality of Cases of Lobar Pneumonia, aged 50 or More, Treated with Sulphapyridine*

	Total of Treated Cases	Deaths
Agranat *et al.*[7]	15	1
Graham *et al.*[9]	15	3
Meakins and Hanson[10]	6	1
Alsted[11]	5	0
Eldahl[12]	14	3
Hjorth[13]	8	0
Lundsteen and Mogensen[14]	14	2
Anderson *et al.*[16]	9	3
Dyke and Reid[18]	2	0
Evans and Gaisford[19-21]	86	21
Marriott[22]	9	0
Römcke and Vogt[23]	61	8
Pepper *et al.*[25]	124	19
Totals	368	61

Average mortality, 16.6 per cent.

4. Sulphapyridine appears to be very effective against pneumococci of all types.

5. Within twenty-four to thirty-six hours of sulphapyridine being begun, irrespective of the day of the disease, the temperature falls by rapid lysis and there is usually remarkable improvement in the patient's general condition. Uneventful recovery in most cases ensues, but the local condition in the lung does not seem to undergo resolution any faster.

6. The incidence of empyema appears lessened, but clear pleural effusions are commoner. Evans and Gaisford[20] regard the latter as empyemata aborted by sulphapyridine, since in their experience the total of empyemata plus clear effusions is the same as used to obtain for empyema alone.

7. In cases of lobar pneumonia treated with sulphapyridine specific agglutinins against pneumococci develop between the fifth and twelfth days of the disease as they do in untreated cases[66]; their appearance is unaffected by the drop in temperature caused by the drug. This development of agglutinins by the body does not occur in cases effectively treated with specific anti-pneumococcus serum.[66]

The excellent results in lobar pneumonia are paralleled in the less clearly defined pneumococcal chest infections. Results in bronchitis, bronchopneumonia,[11 19 23 58] and post-operative pneumonia[68] are good.

Pneumococcal Meningitis and Peritonitis

Pneumococcal meningitis has in the past been generally considered to be invariably fatal. Sulphapyridine permits revision of the hopeless prognosis, though the condition is still to be regarded as very serious. A number of cures[77-84] and a number of failures[81 85-87] have been reported. In meningococcal meningitis sulphapyridine, like sulphanilamide, is extraordinarily successful. Not infrequently in practice the exact bacteriological diagnosis in a case of meningitis is not immediately obtainable. In all such cases, where the infecting organism is in doubt, sulphapyridine should be given[81] because not only is it the best agent against the pneumococcus, but it is as good as or better than sulphanilamide against meningococcal, streptococcal, and staphylococcal infections.

The prognosis in pneumococcal peritonitis is also likely to be very much changed for the better by sulphapyridine. Barnett and his associates[58] record three cases of pneumococcal peritonitis in children treated with sulphapyridine (one received serum too), and MacColl[88] has also published a similar case. All four recovered. Chemotherapy,[120] combined with the other recently introduced measures of gastro-duodenal suction drainage and continuous parenteral fluid administration, will enormously reduce the mortality in all forms of peritonitis.

Toxic Effects of Sulphapyridine

Dangerous toxic effects from sulphapyridine in therapeutic doses are rare.[7-26] Gaisford, Evans, and Whitelaw,[89] in more than 1,000 cases, have not met with any serious complications due to the drug. Pepper and his associates[25 90 91] have administered sulphapyridine to 500 patients without a death attributable to it.

Nausea or vomiting occurs in about half of all patients receiving sulphapyridine; the incidence is said to be less in children. In addition many patients feel depressed and languid and may have headache. These effects are unpleasant but not of serious significance. The vomiting appears most likely to be due to a central effect rather than to local gastro-irritation as was at first supposed. Cyanosis is less often seen with sulphanilamide. According to Campbell and Morgan[92] the cyanosis due to sulphapyridine is from methaemoglobinaemia and not from sulphaemoglobinaemia as with sulphanilamide. Methaemoglobinaemia does not persist as long as sulphaemoglobinaemia. If considered to be dangerous, because affecting already anoxic patients, it may be quickly abolished by the administration of methylene-blue.[9 56 92] This should very seldom be necessary.

Not strictly a toxic effect, but an effect consequent upon its insolubility, is the formation in the urine of jagged crystals or small calculi of acetylated sulphapyridine. The subject has been studied in laboratory animals.[93 94] In patients receiving sulphapyridine red cells are found in the urine in a small proportion of cases. Rarely, gross haematuria, ureteric or bladder pain, and anuria may occur.[9 12 21 25 95 98] Such effects have, however, been inconspicuous in the experience of observers of large series.[7-26] There is evidence that they are commoner in children, perhaps because of relatively larger dosage.

When sulphapyridine administration is continued beyond five days, which should not as a rule be necessary, drug fever and rashes[99 100] become unpleasant and not infrequent features. The rarer but very dangerous manifestation of granulocytopenia may also occur.[101-110] With drug fever the temperature may rise as high as 104° F. The rashes[99 100] usually resemble the rashes of measles or German measles; occasionally they are urticarial or scarlatiniform. Differential diagnosis from the mentioned specific fevers may be difficult.

Dosage and Practical Points in Administration

It is necessary in treating pneumonia to aim at securing and maintaining a blood concentration of sulphapyridine of not less than 4 mg. per 100 c.cm. In adults this level is usually achieved by a dosage of 2 grammes, followed in four hours by 2 grammes, followed by 1 gramme four-hourly.[2] What sulphapyridine does it does quickly, but at the same time too early discontinuance may lead to relapse from spread of infection. Hence, after the patient has received a total of 18 grammes on the above scheme of dosage (that is, after two and a half days) the dose should be reduced to 0.5 gramme four-hourly for twenty-four hours and then to 0.5 gramme eight-hourly for thirty-two hours—a total of 23 grammes administered on a decreasing scale during five days.

For children the dosage should be in proportion to the body weight,[19] but it is desirable to increase the dose relative to that of adults by 50 per cent. to secure adequate blood concentrations of sulphapyridine. Wilson and his collaborators[111] advise doses equivalent to twice those usually given to adults.

The estimation of sulphapyridine in the blood and body fluids is possible by relatively simple methods,[6 64 112-114] and checking of the blood level is important if there is any doubt in regard to the attainment of an adequate concentration. This may be of particular importance if there is much vomiting. The same dosage should be used whether the infection is mild or severe.[3] The tablets should be administered crushed and suspended in water, milk, or fruit juices. In general the course of treatment should be neither less nor more than five days. Less may result in incomplete cure. More brings the risk of complications,[2] and particularly the grave danger of granulocytopenia; if continuance is deemed desirable, then close watch should be kept on the skin and temperature, and blood counts should be made on alternate days.

In all cases the ordinary general measures of medical and surgical treatment should be carried out. An adequate intake of fluid is of the greatest importance to avoid urinary crystallization.[97] Five pints (2,850 c.cm.) per twenty-four hours should be taken by an adult. The urine must be measured, and an output of less than 50 oz. (1,400 c.cm.) per twenty-four hours regarded as unsatisfactory. The urine should be examined daily for blood. Liberal administration of glucose is desirable not only because of its nutritional value but because it helps to prevent nausea and vomiting. In anoxic cases oxygen administration should not be delayed; Whitehead and Carter[74] suggest that it may abolish nausea and vomiting.

Sulphapyridine is not a substitute for surgery. Collections of pus must be drained in accordance with established general principles. Vomiting is not an indication for stopping or reducing sulphapyridine. If administration is persisted with it is often found that the vomiting decreases or ceases.[2 9] If an adequate blood concentration of sulphapyridine is not being sustained, then it may be necessary to pursue administration by the rectal introduction[56] or intramuscular[84 89 117] or intravenous[118] injection of the soluble sodium salt.[3 115 116] This salt is now put up in ampoules containing 1 gramme in 3 c.cm. This amount may be given intramuscularly four-hourly. It should not be given subcutaneously because its high alkalinity causes severe pain and may induce sloughing. The technique of intravenous administration is not fully worked out; there would seem to be considerable possibilities in continuous-drip administration of dilute solutions. It might be possible to achieve rapidly and regulate accurately optimum blood levels.

When sulphapyridine is being administered it may induce photosensitivity in the patient. Hence exposure to strong natural or artificial sunlight must be avoided; such exposure may result in severe dermatitis.[101] During the time the drug is being given it is very important that other drugs with a tendency to produce granulocytopenia, such as amidopyrine, should be avoided. In conditions such as gonorrhoea sulphapyridine may sometimes unavoidably be administered to ambulant patients. Like the other sulphonamide drugs, it may produce impairment of judgment of speed and distance.[119] Patients taking it should be prohibited from driving cars or flying until two days after the last dose.

There is no antagonism between sulphapyridine and any form of associated treatment.[3] In particular there is no reason why it should not be used in conjunction with serum[121 122] or vaccines[61-64] in pneumonia or other conditions.

Summary

The main facts relating to sulphapyridine are reviewed and special attention is paid to its use in pneumococcal infections.

I wish to thank Dr. Lionel Whitby for help in the preparation of this paper.

In maintaining the flow of arms and munitions the health and well-being of the industrial worker is clearly of the utmost importance, and no single factor has greater influence than the provision for nourishing and attractive meals during the hours of work. Industrial canteens have long been established, but the conditions of war production are likely to increase their usefulness greatly and to add to the number of firms who find it necessary to make arrangements for meals during working hours. The extension of the hours of work, the increase of night shifts, difficulties in transport, "black-out" conditions, all contribute to the strain of war-time production; the evacuation of the family often includes the wife of the industrial worker, and the industrial canteen to-day not only meets the needs of the workers during work hours, but in many factories canteens are already providing facilities for breakfasts and suppers for those workers who are left without anyone in their homes to prepare these meals. How best to organize canteen facilities is the practical question which the Industrial Welfare Society has attempted to answer in a booklet, *Canteens in Industry*, issued at 1s. from 14, Hobart Place, S.W.1. Though primarily concerned with the organization of canteens in industrial concerns, most of the booklet should be no less useful to those responsible for the provision of meals in schools, hospitals, or other institutions, or to those now arranging meals for evacuated school children and mothers and for A.R.P. workers.

PRODUCTION OF ANTIGONADOTROPHIC ACTIVITY IN MAN BY INJECTION OF EXTRACT OF PREGNANT MARES' SERUM

BY

I. W. ROWLANDS, Ph.D.
National Institute for Medical Research, Hampstead

AND

A. W. SPENCE, M.A., M.D., F.R.C.P.
Assistant Physician and Cattlin Research Fellow, St. Bartholomew's Hospital

The presence of a gonadotrophic substance in the serum of mares during the second and third months of pregnancy was discovered by Cole and Hart (1930). Highly purified extracts are now prepared from this source and are used clinically for various manifestations of hypogonadotrophism. In common with gonadotrophic extracts of the anterior pituitary gland and of human urine of pregnancy, the prolonged injection of extract of pregnant mares' serum to animals of a different species from that from which the preparation originated does not cause prolonged stimulation of the reproductive organs (Meyer and Gustus, 1935). This refractoriness is caused by the appearance in the blood of inhibitory substances, which can be demonstrated by the fact that the serum of desensitized animals has the power to inhibit, in other test animals, the activity of the extract in question.

The formation of these substances in the blood as the result of prolonged treatment with gonadotrophic extracts is likely to set a limit to their use as therapeutic agents. It was observed previously, however, by Spence, Scowen, and Rowlands (1938) that the prolonged administration to human patients of extracts prepared from the urine of pregnant women did not evoke the formation of these inhibitory substances, so that treatment could be carried on indefinitely. The presence of such inhibitory substances in the blood of man treated with extract of the serum of pregnant mares does not seem to have been demonstrated, but, as will be seen below, they are undoubtedly produced. It is obvious, therefore, that to continue treatment after such substances have formed would be futile, as most, if not all, of the extract would be neutralized in the circulation. Until a level of dosage and a method of spacing the injections have been found which will not induce the formation of these inhibitory substances care must be exercised in the clinical use of extracts of pregnant mares' serum.

Methods

PRODUCTION OF ANTISERUM

Nine patients with undescended testes were injected intramuscularly with a gonadotrophic extract prepared from the serum of pregnant mares by N.V. Organon (Oss, Holland). The extract was assayed in "rat units" by the manufacturers, there being at that time no international unit. An international standard and a unit defined in terms thereof are now being established,* however, and enough information is available to allow of an approximate estimate of the activity, in international units, of the serum preparation used. The manufacturers stated that 150 μg. was equivalent to 1 "rat unit," but the dosage is recorded here in milligrammes—1 mg. being found to be approximately equal to 80 international units.

---

* See *Bulletin of the Health Organization of the League of Nations*, 1938, **7**, 894.

Three of the patients (Nos. 32, 19, and 18) were injected daily for twelve weeks with 6, 12, and 13.5 mg. respectively. The remaining six patients were divided into two groups: (*a*) three (Nos. 24, 25, and 26) who were injected with 18 mg. twice weekly for twelve weeks; and (*b*) three (Nos. 22, 23, and 27) who were injected with 36 mg. twice weekly for a similar period.

Immediately before treatment blood samples were taken from the median basilic vein, and subsequently as near as possible four, eight, ten, and twelve weeks after treatment was begun. To determine the rate of disappearance of the substance, samples were also taken, usually two, four, and eight weeks, and if necessary at a later stage, after treatment.

BIOLOGICAL ASSAY

The extract of pregnant mares' serum used in all the biological assays was the same as that employed in the production of the antisera. The extract was assayed for gonadotrophic activity by its ability to increase the weight of the ovaries of the immature rat. Groups of ten to twenty rats weighing 40 to 50 grammes were injected subcutaneously once daily for five days with different amounts of extract. The animals were killed twenty-four hours after the last injection, and their ovaries and uterus dissected, fixed in Bouin's fluid overnight, and on the following day weighed from 70 per cent. alcohol. A dose/response curve was drawn from the results, which are given in Table I. The antigonadotrophic activity of the serum was assayed by its ability to inhibit this response to the gonadotrophic extract when injected simultaneously.

TABLE I.—*Gonadotrophic Activity of the Extract of Pregnant Mares' Serum*

Number of Rats per Group	Total Amount of Extract Injected (mg.)	Average Weight of Ovaries (mg.)
10	0	10
20	0.25	33
10	0.375	56
20	0.5	91
10	0.75	131
10	1.0	203

In all tests on the inhibitory activity of the sera a standard total amount of 0.5 mg. of extract was injected. Both serum and extract were injected into groups of five immature female rats once daily for five days; injections were made into opposite flanks of each animal. The ovaries were weighed as described above. The antigonadotrophic activity of the serum was determined as follows:

An amount of serum was injected which was estimated to cause a partial reduction in the response (weight) of the ovaries to the standard amount of extract. From the dose/response curve the amount of extract was calculated which, given alone, was required to produce the same ovarian weight as that resulting from the combined injection. The difference between this calculated amount and 0.5 mg. would therefore represent the amount of extract inhibited by the quantity of serum injected into the test rat. The results are expressed throughout as the number of milligrammes inhibited by 1 c.cm. of serum.

Results

The Development of Antigonadotrophic Activity.—The results obtained are shown graphically in Figs. 1–3. No

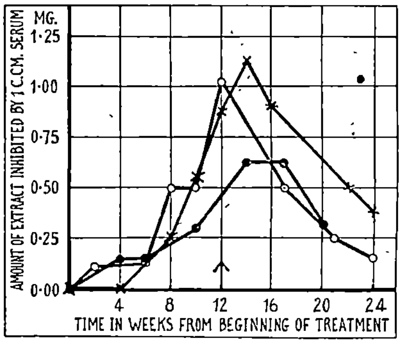

FIG. 1.—Antigonadotrophic activity of the serum of three patients injected daily with extract of pregnant mares' serum. × = patient No. 32, injected with 6 mg.; ● = patient No. 19, injected with 12 mg.; ⊙ = patient No. 18, injected with 13.5 mg.

The arrow in each figure indicates the time when treatment was stopped.

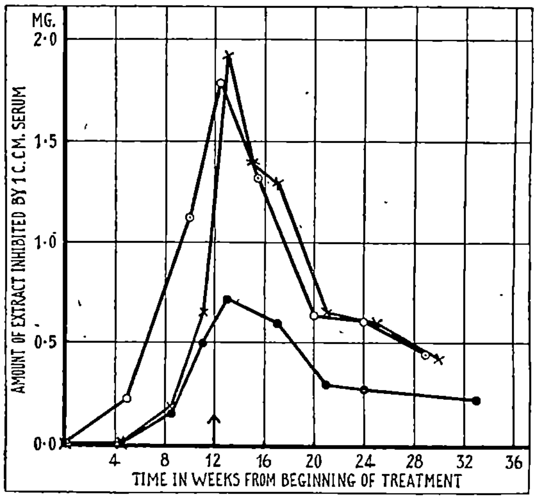

FIG. 2.—Antigonadotrophic activity of serum of three patients injected bi-weekly with 18 mg. of extract. × = No. 24; ● = No. 25; ⊙ = No. 26.

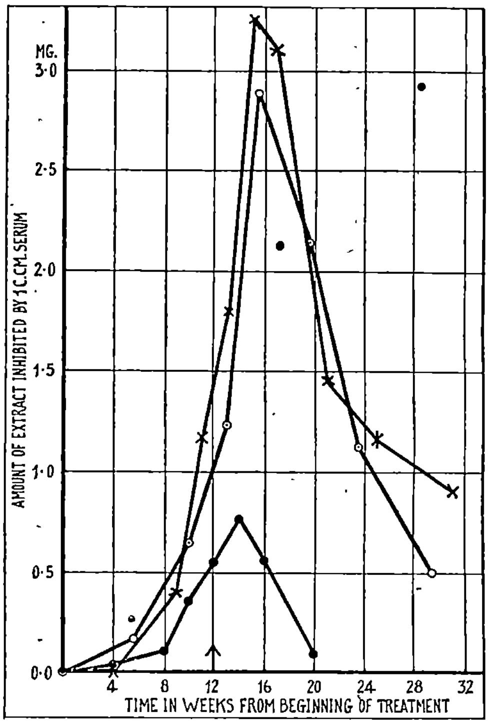

FIG. 3.—Antigonadotrophic activity of serum of three patients injected bi-weekly with 36 mg. of extract. ✱ = No. 22; ● = No. 23; ⊙ = No. 27.

antigonadotrophic activity could be detected in the serum of any of the patients before treatment began. After about six weeks' treatment, whether by daily or by twice-weekly injection, the serum of most of the patients contained some antigonadotrophic activity, which, on the whole, rapidly increased throughout the remainder of treatment. In most patients little, if any, increase in the activity occurred after the treatment was stopped. However, the activity of the serum of two patients (Nos. 22 and 27) injected with 36 mg. twice weekly continued to rise for another four weeks. One week after the end of treatment 1 c.cm. of each serum neutralized 1.8 and 1.35 mg. of extract respectively, whereas three weeks later the same amount of serum inhibited 3.3 and 2.85 mg. respectively. The total volume of serum being assumed to be 1.5 litres, it can be calculated that about 4.5 grammes of the extract would be neutralized completely by the total antigonadotrophic activity in the blood of each of these patients. Each patient had received only 0.864 gramme of extract. The antigonadotrophic substance in the circulation alone at the end of the course was therefore enough to neutralize more than five times the total quantity injected. After reaching its maximum the activity diminished, at first rapidly, but subsequently more gradually, so that in most cases it was still demonstrable three months or more after treatment was terminated.

Specificity of the Action of the Serum.—Some antigonadotrophic sera, in addition to inhibiting the action of the extracts used in their production, can also inhibit the action of gonadotrophic extracts prepared from other sources. A number of cross-reactions between various extracts and their antisera carried out by Rowlands (1938) showed that an antiserum prepared in rabbits to an extract of pregnant mares' serum was highly specific in that it inhibited only extracts prepared from this source. This specificity was also observed in the present experiments. Thus the serum of patient No. 18, at the time when it contained its maximum antigonadotrophic activity, did not neutralize the action of extracts of human pituitary tissue or human urine of pregnancy. The results are summarized in Table II, which shows that the simultaneous administration of the antiserum did not reduce the response of the ovaries of rats injected with the extracts of human origin. It is concluded, therefore, that the antigonadotrophic substance present in the blood of patients treated with extracts of pregnant mares' serum would not inhibit the gonadotrophic hormone secreted by the patients' own pituitary glands, nor is it likely to inhibit the action of gonadotrophic extracts prepared from other sources. Some proof of this was obtained clinically.

TABLE II.—*The Effect of Antiserum to Extract of Pregnant Mares' Serum on the Gonadotrophic Activity of the Human Pituitary Gland and on that of the Urine of Pregnant Women*

Extract Given	Total Amount of Extract Injected (mg.)	Serum Given	Total Amount of Serum Injected (c.cm.)	Average Weight of Ovaries (mg.)
Human pituitary gland (AP 47) -	2	—	—	40
" " "	2	No. 18	1	42
Urine of pregnancy(UP 10)	1	—	—	30
" " "	1	No. 18	1	30

Clinical Effect of Extract of Pregnant Mares' Serum.—In none of the patients was any improvement in the position of their testes observed at the end of twelve weeks' treatment. This might be due to an inherent ineffectiveness of this type of gonadotrophic extract for this condition, but it seems much more probable that it is the result of the development of refractoriness. If this were so, then the extract which was injected would almost certainly be neutralized in the blood of the patient, thus rendering it ineffective. Three months after treatment with extract of pregnant mares' serum was discontinued, treatment with bi-weekly injections of gonadotrophic extract of human urine of pregnancy (" pregnyl ") was instituted. As the majority of the patients have only just begun this form of therapy a full description must be deferred. It may be mentioned, however, that of three patients (Nos. 18, 19, and 23) who have received the full course of treatment with the urinary extract, two (Nos. 18 and 19) responded favourably, a successful result being obtained after two and four months respectively. Three other patients with undescended testes, whose blood was not assayed for antigonadotrophic activity, were treated with extract of pregnant mares' serum for twelve weeks, two patients receiving 18 mg. and one 12 mg. intramuscularly twice weekly. At the end of treatment no improvement was observed. They were then treated with extract of human urine of pregnancy without any intervening rest period between the two forms of therapy. A successful result was obtained in one patient after two and a half months.

Thus three patients who did not respond to extract of pregnant mares' serum responded subsequently to extract of human urine of pregnancy, in spite of the presence in their blood of a substance inhibitory to the former extract. This, therefore, is a further demonstration of the specificity of the antigonadotrophic substance produced by extract of pregnant mares' serum, and, although the number of cases so far is small, it suggests that extract of human urine of pregnancy is more effective than extract of pregnant mares' serum in treating this condition.

Discussion

The data recorded above provide information on two points—(*a*) the relation between amount and method of dosage and degree of antigonadotrophic activity evoked, and (*b*) the rate of disappearance of this inhibitory activity after the end of treatment. It appears that the degree of antigonadotrophic activity is not proportional to the amount of extract injected. The activity of the serum of the patients treated with bi-weekly injections was nearly twice as great as that of the patients given daily injections, although the latter received the same or even greater total amounts. Moreover, the activity of the serum of patient No. 32, who was injected daily with 6 mg. of extract, was as great as that of either of the other patients injected daily with 12 and 13.5 mg. respectively. The method of bi-weekly injections appears to be more conducive to the formation of inhibitory sera, as shown by the fact that the activity of the serum of two of the patients injected with 18 mg. of extract twice weekly was greater than that of the serum of the patients injected with 13.5 mg. daily—two and a half times the total weekly amount.

The intensification of antigonadotrophic activity after the treatment had been discontinued, such as was observed in two of the three patients who received the larger bi-weekly injection, is unusual in our experience. It is difficult to explain why it should have occurred in these patients and not in Nos. 18 and 19, who were injected with an even greater weekly amount of extract. Until further confirmation of this is forthcoming it would be premature to discuss the significance of this finding.

Summary

Antigonadotrophic activity was demonstrable in the serum of nine patients with undescended testes who were injected intramuscularly, either daily or twice weekly, for twelve weeks with an extract of the serum of pregnant mares.

The antigonadotrophic activity (*a*) developed after four to six weeks' treatment, and subsequently in most cases rose rapidly; (*b*) was not proportional to the amount of extract which was injected; (*c*) usually decreased at the end of treatment, but was still present for three months or more—in two patients, however, activity increased for about three weeks after injections were discontinued; (*d*) was greater in patients who received twice-weekly injections of extract.

The previous observation of Rowlands (1938) on the specificity of a similar antiserum, raised in rabbits, was confirmed. The human antiserum did not inhibit, in immature rats, the action of extracts of either human pituitary gland or urine of pregnancy.

No improvement in the position of the testes of the patients was observed during treatment with this extract, but in three of six patients subsequently treated with extract of urine of pregnancy descent of the testes was successfully obtained.

We desire to thank Dr. A. N. Macbeth of N.V. Organon for supplies of the extract of pregnant mares' serum and extract of human urine of pregnancy ("pregnyl").

BRONCHOGRAPHY*

BY

E. J. GILROY GLASS, M.B., F.R.C.S.Ed.

Assistant Surgeon, Ear, Nose, and Throat Department, Nottingham General Hospital; Laryngologist, City Hospital, Nottingham

Bronchoscopy has its limitations. For example, the upper lobe bronchus, except for a very small portion at its mouth, cannot be explored, and the lesser bronchi of the middle and lower lobes are too narrow to permit the passage of a bronchoscope. As pulmonary disease frequently affects just those parts which are invisible, how can this difficulty be overcome? Bronchography will, to some extent, provide a remedy. By the injection of radio-opaque oil the whole bronchial tree can be demonstrated with little or no distortion on the fluoroscopic screen. The projection of a mere shadow cannot, of course, have the accuracy of direct vision, but it is an excellent substitute. Originally it was for therapeutic reasons that lipiodol was injected into the lung by Lafay (1901). Twenty-one years later it was advocated as a contrast medium by Sicard and Forestier (1922).

Clinical Application

The importance of bronchography has developed with the advance of thoracic surgery. In bronchiectasis the smaller bronchioles beyond bronchoscopic vision are principally affected, and great scope is therefore provided for bronchography. It is upon the injection of radio-opaque oil that we must rely for confirmation of the diagnosis and for the determination of the extent of the lesion.

Neoplasms also afford a considerable field for bronchography, especially as there may be no endoscopic signs when the smaller bronchi are invaded. Now these are the cases most suitable for operation. A bronchogram demonstrating blockage of a bronchiole, taken in conjunction with clinical and other radiological signs, will make diagnosis of neoplasm possible at a stage when lobectomy holds out a good prospect of success. Investigation of an obscure shadow seen in the radiological examination of the chest may call for the determination of its relation to the bronchial tree on the one hand and the mediastinum on the other. Here a bronchogram is most helpful, particularly if bronchoscopy has been negative.

Interpretation

Nowadays lobectomy is being more frequently performed for the treatment of bronchiectasis, and the accurate interpretation of a well-taken bronchogram is essential for the success of the thoracic surgeon. In bronchiectasis the ideal case for lobectomy would be one confined to a lower lobe, and it is as well to point out here that lobectomy will fail in such a case if cavitation of the lingula has escaped recognition. Bronchography alone will avert this and enable the surgeon to deal with the lower lobe and the lingula at the same time. To investigate a case completely a series of bronchograms of both lungs is essential.

It must be realized that in the antero-posterior film the upper lobe overlaps the greater part of the lower lobe, and it may be impossible to determine whether a dilated bronchus lies in the upper, middle, or lower lobe. A lateral film is therefore a *sine qua non*, and only one lung must be delineated, otherwise the bronchial shadows of the opposite side will obscure the view. Stereoscopic pictures are difficult to obtain and have not proved of the same value in bronchography as in ordinary chest photography.

Technique

To satisfy the requirements of the surgeon the injection of radio-opaque oil must be confined to one lung, or even one lobe of a lung. There is a choice of two methods: the oil may be injected under direct vision through a bronchoscope or through a catheter inserted into the bronchial stem under fluoroscopic guidance. The bronchoscopic method has been extensively used but has drawbacks, as pointed out by C. L. Jackson and Bonnier (1937) of Philadelphia. I will quote their words: "Too much of the lipiodol was coughed out, especially in children; and often there was some delay in transportation of the patient to the *x*-ray department or in taking the picture." The instillation of lipiodol by means of a catheter passed into the trachea was first described by Iglauer (1926), and modifications of the method have been in use ever since. By this means radio-opaque oil can be delivered into any part of the bronchial tree under fluoroscopic control. The manipulation is simple and is free from danger. Attention to detail is, however, essential to success.

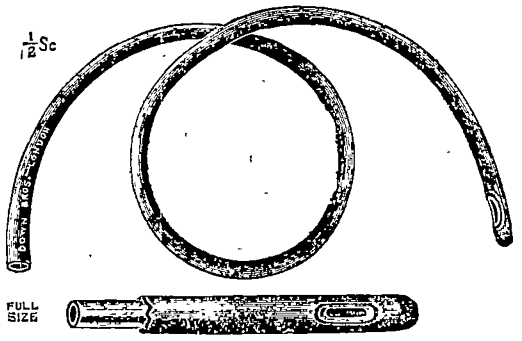
In adults the pharynx and larynx are anaesthetized with 10 per cent. cocaine or one of its substitutes. My preference is for 2 per cent. decicaine (pantocaine), which produces sufficient anaesthesia and is less toxic. A fine spray is used for the pharynx, and for the glottis either a laryngeal spray or the fractional instillation of Luken, which has the advantage of anaesthetizing the trachea and thus inhibiting the cough reflex. A soft rubber catheter

---

* Read in opening a discussion in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

(16 F gauge) is threaded on a curved stylet. The tip is passed through the glottis by indirect laryngoscopy. With the stylet *in situ* the catheter is slipped forward until some three inches have entered the trachea. The stylet is then withdrawn, and the catheter advanced till only the proximal two inches project from the mouth. At this stage there is generally some coughing, which soon subsides, but if it persists a little local anaesthetic should be injected through the catheter. This will prevent recurrence of cough when the oil is injected. The upper end of the catheter should now be anchored to the cheek with adhesive strapping and the patient transferred to the *x*-ray department.

I have found that the use of a catheter with a malleable radio-opaque tip is a great advantage in directing it by fluoroscopic guidance into the lobe chosen. Such a catheter was made for me by Messrs. Down Bros. (See Fig.) It consists of an ordinary rubber catheter into the distal two inches of which is inserted a fine lead tube with a hole corresponding to the eye of the catheter. This is very malleable and is readily detected on the fluoroscopic screen. A slight bend at the tip facilitates introduction into the selected bronchus. The technique of introduction is the same. I have found no contraindication to its use in adults.



In children the method must be modified owing to the difficulties of indirect laryngoscopy and to the risks of local anaesthesia. It is generally easy to pass a catheter through the nose to the larynx and trachea, introduction being facilitated by extension of the head and flexion of the neck. If this route is chosen the lead-tipped catheter cannot be used.

Bronchography is rarely called for in children under the age of 5, but if it has to be carried out it is better to pass the catheter by direct laryngoscopy.

The positioning of the catheter and the oil injection are controlled by fluoroscopy: 5 to 10 c.cm. will delineate a lobe; 15 to 20 c.cm. is required to outline an entire lung. The position of the patient will vary with the lobe to be dealt with. The erect posture is the most suitable for the lower and middle lobes, and for the upper lobe the patient lies on the back with the opposite shoulder raised. To exclude cavitation of the lingula the anterior part of the upper lobe has to be filled, and the patient should be rolled slightly over on the face.

The film should be made immediately after the lobe has been filled, as even one cough may so spread the oil that definition of the bronchial tree is impaired. For this reason it is advisable to make the exposure on the screening stand. Some loss of accuracy results, but compensation is found in a higher percentage of successes. If coughing has been avoided the patient can then be taken to the usual photographic unit and a second exposure made. The catheter should be left *in situ* till all necessary films have been taken. The depth of exposure is of great importance. The standard exposure is too short to provide the necessary contrast, particularly if the lesion lies behind the cardiac shadow or below the dome of the diaphragm. Increase is obtained by doubling the penetration, and, if necessary, the time also. By this method lesions have been demonstrated which were not visible in plates taken with the usual exposure. Two weeks should elapse before a second bronchogram is taken, so as to allow the lipiodol to be eliminated.

Conclusions

Bronchography is not a substitute for bronchoscopy; it is an adjuvant.

In most cases bronchoscopy should precede bronchography, but in some patients it may be advantageous to reverse the order. In young or nervous subjects, for example, the manipulations of bronchography will prepare them for the more trying ordeal of bronchoscopy.

CRATAEGUS OXYACANTHA IN HYPERTENSION

BY

JAMES D. P. GRAHAM, M.D.

(From the Institute of Physiology and the Medical Wards, Stobhill Hospital, attached to the Department of Materia Medica, University of Glasgow)

Crude extracts of hawthorn (*Crataegus oxyacantha*) have been used as a curative agent for cardiac disease, hypertension, and morbid conditions of the chest since the Middle Ages. The claims of the few who advocate the use of crataegus in such conditions have never been satisfactorily tested. The drug was introduced to medicine in Britain about 1880 by Green, a non-registered practitioner in Ireland. Subsequently it was adopted by the homoeopathic school and incorporated in their authoritative works (Assmann, 1930). In America, Jennings (1906) advocated the use of tincture of crataegus as an adjuvant to and even a substitute for digitalis in the treatment of cardiac disease, while Reilly (1910) recommended its use in cases of cardiac failure with arteriosclerosis and high blood pressure. In France it has long had a certain vogue, and Huchard (1903), Leclerc (1912), and Renon (1915) recommend the use of five minims of the tincture of hawthorn twice daily in order to keep the blood pressure of cases of hypertension within reasonable bounds.

Pharmacology

A series of investigations into the pharmacology of *Crataegus oxyacantha* was undertaken; they may be summarized as follows:

Tincture of crataegus causes sterile abscesses in guinea-pigs into which it is injected subcutaneously. Intravenous infusion of dilutions of the tincture from which the alcohol has been removed increases the gastric motility in anaesthetized guinea-pigs. The motor gradient of the isolated bowel of rabbits is reversed. In mammals intravenous infusion of similar dilutions of the tincture leads to slowing of the heart-beat, prolongation of the diastole with a tendency to idioventricular rhythm, and heart-block. The vagal centre in the medulla is stimulated, the early effects on the heart being inhibited by atropine. The isolated mammalian heart exhibits interference with the conducting system, while the avian heart reacts in a similar way to the mammalian heart. The coronary arteries of the sheep and rabbit and the pulmonary arteries and bronchi in the guinea-pig are constricted by crataegus. The carotid blood pressure of cats anaesthetized with 0.5 grain of nembutal per kilogramme of weight is profoundly depressed by 0.5 c.cm. of non-alcoholic tincture of crataegus per kilogramme of weight. This effect is unaltered by atropinization of the animal, and agrees with the findings of Martini (1932) on the blood pressure of dogs. Subcutaneous injection of tincture of crataegus has an antidiuretic effect on rats. The tincture is toxic to the liver of mammals if repeatedly administered subcutaneously, but does not induce morphological changes in the heart.

It is interesting to note the considerable similarities between the actions of tincture of crataegus and tincture of digitalis.

Pharmacy

A large volume of the tincture of *Crataegus oxyacantha* was made by macerating two kilogrammes of dry powdered whole fruits of hawthorn with 5 litres of 70 per cent. alcohol for seven days, with occasional stirrings, filtering, pressing the marc, and mixing the fluids.

This was assayed against international standard (1926) tincture of digitalis prepared from samples of leaf provided by the National Institute for Medical Research, Hampstead. Biological assay was carried out by the frog and the cat methods on tincture of crataegus from which the alcohol had been removed by maintaining a temperature of 50° C. until the volume was reduced to 20 per cent. of the original volume. The average result of these investigations was that tincture of crataegus has a potency of 14.5 per cent. of standard (1926) tincture of digitalis.

Therapeutics

With the knowledge obtained from the investigations into the pharmacology of *Crataegus oxyacantha* clinical trial of the efficacy of the tincture in cases of cardiac failure and cases of hypertension was begun. Tincture of crataegus is unpleasant to take in large quantities, but does not cause vomiting. It is rejected by the rectum even when given in considerable dilution.

Auricular Fibrillation and Cardiac Failure

In two cases of auricular fibrillation and two of mitral stenosis with orthopnoea, oedema, and tachycardia, massive dosage with tincture of crataegus was employed. Half an ounce of tincture of crataegus was administered six-hourly up to a total amount of twenty ounces in ten days. There was no improvement in the cardiac condition, and oedema advanced steadily. The drug was therefore abandoned as a competitor of digitalis, administration of which rapidly led to improvement in these same patients. The blood pressure of these cases was not affected by the treatment with crataegus.

Hypertension

A series of ten cases of men and women with high blood pressure was chosen. These were in part cases of arteriosclerosis of unknown origin, in part cases of chronic nephritis. All had old-standing hemiplegic lesions and several suffered from mild dementia. The blood pressure in the unaffected arm was recorded daily by the one observer using the same instrument. Only those cases which had been shown to have a stable blood pressure over several weeks were chosen for intensive investigation, and the blood pressure was registered daily for ten consecutive days to establish a basic or normal level for each case. Tincture of crataegus, 1 drachm three times daily in water, was then administered by mouth. The daily readings of the pressure were charted, and the drug was discontinued when it was felt that the pressure had been reduced enough. No ill effects were complained of by any of the patients as a result of this administration. In every case the systolic and diastolic pressure was reduced, often sharply, and returned to its former level some fourteen days after stopping medication. No other treatment was given, the patients being at rest in bed on a light diet. The results of the treatment with tincture of crataegus are summarized in the table and illustrated in the diagram.

Table showing the Effect of Tincture of Crataegus on the Blood Pressure in Ten Cases of Hypertension

Case No.	Age in yrs.	Diagnosis	Systolic B.P.		Diastolic B.P.		Time to Return to Initial Value (Days)
			Initial	During Crataegus Therapy	Initial	During Crataegus Therapy	
1	82	Cerebral haem.	190	150	105	90	10
2	71	„	195	150	115	80	14
3	84	Arterio-sclerosis	210	150	120	90	14
4	76	„	200	140	110	80	14
5	67	Cerebral thrombosis	200	150	100	85	12
6	65	Cerebral haem.	240	165	120	90	16
7	66	Chronic nephritis	200	175	115	100	10
8	63	„	215	160	150	90	17
9	75	„	195	110	110	70	6 (death)
10	68	„	200	150	70	55	14

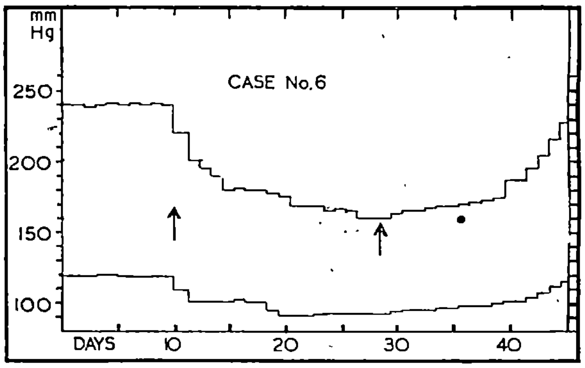

Diagram showing daily blood-pressure readings in a case of hypertension in a man, aged 65, with old-standing hemiplegia. Tincture of crataegus, half a drachm three times daily, was given during the period between arrows.

While the number of cases reviewed is small and the difficulties of adequate control in any investigation on hypertension are notorious, it is felt that a prima facie case has been made which justifies further investigation of tincture of crataegus as a depressor of the elevated blood pressure. In therapeutic doses digitalis produces slowing of the heart, promotes diuresis, and rapidly removes oedema of cardiac origin. The blood pressure in patients so treated is not affected, nor is it appreciably affected in cases of hypertension. Tincture of crataegus, on the other hand, has but little effect in slowing the heart rate, and diuresis is not induced by it. It, however, reduces elevated blood pressures, though large quantities may be taken with but little effect on the normal blood pressure. It is noteworthy that there is no sign of cumulative action, and that after cessation of the drug the blood pressure returns to its previous level.

Summary

The published work on *Crataegus oxyacantha* is briefly reviewed.

The pharmacology of crataegus is summarized and its resemblance in action to digitalis discussed.

The effect of tincture of crataegus in massive doses on cardiac failure, if there is any, is slight.

Ten cases of hypertension are reviewed and the result of treatment with 1 drachm of tincture of crataegus three times daily is shown to be that of a uniform lowering of the systolic and diastolic blood pressure.

This work was carried out with the aid of a grant from the Medical Research Council. Grateful acknowledgments are due to Professors E. P. Cathcart and N. Morris of the Departments of Physiology and Materia Medica for help and advice.

Clinical Memoranda

Treatment of Pneumonia in Children with Sulphapyridine and Vaccines

Recent evidence (experimental, not clinical) indicates that in pneumonia treatment by sulphapyridine (M & B 693) is enhanced by vaccines, because it was found that the resulting antibodies were bactericidal while the drug was merely bacteriostatic (Maclean, Rogers, and Fleming, 1939; Fleming, 1939).

CLINICAL EVIDENCE

I now submit the clinical evidence of combined sulphapyridine and vaccine treatment in fifty-two cases of pneumonia (lobar and lobular) under Dr. F. C. Eve at the Victoria Children's Hospital, Hull, during the first half of this year. These were all children between the ages of 1 and 12 years. The results have been remarkably good, as indicated by the reduction of oxygen treatment almost to *nil*. In all cases the temperature fell within three days and remained down, except in the case of one patient to whom the full dose of sulphapyridine had not been given. Sequels arose in only two cases. In one there was an empyema in an infant aged 2 years, which was due to pneumococci only; this disappeared without operation after one small aspiration (clear, according to *x*-ray examination, after six weeks). In the other case spontaneous pneumothorax occurred twice in a child aged 4 years, with complete recovery.

The average stay in hospital of these fifty-two cases was ten days and there were no deaths, whereas in the corresponding six months of 1938 ten cases of pneumonia were treated, with one death and an average stay in hospital of 16.6 days. In 1937 eleven cases were treated, with one death and an average stay in hospital of 18 days. In 1937 and 1938 vaccine treatment alone was given.

Regardless of the age of the child Wynn's vaccine was given as follows: 1/3 c.cm. on the first day; 2/3 c.cm. on the second day; 1 c.cm. on the third day. Sulphapyridine was administered in the following doses, four-hourly, and was stopped after three days' absence of fever: ¼ tablet under 6 months; ½ tablet under 2 years; ¾ tablet under 5 years; 1 tablet under 12 years.

Clear cases of bronchitis were not thus treated, but in children it is often impossible to be sure of a diagnosis on admission, and it was felt safer to treat all cases thought to be of pneumonia rather than to wait and see. In this series there was no evidence of any harmful effects from sulphapyridine except in two cases in which mild vomiting occurred, which stopped on omission of the drug, and one mild rash, which also subsided quickly.

In conclusion, our impression of sulphapyridine used in combination with Wynn's vaccine is that (1) the pneumonia is shortened; (2) the drug is entirely harmless; (3) the death rate is probably reduced; (4) it is necessary to give full doses of sulphapyridine.

My thanks are due to Dr. F. C. Eve for suggesting the publication of these cases.

DEIRDRE M. LEWIS, M.B., Ch.B.,
House-physician, Victoria Hospital for Sick Children, Hull.

A Wound of the Left Common Carotid Artery

The following case seems interesting enough to be placed on record.

An engineer aged 26 was admitted to the Willesden General Hospital on the afternoon of July 30, 1939, about twenty minutes after an accident sustained while at work. It is understood that a workmate, being of an inquiring disposition, had screwed up a boxful of phosphorus match heads in a vice, thereby producing an interesting explosion. The explosion, however, was considerably more violent than expected: a small piece of steel was projected some yards and struck the patient violently on the left side of the neck, causing him to fall unconscious. He soon recovered consciousness, and was given first-aid treatment and then removed to hospital. It is stated that there was profuse arterial bleeding.

CONDITION ON ADMISSION

On admission the patient was grey and shocked, and arterial blood was spurting from a small punctured wound over the left sterno-mastoid muscle at the level of the hyoid bone. The casualty officer, Mr. Campbell, suspected a wound of one of the major vessels, and while waiting for me applied a firm pad and bandage. When I saw the man a few minutes later he was complaining of a tight feeling in his neck and a difficulty in breathing. I removed the bandage and found that the external haemorrhage had ceased; but his symptoms continued, and it became obvious that the dyspnoea was due not to the tight bandage but to marked displacement of the larynx to the opposite side of the neck. The history and physical signs certainly suggested that the carotid artery had been punctured, and although it appeared that haemorrhage had ceased there remained a definite possibility that this might recur either when the blood pressure rose to normal or when some sudden movement was made. I concluded, therefore, that immediate exploration was the safest procedure.

OPERATION

One hour after admission operation was performed under gas-and-oxygen anaesthesia preceded by intravenous pentothal sodium. The skin edges of the wound were excised and the wound enlarged. An ill-defined track passing vertically through the sterno-mastoid muscle was visible and was very gently palpated for the presence of a metallic foreign body. The result of this manœuvre was a sudden and furious arterial haemorrhage, so severe as to indicate that either the common carotid artery or one of the main terminal branches was involved. Direct pressure through the sterno-mastoid by means of a gauze pad and two fingers gave complete control of bleeding, and while this control was kept up it was decided to try the effect of temporary ligation of the common carotid artery.

The wound was extended to the base of the neck, and the artery exposed and isolated with some difficulty owing to the presence of blood and clot both in the deeper planes of the neck and in the muscular belly of the sterno-mastoid muscle; occlusion of the vessel was accomplished and the pressure at the site of the haemorrhage was then released, with the result that haemorrhage restarted as furiously as ever. The wound was then extended up to the tip of the mastoid process, but dissection was greatly impeded owing to difficulty of access caused by the presence of the pressure pad and fingers of my assistant at the site of the original wound. Eventually this pressure had to be released while rapid dissection and swabbing enabled me to expose the bifurcation of the common carotid artery, which was the situation of the arterial wound. This was seized with a pair of artery forceps, and the common, external, and internal carotid arteries were ligatured. The wound was then closed with drainage and a blood transfusion was administered. This resulted in immediate improvement in the man's general condition, which had become rather poor towards the end of the operation.

No abnormal symptoms and signs were evident during convalescence except for a very severe occipital headache, which lasted from the fifth to the tenth day after operation, and the man was discharged from hospital on the fourteenth day.

COMMENTARY

The recurrence of severe haemorrhage at the time of operation, when only the very gentlest palpation was used, shows to what risks the man would have been subjected if a policy of wait and see had been conceived. My decision to operate, so amply justified in the end, was not taken without some hesitancy, as it seemed possible that direct pressure by a firm pad might have sufficed, although perhaps with the ultimate dangers of embolism and aneurysm. It is worthy of note, too, that at the time of operation quite gentle pressure through the sterno-mastoid against the transverse processes of the cervical spine was enough to control haemorrhage. It was also instructive to find that temporary occlusion of the common carotid artery was so completely ineffective in this case, the possible explanation being that the arterial anastomosis in young adults is very free. Temporary occlusion of the common carotid has been reported on as being very effective, so that the lack of control on this occasion was most disappointing and added greatly to our own difficulties and to the danger to the patient.

One has been taught that ligation of the common carotid artery is an operation particularly apt to be followed by hemiplegia. The hemiplegia is thought to be caused either by an immediate cerebral anaemia or by the effect of embolism. The latter hypothesis is said to be more probable because the onset of cerebral symptoms is often delayed until between the fifth and eighth days following operation, when, it is suggested, a portion of clot is washed up the internal carotid by back flow from the external carotid, the latent period having covered the establishment of an effective collateral circulation through the branches of the external carotid and the gradual extension of thrombosis from the site of ligation to the bifurcation of the common carotid.

In the case described this cycle of events obviously could not occur, as the three major vessels were ligated simultaneously, but it is interesting to note that the unexplained and severe occipital headache, while probably only a coincidence, did not become evident until the fifth day.

F. W. M. PRATT, M.S., F.R.C.S.,
Surgeon to the Willesden General Hospital.

Reviews

A FRENCH SYSTEM OF OPHTHALMOLOGY

Traité d'Ophtalmologie. Edited by P. Bailliart, C. Coutela, E. Redslob, and E. Velter. Volumes I and II. (Volume I, pp. 1,042; 755 figures; 7 plates. Volume II, pp. 1,144; 692 figures; 5 plates.) Paris: Masson et Cie. 1939.

French ophthalmology has a great tradition. During the eighteenth century it laid the basis of modern clinical practice, a brilliant galaxy of clinicians like Brisseau, de la Hire, Maître Jan, Saint-Yves, Daviel, and many others building solidly on the new anatomy and physiology that had developed in the seventeenth century following the break with Galen that the Renaissance had brought about. The dominating position of French ophthalmology can be seen from the fact that both the recognition of the nature of cataract as an opacity of the lens, and not as an effusion in front of it, and the radical treatment by extraction that is still practised to-day, were developed in France. In fact, a new pathology of ocular disease was created by this work, for it made untenable the fallacious theories concerning other lesions. In the succeeding century ophthalmology developed greatly in other centres, so that while French supremacy was no longer maintained the ophthalmology of France has always occupied an honoured and prominent position. The present system of ophthalmology, published under the auspices of the French Ophthalmological Society, is planned to run to eight volumes, and judging by the first two the effort is worthy of the great tradition behind it. The editors of the system have not confined themselves exclusively to French contributors, for a few of the hundred or so writers come from adjacent French-speaking countries like Belgium and Switzerland.

The first volume is devoted to the history of ophthalmology, the human and comparative anatomy of the eye and its adnexa, their embryology and teratology. There is also a chapter on heredity in ophthalmology. In the opening chapter, on the history of ophthalmology, Professor Villard covers this big field in a manner both concise and interesting; the information is up to date. The twelve chapters on the anatomical aspects of the eye and its adnexa cover eight hundred pages and constitute a really superb treatise, different aspects being dealt with authoritatively by different contributors. Special reference must be made to Dr. Rochon-Duvigneaud's comprehensive contribution to the comparative anatomy and physiology of the eye. This is a subject to which the author has contributed extensively, and his review leaves nothing to be desired in the way of completeness or clarity. The two concluding chapters, on heredity and teratology, by Professor Van Duyse, though excellent in themselves, do not quite maintain the high standard of the rest of this volume, for much recent work has been overlooked.

The second volume is devoted to the physiology and methods of examination of the eye. The fifteen chapters on physiology show the same modernity as the first volume—a not inconsiderable achievement in view of the rapidly changing character of this particular study. Thus in addition to the more established knowledge of physical and physiological optics there is the excellent account by Professor G. Leplat of the biological action of radiant energy on the eye. The twelve chapters on methods of examination cover fully the standard techniques and contain such newer developments as the measurement of the pressure in the retinal arteries and the photography of the eye. It would be a thankless and futile task to point out minor omissions in a work of this character. It is more gratifying to see a book of this type worthily produced—a feature in which French publications are sometimes apt to fail.

SURGICAL PATHOLOGY OF THE SPLEEN

Pathologie Chirurgicale de la Rate: By Pierre Goinard. (Pp. 174; 4 figures; 11 plates. 55 francs.) Paris: Masson et Cie. 1939.

In 1867 Péan, under the mistaken impression that he was operating for an ovarian cyst, successfully removed a cystic spleen. The author of this monograph tells us that this was the first authentic successful splenectomy, since when it was realized that an apparently normal life could be lived without the spleen. Various operations such as splenopexy and splenorrhaphy have been performed, but to-day the surgery of the spleen may be said to be almost synonymous with splenectomy. Splenectomy has contributed largely to our knowledge of the morbid anatomy of the spleen, and Goinard believes that we have now reached a stage at which stocktaking is desirable and the results of and indications for splenectomy can be set forth. Too many splenectomies have been performed and are still being practised. In a well-arranged and attractive volume, printed in large clear type which is easily read and appropriately illustrated, the author summarizes present knowledge of those diseases of the spleen which have some surgical bearing. As an indication of the lesions considered we may refer to ptosis and torsion of the splenic pedicle, contusions and rupture, wounds and hernia, abscess, tumours, cysts, the various forms of splenomegaly, particularly those encountered in the Tropics and especially the Algerian enlargement, on which the author of this volume may be said to be an acknowledged authority, and the spleen in blood diseases such as acholuric jaundice and purpura haemorrhagica.

The greater part of the book will be of interest to the surgeon: distinctions between Gaucher's and Pick-Niemann disease are perhaps of more interest to physicians or pathologists, but their inclusion serves to make this monograph more complete. The penultimate chapter deals with surgical technique, while the final chapter briefly summarizes the conclusions of the review. With the introduction of radiotherapy for splenomegalic leukaemia, liver therapy for pernicious anaemia, and chemotherapy for kala-azar, and with our wider knowledge of what may be expected from splenectomy, the operation is nowadays less often indicated, and except for purely surgical lesions such as injuries should only be considered after careful discussion between physician and surgeon. In our opinion this monograph would be an admirable aid to such discussion.

UNCONSCIOUS CAUSES OF WAR

War and Peace. Essays in Psychological Analysis. By William Brown, M.D. (Pp. 93. 5s. net.) London: A. and C. Black. 1939.

Dr. William Brown's short book on *War and Peace* consists of lectures given at Oxford and some reprinted letters to the *Times*. The substance of them will be already familiar to those who have read his other books, but the language is simpler and less technical, as is necessary if the contents are to have a general appeal. It is perhaps in some respects already out of date because last April war did not appear to him or to many others as inevitable in the near future, and his arguments are partly based on that belief, while convinced that the latest war would not be the last. As is well known, he had wide experience during the last war of the psychology of the soldier both in the field and in hospital, which gives him an advantage over the arm-chair theorist. Here he applies the results of an analysis of the general primitive tendencies of self-preservation and aggressiveness in the individual to the like tendencies in the State. His conclusions are not very different from those reached by Dr. Edward Glover in his book *War, Sadism and Pacificism,* and both authors agree that the leaders of a nation should be aware of the mental forces at work below the surface. Starting with the postulate that war and even rumours of war release emotional and irrational forces which make for more primitive methods of thought, he shows, as Wilfred Trotter did in his small masterpiece *The Instincts of the Herd,* that under those conditions the people become highly dependent upon a leader and, forsaking all others, can only hear his voice. This of course is much more marked in a totalitarian than in a democratic State, which gives an initial advantage to the former as long as the leader can show results. Dr. William Brown goes on to point out in an interesting manner that under such conditions the Freudian super-ego of the individual is for the time being virtually transferred to the leader. We are familiar with the type of mind that is happiest when it can cast all responsibility on to someone else.

It is inevitable that the author's analysis of the unconscious causes of war is more convincing than his constructive policy of peace. His amusing comments on the pugnacity of pacifists helps to explain that. The book finishes appropriately enough with an appendix on paranoia! One is left with a sensation of the near presence of that grim ἀνάγκη of Greek tragedy and Hardy's *Dynasts,* "of the working of fundamental parts of the mind not under the full control of the conscious personality." Plautus might say, "In wondrous ways the gods make sport with men," but it is for us to learn where the blame should really be laid.

PATHOGENESIS OF PERIDIVERTICULITIS

Acta Pathologica et Microbiologica Scandinavica. Contribution to the Pathological Anatomy of the Complications following "Diverticulosis Coli"—with Special Regard to the Pathogenesis of "Peridiverticulitis." By Dr. Hans Thomsen. Volume XVI, fasc. 3. (Pp. 215–345; illustrated. 1 volume (generally 4 numbers) 35 Danish crowns.) Copenhagen: Einar Munksgaard. 1939.

Dr. Hans Thomsen of Juelsminde, Denmark, published in 1934 a brochure on the symptoms and clinical recognition of inflammation in the region of diverticula of the colon. In his contribution to the pathological anatomy of the complications of diverticulosis coli he distinguishes from the chronic adhesive perisigmoiditis the forms which are due to local abscess formation in the intestinal wall or mesentery occurring as inflammatory tumours or stenoses. L. B. Wilson, who first drew attention to the subject, regarded such inflammation that occurred in the fatty connective tissue surrounding the diverticulum without traceable alterations of the diverticular wall itself as due to diffusion of bacteria and their metabolic products through the wall. This explanation appears to have been accepted by other pathologists without comment, but Thomsen, in the study of six cases, sets out a different explanation which appears more natural and probable than that stated by Wilson. By careful serial section he found that the contents of these tiny abscesses were not only polymorphonuclear leucocytes, round cells, eosinophils, and blood, but fairly numerous giant cells were found at the edges, and in several places foreign bodies in the shape of long, somewhat twined threads of cellulose. The only explanation of this picture, in which acute and chronic processes are found, can be that these multiple foreign bodies have gradually perforated the thin walls of the diverticula and thus made their way outside the lumen of the bowel; here the organism has then tried to encyst them. In some instances the reparative processes may be so strong as to enclose the foreign body in an abundant new formation of connective tissue, or a single abscess round a foreign body may perhaps perforate to the intestinal lumen and so be evacuated.

Using the analogy of the giant cells found in anal fistulae, now recognized as giant cells of foreign bodies, Thomsen offers this explanation of the pathogenesis of the inflammatory tumours found with diverticulosis. There is thus a close relationship between the inflammatory tumour or peridiverticulitis and perforation of diverticula leading either to peritonitis or to fistula into bladder or to the surface skin. The demonstration of the causative foreign bodies—splinters of vegetable cellulose—is a laborious job involving cutting serial sections of strips of the bowel wall. The author points out that the tissue must be specially hardened to bring the viscus to a state of firmness about equal to that of the foreign bodies, otherwise the sections merely present a torn appearance and make the recognition of the foreign bodies, which are sometimes not very numerous, almost impossible. Dr. Thomsen's studies open up a new and interesting field in intestinal pathology.

PHYSICAL TRAINING FOR WOMEN

Sport, Physical Training and Womanhood. By Stephan K. Westmann, M.D., L.R.C.S., L.R.C.P., L.R.F.P.S. With a foreword by Sir Kaye Le Fleming, M.D. (Pp. 222; 73 figures. 12s. 6d.) London: Baillière, Tindall and Cox. 1939.

Formerly obstetrician and lecturer in the Berlin Postgraduate School, and holding the diploma of medical officer of sport, Dr. Westmann has experience on which to base his opinions. His thesis that the whole female organism takes its cue from the gradual rise and fall of uterine contractions is perhaps rather tenuous for the weight of deduction it is asked to support. If sudden overstrained muscular activity is disastrous for the female body, can it be argued that it is any more advantageous to the male? To envisage physical training for women solely as training for child-bearing is perhaps to narrow the issue too much; but there is great value in pointing out how wrong it is to make it merely a poor imitation of that suitable for men. This teaching is emphasized again in Sir Kaye Le Fleming's foreword.

Dr. Westmann begins by inveighing against competitive sport for women. If statistics are confessedly scanty, and deductions are influenced by personal conviction, the possible bad effects of professional or excessive athletics upon the pelvis, and upon the admired type of woman, are made clear. The different kinds of physical exercise, including games, are described at length, with interesting comments. Reference is also made to the effect of manual labour in industry. The anatomical and physiological considerations as reviewed are useful, provocative, and corrective to much current practice in physical training. There are sentences, however, of surprising inaccuracy. As the premier exercise suitable for women Dr. Westmann chooses swimming, but objects to diving. He fears the sudden shock of cold water; and jumping in any form seems to be anathema to him. There are unpleasing photographs of women athletes, and attractive ones of women training for the tremendous muscular effort of confinement, and doing restorative exercises graduated from the second day of the puerperium.

The aims of physical culture are set forth in a lively last chapter, from the Greeks to Botticelli and the Olympic Games of modern Europe. Dr. Westmann looks upon exercises as "a form of provocative therapy," and part of every doctor's equipment. He insists that there is an increasing number of women with small pelves, partly due to our down-grade civilization, so that it is doubly foolish to allow faulty training to develop the masculine type of woman, the dreaded virago. Moderation in all things is the penultimate word; the final is, "Woman does not merely become Mother; rather, to this end she was born."

Certain statistics in process of collection by the National Physical Fitness Council, and experiences of women athletes, weigh in against the alarmist attitude of Dr. Westmann. But no warning about the danger of competitive sport and excessive training can be disregarded, while positive teaching on the theory and right application of the various forms of physical training for women is very welcome.

Notes on Books

The Art of Mothercraft, Part II, by Dr. Leslie Housden, is subtitled "The Study of Detail," and serves to apply the general principles laid down in the first volume of the series. The author writes attractively and accurately and, above all, with sound common sense. Parents and others interested in the care of the young will find it of much value. The section on bottle-feeding is rather inadequate, but this may be a deliberate effort to support the author's well-known enthusiasm for breast-feeding. The book is published at 1s. 6d. by the National Association of Maternity and Child Welfare Centres.

The fifth volume of *Traité de Biocolloïdologie*, by Dr. W. Kopaczewski, is entitled "The Colloid State and Medicine." Half the volume deals with the blood and the remainder with tissue fluids, sweat, urine, and the body tissues. There is an abundance of tabulated material (255 tables), and in particular the author has collected data showing the chemical composition of fluids in different species. The chapter on the physical characteristics of the blood is noteworthy because the author has done much original work on this subject. The volume contains a large mass of information, and constitutes a very useful work of reference to the chemical and physical properties of the body fluids and tissues. It is published in Paris by Gautier-Villars at 100 fr.

Professor W. Catel, with the help of seven collaborators, has produced a massive textbook on the nursing of healthy and sick children, *Die Pflege des gesunden und kranken Kindes, zugleich ein Lehrbuch der Ausbildung zur Säuglingspflegerin und Kinderkrankenschwester* (Leipzig: Georg Thieme). It is intended primarily for the nurse who is specializing in the nursing of children, but it is also intended to be of service to medical students and practitioners and to be a work of reference for mothers or students of mothercraft. It is a comprehensive work, containing long sections on normal function and structure, legal aspects, eugenic considerations, and racial matters, occupying nearly one-third of the book, before the actual details of nursing, management, and treatment of the healthy child are discussed. The remainder, just under half of the whole, is devoted to the care of the child in sickness. Concluding chapters deal with questions of diet, drug therapy, disinfection, physiotherapy, and with the prevention of accidents. Over four hundred illustrations help to make plain matters of importance, and for the most part are well reproduced. Coloured plates of certain rashes are most successfully used. The book as a whole is well planned and the details appear to be well executed. Great care has been taken with sections, such as that on the occupation of the child (games, toys, and so forth), in which most children's nurses lack specific instruction.

Surface Anatomy, by Dr. W. E. ROBERTS of Sydney, Australia (Angus and Robertson, 7s. 6d.), consists of a series of plates which have been made from photograghs of the living model. The position of the underlying structures is clearly indicated on the surface, and the captions are arranged so that they appear either on the same page as the figure or opposite to it, and it is thus unnecessary to turn over pages in order to compare text with illustrations. The legends are patterns of brevity, pertinence, and exactitude, and the only criticism we feel tempted to make is of the likelihood of an impression being conveyed of an absolute constancy in position of the organs depicted beneath the surface, which is not warranted by the findings of recent researches on normal individuals by means of *x*-ray examinations. The relative positions of certain organs are, as is well known, altered by posture, and vary with the type-form of the individual age, and the distension or contraction of certain viscera during physiological action such as occurs during respiration, ingestion of food, or with the distension of the bladder and the loss of tonicity of the muscles of the abdominal wall. A few notes and radiographs indicating the extent and direction of some of these variations, while not greatly increasing the size of the book, would add much to its practical utility and surgical interest.

Preparations and Appliances

THE VEIN-SEEKER

A Simple Instrument for Entering Collapsed Veins

Mr. F. RONALD EDWARDS, M.D., Ch.M., F.R.C.S., writes from the Department of Surgery, University of Liverpool:

Experience with the use of bottles of stored blood, with their coincident delivery apparatuses, has shown that the entering of a collapsed vein in a shocked patient with a needle attached to a tube full of blood is on many occasions no simple matter. Numerous methods have been devised to overcome this difficulty, and of these the following are the most frequently used:

1. The needle may be removed from the end of the tube and attached to a Record syringe. When the vein has been found the syringe is removed and the tube reattached. This method is "messy," and with the manipuations to fix the tube back in position the needle may be pushed out of the vein or through its opposite wall.

2. The vein may be exposed and a cannula inserted. This method, although reliable, is time-consuming, and leads to the loss of that vein for any further intravenous work.

3. A Kaufmann's syringe may be attached to the end of the delivery tube, and this utilized for finding the vein. This is a very excellent method, but the syringe is rather expensive and easily broken. Under war-time conditions, where a large number of transfusions may be proceeding at the same time, hospitals may run short of a supply of these.

The following instrument, or "vein-seeker," is simple and cheap and any hospital may have an adequate supply by the expenditure of a few shillings.

The "vein-seeker" serves two purposes; first, it helps to find and enter a difficult vein, and, secondly, it in effect brings that vein upon the surface. It consists of four pieces: (1) A stainless steel needle of fine serum size cut down to 2.5 cm. length. (2) A piece of good-quality rubber tubing 3.5 cm. long and of 4 mm. bore. (3) A piece of glass tubing with flanged ends 4 cm. long and of 4 mm. bore. (4) A rubber teat which is slipped on the glass tubing over a second piece of rubber tubing a quarter of an inch long.

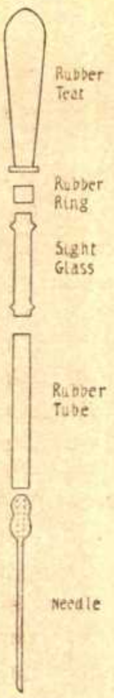

FIG. 1

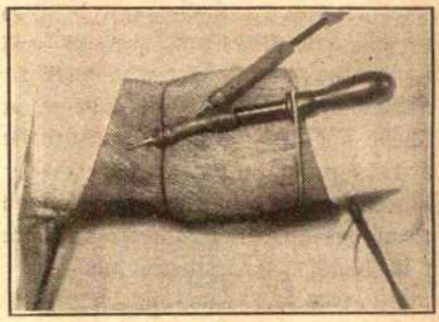

FIG. 2.

The dissected instrument is shown in Fig. 1. Fig. 2 shows the apparatus in use.

METHOD OF USE

The whole is filled with 3.8 per cent. sodium citrate solution, and the instrument held with the hand in the supinated position. The length of the instrument from the butt of the needle to the teat is four inches, and this allows the butt of the needle to be held between the index and thumb, and the teat to be compressed by the fourth and fifth fingers against the hypothenar eminence.

The teat is now compressed to empty it of citrate solution, but leaving the rest of the instrument filled. The point of the needle is inserted under the skin where the vein is suspected to be, and the pressure on the teat released. The teat remains collapsed, for air will not enter the instrument owing to the point of the needle being buried in the subcuticular tissue. The vein is now sought with the point of the needle, and as soon as it is entered the negative pressure caused by the collapsed bulb will draw blood up into the instrument, and it can be seen in the glass tube. The whole is then fixed in position by two rubber bands (which are conveniently placed beforehand on the arm, one above and one below the elbow-joint) or by two pieces of thin strapping.

The needle leading from the bottle of blood is then inserted through the rubber tubing of the seeker and the transfusion proceeds. The flexible tube in the hollow of the elbow bends if the elbow is moved and the needle does not jump out of the vein. A second safety joint is also provided where the main needle from the bottle enters the rubber tube of the seeker. The transfusion may now be safely left, and if the patient is in any way restless a splint can be fixed to the back of the arm. Thus a number of transfusions can be carried out by one person at the same time.

If a second bottle of blood is necessary for the patient this can be put into circuit by pushing the delivery needle of this second bottle into the seeker's rubber tube. Saline or gum acacia saline can similarly be given after the transfusion by the same method. The rubber tube of the seeker thus acts as an external vein and can be used time and time again. An intravenous anaesthetic or a cardiac stimulant can be given by puncturing the rubber tube with the needle of the syringe. If for any reason the needle of the seeker becomes blocked, it can be cleared by pushing a stylet through the rubber tubing and down the needle without in any way disconnecting the apparatus.

This instrument is now standardized for use in the Merseyside War Blood Bank and is distributed with each delivery apparatus. It has been made by and is obtainable from Messrs. Evans Sons Lescher and Webb, 56, Hanover Street, Liverpool, 1.

ANAESTHESIA IN WAR TIME

Organization of medical activity on a war-time basis has led to the ventilation of many problems, among them those with which anaesthetists are particularly concerned. In our correspondence columns there have been revealed surprising differences of opinion as to the best and safest methods to employ in order to ensure adequate anaesthetic services to the community. To the many practitioners who have a good working knowledge of the simple methods of anaesthesia but who have not had the opportunity to become familiar with the more modern anaesthetic agents and techniques it may well appear that much of the recent comment has obscured rather than clarified the problems in hand. Anaesthesia has seen great changes during the past few years, and the present situation has naturally become an opportunity for the airing of personal opinions upon the question of the most expedient type of anaesthesia. Individual anaesthetists have advocated their own favourite methods and have seen the chance of introducing these to wider use. Such publicity has its value in revealing developments in technique, but the wind of enthusiasm must be tempered. In some cases there has been an ill-founded prejudice for one or other method, and enough stress has not been laid on the necessity for due appreciation of the simple methods of anaesthesia. The advances that have been made have in no way diminished the importance of these methods, especially during war.

Anaesthesia will be conducted under a wider diversity of conditions during a war than in times of peace. In many of the base hospitals it will be possible to use modern equipment and the refinements of anaesthetic technique which have been developed in civilian life. The bulk of the anaesthetic work in these hospitals will be done by the specialist anaesthetist. In the less well equipped hospitals simplicity of technique will be all-important. In addition, many of the anaesthetists will be practitioners without a wide experience of anaesthesia and be suddenly called upon to do work of a scope far beyond their peace-time duties. It is essential that such men should employ methods with which they are familiar. The result of much of the recent correspondence will be to set many a conscientious practitioner wondering if he is rendering adequate service by using the methods he knows well. He can rest assured on this point. Although it is undoubtedly true that more recent anaesthetic agents and techniques have made induction of and recovery from anaesthesia more pleasant and have helped to reduce post-operative complications, ether is probably still the safest anaesthetic available. Open-drop ether might well be regarded as the standard method of anaesthesia, and competence in the administration of ether is of far more practical value than a smattering of experience of up-to-date agents. There is, however, one technique with which the practitioner should become familiar—that of endotracheal intubation. He should become familiar with the use of a laryngoscope. For cranial surgery and for plastic operations on the face and the neck endotracheal anaesthesia is essential, and for upper abdominal surgery it facilitates the maintenance of smooth uneventful anaesthesia.

It is reassuring to know that unlimited supplies of ether, ethyl chloride, and chloroform will continue to be available. With regard to drugs imported from foreign countries present stocks are estimated to be adequate for at least one year ; there may not be so wide a choice of drugs in certain groups, but in time of war individual fads and fancies are of little consequence. There need be no fear that anaesthetic services will suffer from lack of indispensable supplies. Nitrous oxide and oxygen will continue to be available in unlimited amounts. It is essential, however, that containers for these gases should circulate freely, since a shortage of containers is the only factor which might lead to any difficulty in maintaining supplies. Hospitals should therefore refrain from storing more cylinders than are necessary for normal requirements. It is advisable for stocks of nitrous oxide and oxygen for current use to be stored as far away as possible from the vital centres of a hospital, since any direct hit from a projectile in the immediate vicinity of the cylinders would result in a violent explosion.

The controversial subject of chloroform is being revived once more. Although the portability, potency, and non-explosiveness of chloroform might appear to justify its employment under emergency conditions, this drug suffers from one serious drawback. No matter how skilled an anaesthetist may be, his experience will not suffice to prevent the occasional fatality of primary cardiac failure from the action of chloroform. For this reason alone chloroform and mixtures of chloroform and ether are nowadays looked upon with disfavour by most anaesthetists in this country. We may quote three contributors to the anaesthetic series recently published in this *Journal.* Dr. C. Langton Hewer wrote, "Chloroform is an extremely toxic drug, and can cause grave metabolic changes." Dr. J. Blomfield observed that chloroform has been proved "to be potentially too dangerous for a routine anaesthetic." And the feelings of many were summed up by Dr. Helen Lukis in these words, "If only chloroform were safe it would be the ideal anaesthetic for general practice." The detached observer cannot deny that ether is able to achieve all that chloroform can achieve and with an infinitely higher degree of safety. The demerits of chloroform in relation to ether must be carefully weighed by those who still advocate the use of the former.

The problem of the shocked patient is of special importance in time of war. Where possible, restorative measures should be instituted before proceeding to extensive surgery, but in many cases anaesthesia will be needed before the shock has been overcome. Chloroform is in any case unsuitable for the shocked patient. Spinal anaesthesia is contraindicated on account of the fall in blood pressure which often accompanies it. The intravenous barbiturates, pentothal and evipan, depress the respiratory centre more markedly than do inhalational agents, and also tend to cause a fall in blood pressure. Nitrous oxide and oxygen anaesthesia, or very light ether anaesthesia, is satisfactory, and light cyclopropane anaesthesia is also suitable for the shocked patient. Cyclopropane is likely to be confined to the specialist anaesthetist; some type of closed-circuit (CO_2-absorption) apparatus is necessary in administration of this agent. It is most important to remember that any shocked patient requires much less anaesthetic to achieve a given depth of anaesthesia than he would if he were in normal health. Practical application of this fact will solve most of the difficulties of anaesthesia in shock.

VIRUSES AND CANCER

Speculation is an exercise for which there is no more fruitful field in the whole of pathology than that of virus diseases. The filterable virus itself is something which leaves a good deal of scope for the imagination; its presence and its properties can often be deduced only by indirect methods difficult of application and of no more than approximate accuracy. Although there is much which remains uncertain about viruses as a whole, including even their essential nature, they become problematic in the highest degree when they are considered as causes of cancer. Nevertheless, in spite of numerous difficulties and of gaps in the facts of the argument which can only be bridged by analogy or conjecture, a hypothesis has been built up which regards malignant disease as due directly to the presence of a virus and relegates all other known causes —notably various well-authenticated carcinogenic " irritants "—to the position of merely predisposing agents. One of the leading advocates of this bold and far-reaching idea is Dr. C. H. Andrewes, whose presidential address to the Section of Comparative Medicine of the Royal Society of Medicine (see p. 969) deals with what is perhaps its most difficult aspect. The general virus hypothesis of cancer makes it necessary to assume that the virus is latent in the body, presumably for a long period and possibly throughout life, until its cancer-producing power is set free by some other, possibly chemical, stimulus. It is therefore appropriate to inquire whether other and less hypothetical viruses are known to behave similarly. A full answer to this question is given in the first part of Dr. Andrewes's address. There are indeed many viruses which behave somewhat similarly. The viruses of influenza and poliomyelitis can infect and immunize without producing manifest disease; those of poliomyelitis, fowl-pox, and possibly others persist in the body after recovery from an attack. Still more apposite is the behaviour of two viruses in a third category, since, like the hypothetical cancer virus, they remain latent in the body without inducing full immunity. The first, the virus of herpes simplex, commonly exists in the mouth; occasionally, as was pointed out by Dr. G. M. Findlay at last week's meeting, it exists in other parts of the body; and attacks the tissues only when their resistance is diminished by other causes. The second, virus iii, is believed to be exclusively latent under natural conditions, and can only be brought into activity by successive injections of tissue suspension from one rabbit to another. That viruses can remain latent for long periods is unquestionable; on the other hand, latency is most often seen in the immune individual, and there is certainly no known example of it in which, so far from immunizing, terminates in a steadily progressive infection.

No observations made in recent years have had a more startling effect in the field of cancer research than those of Bittner, which can be used as another item in this argument. Susceptibility to cancer of the mamma in mice, previously thought to be an inborn character, must now be regarded as due to something transmitted from mother to offspring after birth. Of the three things which, according to Bittner himself, this something may be, a virus is certainly the most credible, and most people will share Dr. Andrewes's difficulty in " swallowing a hormone which when taken in infancy will condemn your grandchildren to the development of cancer in their years of maturity." But in spite of suggestive collateral evidence, of which this is an example, it is difficult to get over the solid fact that the presence of a virus cannot be demonstrated in malignant mammalian tumours, whether naturally occurring or chemically induced—at least by those direct methods which serve to demonstrate its presence in tumours of birds. For this formidable difficulty Dr. Andrewes suggests a new explanation, which is both ingenious in conception and picturesque in his elaboration of it. The idea of a " toothless " virus, so happily established in the cells of one individual that it loses its capacity to bite those of another, will serve as a hypothesis until facts are forthcoming either to support or to condemn it. It may be observed in passing that among bacteria enhanced pathogenic activity in one host is usually accompanied by an increase in capacity to attack others and not a diminution, but the metabolic habits of bacteria and viruses are so different that this comparison may be invalid.

It is not easy to see how the present methods of approach are going to carry this problem much further. Hitherto the study of viruses has proceeded mainly on lines which were first found useful in dealing with bacteria, and where all others have failed the serological method has had to be relied on to yield results unattainable by other means. Any doubts of the specificity of some of the immune reactions observed would seriously imperil the conclusions which have been drawn from existing data. Can the study of this subject only be pursued by adapting to it the methods of bacteriology? Just as viruses differ fundamentally from bacteria, so perhaps do the most instructive methods of studying them. It is difficult to escape the feeling that something is lacking in this obscure subject, and that more of the concrete and less of the abstract and conjectural will only be produced by some altogether new line of attack. That the virus hypothesis of cancer in general is unsatisfying to some minds is due both to this essential uncertainty. and to the number of questions which in its present form it leaves without an answer. Let us consider a few of these. Is the cancer virus omnipresent in the human race, or, if not, how and when does the individual acquire it? What is its distribution in the body, and does this vary? Does it ever act in man as the sole cause of malignant disease, or is there always a predisposing cause in addition? Does the body ever develop an immunity to it, and is there one such virus or are there many? Until such questions as these can be answered this hypothesis can have no force or practical interest, and they are not likely to be answered until a means is found of bringing the ordinary run of mammalian cancers within the scope of study from the virus standpoint.

THE STREPTOCOCCI OF SCARLET FEVER

Ever since Sydenham's classical description of scarlet fever it has been recognized as one of the chief causes of morbidity among children and young adults. For decades various devices of administrative control have been directed towards limiting its spread. Innumerable workers in the laboratory and in the field have spent their energy in trying to find effective means of combating the infection. Local authorities have spent vast sums in providing isolation for those with recognizable symptoms of the malady, hoping thereby to protect the public at large. The bacteriologist has been hard on the trail of "the" causative organism. The results to date of these various campaigns can be summed up briefly. Administrative control has failed to accomplish its avowed object, for it is seldom that a case or even a group of cases can be traced to the source. There is no specific remedy, though modification of severe types can be effected. Hospitalization, except for treatment of complications and sequels in individual cases, is futile, for there are always more carriers and potential sources of infection outside the isolation wards than could ever be contained within them. Recent research tends to show that not one sort, but several groups, of streptococci can cause the disease, and what determines pathogenicity is unknown. On the other hand, scarlet fever is not the deadly disease it used to be, nor is it so highly contagious; but can we take credit for this? Scarlet fever is but one of the several manifestations of invasion of the body by certain haemolytic streptococci, and if it is studied from that aspect only solution of the problem will be hard to come by. Would it not be logical, on the analogy of that multiform infection tuberculosis, to group together the different forms of streptococcal invasion under a comprehensive title, "haemostreptosis" (to coin an ugly but expressive word), and study the disease from a point giving a wider view? Already a good beginning has been made in sorting out from the immense genus of streptococci those species that possess haemolytic properties and again dividing them into recognizable groups with marked characteristics. A further step in systematic study is to "locate" them —to find their usual habitat and the circumstances that condition their pathogenic activities. Two pieces of work in this connexion have been recently recorded.[1] In one the precipitin tests have been used with some effect to identify different groups and to distinguish between healthy carriers of non-pathogenic streptococci and carriers of potentially pathogenic varieties. In the other, classification was determined by toxin-antitoxin tests on the white rabbit with a view to discovering the characteristic virulence of certain groups, the types of streptococci prevalent in schools during epidemic periods, and the relation between the haemolytic streptococci found in healthy school children and those found in scarlet fever patients. These researches are but trial borings on the face of the rock, but they show that there is a mine of knowledge waiting to be opened up.

DURATION OF PREGNANCY

Variations in the period of gestation in man are of more than academic interest. Premature delivery has long been recognized as an important cause of neo-natal mortality and morbidity, and there are many who believe that post-maturity is also associated with an increased risk to the foetus. Hauptstein and M. Stockert[2] have investigated a series of cases to determine how far the duration of pregnancy might be influenced by extrinsic factors. They compared results from three distinct periods—the pre-war (1905–13), the war and inflation period (1915–23), and the post-war period (1929–37). All cases were excluded in which (*a*) the first day of the last menstruation was not known for certain; (*b*) the menstrual cycle was not regular and of the twenty-eight-day type; (*c*) labour did not begin and terminate spontaneously; and (*d*) the pregnancy was complicated by a chronic illness. The analyses revealed that there was no difference in the average length of gestation in the three groups, which was 281 to 282 days. One curious observation was that when delivery occurred between January and March the average duration of pregnancy was increased to 283 to 284 days. A similar slight increase was also observed in primiparae. The constant average figure obtained in spite of variations in the social and economic circumstances of the mother can be understood when it is remembered that the German observers carefully excluded all patients whose menstrual cycles were not of the twenty-eight-day type. The evidence submitted by Ogino, Knaus, and others that ovulation occurs approximately a fortnight before the onset of menstruation, irrespective of the length of the cycle, is now widely accepted. If it is admitted that the life of the human ovum after ovulation is only a few hours, and the life of the sperm in the maternal passages only a few days, it follows that the date of delivery as estimated from the first day of menstruation may be considerably in error if the patient has irregular periods or a prolonged intermenstrual phase. For example, with a six-weeks cycle the calculated date of delivery would be approximately a fortnight too early, and in such a case there is an obvious chance of regarding the full-term foetus as being two weeks post-mature. An unusual case, and one which cannot be explained on this basis, was recorded in the *Journal* of June 3 this year (p. 1155) by G. F. Walker. Intercourse took place on three occasions on consecutive days, the first of these on the day following cessation of menstruation. On the third day the husband was accidentally killed, and 315 days later a healthy male child was delivered. Questions of compensation raised a medico-legal problem, and as the chastity of the mother was not doubted the court entered judgment for the child, thus giving legal recognition to a pregnancy of 320 days as calculated from the first day of the last period. In the case of Clark *v.* Clark, recorded in the medico-legal columns of this *Journal* on March 25 of this year (p. 647), the point in dispute was the shortness of the gestation period. The husband alleged adultery by his wife on the grounds that she had given birth to a living female infant 174 days after the earliest possible date on which he could have been responsible. When evidence was produced that labour began after a severe fall and that the infant was markedly premature the president of the court ruled in the wife's favour. It would appear, therefore, that although, as Hauptstein and Stockert have shown, the average duration of pregnancy is 281 to 282 days, a wide possible margin must be allowed for both prematurity and post-maturity.

GASTRO-INTESTINAL DYSFUNCTION

Struck by the number of patients referred for *x*-ray examination of the stomach, gall-bladder, and intestinal tract in whom the most painstaking examinations fail to reveal any sort of organic disease and, further, who apparently respond poorly to treatment, Dr. Barton A. Rhinehart, a radiologist working in Arkansas, has been led to compile an extensive review of his own experiences and of the available literature.[1] Of the large number of dyspeptic patients about one-third have no organic disease, and of the remaining two-thirds many have functional disturbance combined with organic disease. The symptoms of functional disorder are distension, discomfort, diffuse irregular or shifting pains, and constipation, all evidence of neuromuscular disturbance; but these abdominal symptoms may be accompanied and at times overshadowed by general, cardiovascular, and nervous symptoms. The likely causes of neuromuscular imbalance are examined—constipation and increased irritability of the alimentary canal are examples—and found to be allergy, food deficiency, and vitamin lack, especially deficiencies in calcium and vitamin D. The author believes that the element of subconscious mental effect in these disorders is secondary to the real cause—nutritional deficiency. Abnormal motor function is more often a cause of distress than errors of secretion; increased activity of the colonic muscles results in constipation and not, as might be supposed, in diarrhoea. Spasms of the anal sphincter and passage of dry and scybalous stools are the most dependable signs of true constipation. Careful attention should be paid to complete history and to physical and *x*-ray examinations to exclude organic disease. Treatment must achieve three purposes: elimination of irritating factors, whether environmental, psychic, or gastro-intestinal; correction of all deficiencies, especially of calcium and vitamin D; and the specific treatment of complications. Rhinehart's experience is that removal of appendix or gall-bladder is unavailing unless the deficiency state is adequately treated. Cases are reported showing symptoms of the conditions, but results of treatment on the lines suggested are not included. The author has developed his thesis before local medical societies, and now appeals to a wider audience for criticism and support of a method of treatment for this numerous company of sufferers.

LAMBLIASIS

In 1681 Antonj van Leeuwenhoek of Delft, who was suffering from a chronic entero-colitis, observed numerous parasites of microscopical size in his stools, but he did not attach any pathological significance to his discovery. The same organisms were recovered from the stools of infants with diarrhoea by W. D. Lambl in 1859. Lambl described them accurately but named them erroneously *Cercomonas intestinalis* in a brochure published in Russian in 1860. Later, Blanchard in 1888 renamed them *Lamblia intestinalis.* This parasite belongs to the genus *Giardia* and has a pyriform body, 10 to 20 μ in length and 6 to 10 μ in width, which tails off and presents on its anterior surface a reniform depression around which there are six flagella; in addition there are two flagella at the tail. The *Lamblia intestinalis* becomes encysted in certain conditions; the cysts are oval and greyish in colour, are surrounded by a thin membrane, and are of slightly less dimensions than the parasite itself. In severely affected cases the daily evacuation of these cysts has been computed in hundreds of millions. The upper part of the alimentary tract is the usual place of lodgment, but any part of the intestine, as well as the gall-bladder and bile ducts, may be infested. Moderate infestation may not give rise to any symptoms, but in the more severe cases the clinical picture may resemble that of amoebic dysentery. Microscopical examination of the evacuations establishes the diagnosis. In a recent review of this subject Chodzko[1] gives quotations from various authors showing that infestation may be intense, prolonged, and apt to set up fatal disturbances—even cancer, according to certain workers. Treatment is not discussed in detail, but it appears that arsenical preparations, especially stovarsol, are effective. Rodents are susceptible to the disease, particularly those associated with humans, and they may, of course, act as carriers. The hygienic aspect of the subject, as the author points out, is important, for the condition is undoubtedly more widespread than is supposed. Figures quoted as to the incidence of lambliasis in some ten or twelve countries can only be regarded as misleading, since they vary so widely according to different observers, though all agree that troops are more often affected by this type of infestation than civilians. In a condition such as this it is difficult to apply preventive measures on a large scale, and if the analogous problem of ankylostomiasis among miners be taken as an illustration of these difficulties the task would appear almost hopeless. Strict attention to individual personal cleanliness is the best safeguard, but at the same time the most difficult to enforce among those principally concerned.

[1] *Gastrointestinal Dysfunction.* By Barton Arthur Rhinehart, M.D. Arkansas: Central Printing Company. 1939.

IS BOVINE TUBERCULOSIS INCREASING?

Under war conditions the quality, as well as the quantity, of home-produced food acquires enhanced importance. The production of milk, for instance, is likely to be increased in spite of the ploughing of some pasture land, and it is imperative that it should not prove the medium for carrying infection to children whose resistance may be reduced by deprivation in other directions as the result of prolonged hostilities. The failure of the Government's attempt to secure the passage of the Milk Bill last year is therefore to be deplored. There is now, of course, no early prospect of enlightened legislation of this kind. It may be remembered that the beginning of the modern grading system dates from the last war, when tuberculin testing was officially recognized by the Ministry of Food and higher prices were allowed for milk from tubercle-free herds. If this gives a glimmer of hope it is damped by the realization that pasteurization—the only measure we now believe to offer sufficient security—would be much more difficult to extend during war. Since the evacuated have mostly been transferred from large towns, where much of the milk is pasteurized, to rural areas without accessible pasteurizing plants, it is probable that even more children will have to consume raw milk than in the recent past. In these circumstances the records of areas where most of the milk is unpasteurized are of interest. Very full information in this connexion is contained in the annual report for 1938 of Dr. J. Greenwood Wilson, Medical Officer of Health of the City of Cardiff. In this large town about 11,000 gallons of milk are consumed daily. Only 13.6 per cent. is sold as pasteurized, 4.1 per cent. tuberculin-tested, and 1.2 per cent. accredited (in June, 1938), although about 42 per cent. of all the milk sold receives some form of heat treatment. Of 301 routine samples of milk, raw, non-graded, and unbulked, examined for tubercle bacilli, twenty, or 6.6 per cent., were positive. This percentage has only once been equalled in magnitude since 1927. These findings may be compared with the results of meat inspection at Cardiff's large public abattoirs, of which full information has been given in the annual reports over a period of years. The sources of meat stock are, of course, not necessarily the same as those for milk, but the particulars given indicate a general trend in the health of bovine animals. In recent years 13,000 to 15,000 cattle have been slaughtered annually, of which about 1,000 have been cows. Up to 1931 the proportion of cows found tuberculous ranged from 20 to 27 per cent. It then began to rise, and in each year since 1934 it has been over 40 per cent., reaching its maximum in 1936, when the percentage was 51.6. In 1938 it was 41.0. A similar increase, although naturally on a much smaller scale, can be observed in the proportion of heifers and steers showing manifestations of tuberculosis. The reason, therefore, does not seem to lie in any new practice of delaying the age of slaughter of cows, which, like bulls, are more likely to show signs of disease with advancing years. In the absence of any other explanation it is reasonable to suppose that these figures reflect a deterioration in the health of cattle, the evil effects of which on the milk supply may require more radical action than either the local authorities or the Ministry of Agriculture are able to take under the present law.

The Nobel prizes for physiology and medicine for 1938 and for 1939 have been awarded to Dr. Corneille Heymans, professor of pharmacodynamics in the University of Ghent, for his studies of the sinus and aorta mechanism in respiration; and to Professor Gerhard Domagk, of Elberfeld, in recognition of his discovery of prontosil.

Confident that war will not dry up the springs of medical charity, Sir Thomas Barlow appeals in our correspondence columns this week for donations towards the Christmas gift account of the Royal Medical Benevolent Fund.

Sir Robert Hutchison, President of the Royal College of Physicians, will deliver the David Lloyd Roberts Lecture before the Medical Society of London at 11, Chandos Street, Cavendish Square, W., on Thursday, November 16, at 3 p.m. His subject is "Medical Literature."

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation.

FRACTURE AND DISLOCATION OF THE PATELLA

BY

E. P. BROCKMAN, M.Chir., F.R.C.S.

The most common injury of the extensor mechanism of the knee-joint is a transverse fracture of the patella, the result of a sudden contraction of the quadriceps while the knee is held in a position of flexion. Often such an injury would seem to occur with relatively slight violence. Other fractures, such as a comminuted fracture or a compound fracture, are due to direct violence and are much less common. They result from falls directly upon the patella or from motor-car accidents.

In addition to fractures of the patella two other injuries to the extensor mechanism may be met with. The first is a rupture of the quadriceps tendon just above the patella or a detachment of the whole tendon from the patella. This injury appears to occur in much the same circumstances as does a fracture. The second injury is a rupture of the patellar tendon, which is torn off from its attachment to the lower portion of the patella. The history of the accident, except when due to direct violence, is always much the same, and it would seem to be a matter of pure chance whether the tendon or the patella is damaged. The usual story is that the patient stumbles or misses his step and a sudden effort is made to avoid a fall. The knee gives way and the patient falls down, with pain in the limb. On attempting to rise he finds he is unable to do so, or, if he does get up, discovers that he is unable to walk or to take any weight on the injured limb. The differential diagnosis is seldom difficult. There is a loss of function, inability to extend the limb voluntarily, and immediate or very rapid swelling and pain.

Transverse fracture of the patella with much separation of the fragments is easy to diagnose, as a depression between the fragments can be palpated. Such fracture without separation, whilst it may be suspected owing to the tenderness upon pressure on the bone, may not be recognized without the help of an *x*-ray examination. Likewise a comminuted fracture may be difficult to differentiate on a purely clinical examination. The same applies to a compound fracture, except that there will be a wound over the patella from which blood and serum may leak.

A transverse rupture of the tendon of the quadriceps is often easy to diagnose; if there is any doubt the knee should be flexed slightly, when the separation becomes obvious and pressure on the hole gives rise to marked tenderness. Rupture of the patellar tendon has symptoms similar to those observed in these other injuries, but upon examination a hollow can be felt below the patella, which itself lies on a higher level than does that of the other limb. In addition we must remember that in both fractures and injury of tendons a haemarthrosis is present, except in rupture of the patellar tendon, which is an extra-articular lesion. Also most fractures are associated with a rupture of the joint capsule and the lateral expansions of the tendon, and if the separation of the portions of the patella is considerable these soft structures must be badly torn. If there is no separation there is unlikely to be much damage to the soft structures.

First-aid Treatment

The patient will be unable to bear his weight on the limb and probably will be found lying upon the floor or may have been carried to bed. If he has to be moved the limb may be splinted temporarily with a back splint or, if this is not available, the two lower limbs should be tied together. If the fracture is compound the wound should be covered with a sterile dressing until arrangements can be made to deal with the condition properly. After removing the patient's clothes a clinical examination must be made to decide the nature of the injury. The limb must be radiographed, but as the patient is probably badly shocked it may be wise to wait until the next day before doing this.

Simple Transverse Fracture with no Displacement

If the injury is a simple transverse fracture of the patella with no displacement it can be assumed that the capsule is not ruptured on either side and therefore, beyond protecting the limb from any further violence, it is not necessary to treat the fracture itself. The condition we have to deal with is a traumatic synovitis with perhaps a little blood in the joint. If the patient is in much pain there is a very definite haemarthrosis. The patient is kept in bed to start with, the knee being supported by a pressure pad and bandage. A layer of wool is applied to the injured knee and a few turns of bandage put on; another layer of wool is then applied, with further turns of bandage, followed by a third layer of wool, the bandage now being finished off. Besides splinting the limb this treatment will help to get rid of the fluid. While rest is indicated for the traumatic synovitis the muscular control must be maintained. It is therefore essential that the patient should have a masseuse—not to do any massage, but to help him exercise the quadriceps and if necessary to give faradism to these muscles. As soon as the very acute symptoms have subsided, active movements of flexion and extension of the knee must be begun; they may be increased in range as rapidly as symptoms permit. Treated in such a way, the patient with a simple transverse fracture of this nature should be on his feet within a few days, and if his work is of a sedentary character and transport is easy there is no need for him to be away from work for more than a week or ten days. When all the fluid has disappeared from the joint a crêpe bandage is preferable to an elastoplast bandage: it can be removed for physiotherapy and does not tend to cut in behind the knee or make the skin sore. If the patient's work is heavy six weeks will elapse before he is fit to undertake it. Should he return too soon the knee will fill up with fluid and complete restoration of function will be delayed.

Transverse Fracture with Separation

This, the most common injury, is best treated by open operation unless the patient is very old and there is some other contraindication. To relegate the patient to a knee cage is a policy of despair rather on a par with the ordering of a calliper for a fractured neck of the femur. Open operation, no matter what its nature, is not a serious procedure, and can be rapidly performed. It is wise, whatever is done to repair the damage, to allow the patient to rest quietly for a few days before operation. After a fracture of the patella the soft tissues become so oedematous that if operation is performed at once it is difficult to identify with any ease the structures one is handling. After a few days the oedema subsides, making the operation easier.

As with most surgical problems, considerable difference of opinion exists as to the most desirable procedure, in the way of open operation, for the repair of this fracture. There are two things we must set out to do at operations: first, the capsule which is torn transversely must be sutured ; and, secondly, the fragments of the patella must be dealt with. These may either be wired together or they may be removed. The former is the more classic procedure, and probably cases still occur in which it should be done ; but for most patients removal of the patella is the most satisfactory operation, and if upon opening the joint there are already signs of arthritis it quite definitely is the operation of choice. The points in its favour are that it is easy to do and that it can be done very quickly. There is nothing to refracture afterwards, and the chance of the development of an arthritis between the patella and the femur is avoided. Wiring the fragments together, however well done, may leave a ridge on the articular surface of the bone and involve the risk of a chronic persistent pain in the joint. The function of the knee after excision of the patella is excellent, and there is no loss of power in the quadriceps. The only thing that the patient notices afterwards is that when the knee is flexed the condyles of the femur appear very prominent.

THE OPERATION

The limb is prepared in the usual manner, from the groin down to and including the foot. The towels are arranged in such a way that the knee can be flexed without risk of any part not prepared becoming uncovered. It is better not to employ a tourniquet or an Esmarch bandage, because they tighten up the quadriceps and may make it difficult to suture the torn surfaces together.

The fracture may be approached through either a longitudinal or a transverse incision about four inches long over the site of the fracture. The torn fibres of the quadriceps expansion which lie over the surfaces of the fracture require clearing away but not removing. The blood clot which fills the joint is removed. The upper fragment of the patella is held with forceps and dissected out of the tendon of the quadriceps, taking care to keep the scalpel close to the bone so that the tendon remains as intact as possible. The lower fragment is then removed in a similar manner. All bleeding is carefully stopped, and the expansion of the quadriceps torn upon either side is sutured with interrupted sutures of No. 1 chromic catgut. It is not necessary to suture the synovial membrane, and in suturing the capsule care should be taken not to shorten the expansion, otherwise this may contribute to difficulty in obtaining full flexion of the knee. The hole left where the patella has been removed can be closed by suturing the capsule longitudinally in this part. It does not matter if closure is not complete. The skin incision is closed with interrupted salmon-gut sutures and a dressing applied. The limb is then bandaged over layers of wool from the middle of the thigh down to the middle of the leg. This will provide all the splintage necessary. The bandage may need slackening after twenty-four hours.

With the limb in extension active contraction of the quadriceps is started after three days and the patient encouraged to begin slight movements of flexion in another two days. The stitches are removed on the ninth day and the limb firmly bandaged. If the incision is satisfactorily healed active flexion continues and, provided that the patient maintains voluntary power of full extension, can be quickly increased in range. After twelve to fourteen days the patient may be got walking with two sticks, the knee being still supported by a firm bandage or, if he is nervous, a posterior plaster slab. The rapidity with which full function is recovered varies greatly, but in six to eight weeks the patient should be fit to resume all but the most strenuous of occupations, such as climbing ladders. He will have to wait to do this until he has complete confidence in the limb. Sometimes full flexion is difficult to obtain in elderly patients, especially if they have been afraid to bend their knee in the first two or three weeks. Rupture of the capsule in the portion where the patella has been excised is known, but it is rare ; when it does occur it calls for a secondary suture.

Suture of Transverse Fracture of Patella

The initial stages of the operation with regard to excision of the fragments are identical with those just given. When the portions of the patella have been cleared they are pulled together so that the fractured surfaces fit, and are held thus by an assistant with two sharp hooks. They may be fixed now by suture, with catgut, of the transverse expansions and the expansion over the surface of the patella, or else the two fragments are drilled transversely and then the material used is threaded through and tied. At one time silver wire was employed for this purpose, but this has been replaced by Viennese twist, size 3. This material has the advantage that it can be tied like an ordinary ligature ; silver wire is much more difficult to tighten, and the knot made was very liable, however well it was bent down and buried, to spring up again and cause trouble under the skin: also it often broke. If the patella is wired in this way it is essential to suture the torn expansions upon either side with catgut. The after-treatment is exactly the same as for removal of the patella, except that flexion cannot be obtained so rapidly ; if it is, the patella is likely to unite with fibrous tissue and not with bone. Subsequent stiffness of the knee is also likely to be more troublesome than when the patella is removed.

Simple Comminuted Fractures

The treatment of this type of fracture will depend upon the degree of comminution and the amount of separation of the fragments. In many of them, although the patella is split up into a number of pieces, there may be little separation and no evidence of the expansion of the quadriceps over the patella, nor of the lateral expansions being seriously damaged. In such circumstances there is no need to operate upon the knee. The fragments will unite up well, and treatment is required only for a bad synovitis or haemarthrosis. The limb is bound up firmly or, if very painful, fixed on a posterior plaster slab until the pain subsides. The quadriceps are treated to prevent wasting, and movements begun as soon as symptoms permit. The prognosis is good unless the patient develops an arthritis. Should this happen it will be necessary to remove the patella, but it does not follow that an arthritis is bound to develop. After such an injury the patella always appears to be larger than does the patella of the other limb. In instances where the fragments are widely separated it is better, as soon as the skin has recovered from the trauma, to remove the fragments of the patella rather than to attempt to fix them together. Such a task must be very difficult, and at the best the result will be a joint which is very sensitive and liable to swell upon even the slightest of injuries or over-use.

Compound Fractures

These are fortunately very rare, but are seen in motor-car or street accidents. In such cases the treatment of the fracture is of secondary importance, and attention must be directed to preventing the knee-joint becoming infected. As soon as possible, under an anaesthetic, the wound must be cleaned and any dirt or fragments of bone sticking out of the wound removed. It may be necessary to enlarge the skin wound to enable this to be done. The joint if widely opened must be washed out, but no attempt must be made to repair the damage to the capsule or patella. The surfaces of the wound may be approximated with salmon-gut sutures but not closed tightly, so that any serum which may collect can drain into the dressing and not collect under tension in the joint. The limb must be fixed in a Thomas splint, with skin extension applied to the leg. The dressing should be changed every day, and the stitches removed if any sign of infection appears. Should the joint become infected it will require treatment as for any other acute infective arthritis. When the joint has recovered from the risk of infection and the skin has completely cleared up, the fractured patella will receive the appropriate treatment.

Injuries Related to Fracture of Patella

There are two injuries very closely related to fractures of the patella which require consideration.

Rupture of the Quadriceps Tendon.—This is usually a complete transverse tear, and in nearly every instance if not treated surgically results in a very weak limb. The operative treatment is simple. Through a transverse incision directly over the site of the tear the damaged tendon, with its expansions, is sutured with interrupted catgut. This does not take very long, and the after-treatment is similar to that used in those cases where the patella has been removed. If the rupture is only partial, conservative treatment will give a satisfactory result.

Rupture of the Patellar Tendon.—This is a very rare accident. If the tear is only partial the limb should be fixed in full extension in plaster for six weeks and the patient permitted to get about on crutches. After removal of the plaster active movements may start and, provided full voluntary extension is maintained, flexion may continue to be increased. If, however, the tendon has been completely torn off the lower hole of the patella, conservative treatment will not be sufficient. The patella is pulled up to a higher level by the quadriceps, while the tendon itself contracts. In these circumstances the site of the injury must be explored and the damage repaired. There is little tissue left on the patella to which to suture the tendon back, and it is therefore necessary to use a fascial graft to repair the damage. The lower part of the patella is drilled transversely so that the graft can be threaded through. It is then sutured to the tendon whilst the patella is held by a sharp hook. The limb must be fixed in plaster for six weeks, after which time the quadriceps must be toned up and active movements of flexion begun. Full function will not be restored for four to six months.

Traumatic Dislocation of Patella

This injury is a very rare one. It is always an outward dislocation. The patient is found in acute pain, with the knee held in a position of flexion at about 45 degrees. It may be that some friend has pulled the limb straight and the dislocation has been reduced before medical aid is sought. If the dislocation is seen soon after it has taken place it may be reduced without an anaesthetic. The limb should be held as straight as possible and, with one hand made into a fist placed behind the knee, the patient is instructed to try to press the knee against the hand. This will result in a relaxation of the hamstring muscles, and quite light pressure upon the outer border of the patella will enable it to be lifted forwards, when it will at once slip back into position. If this cannot be done, or if the patient is very nervous, the dislocation may be reduced under gas. Subsequent treatment deals with the traumatic synovitis which results. A pressure pad and bandage are applied to prevent the collection of fluid in the joint, and treatment given to the quadriceps. The joint will lack strength and be sensitive to stress for perhaps a week or two, so that it may swell up. Traumatic dislocation of the patella seldom recurs, and in this respect is essentially different from the habitual or recurrent dislocation which is due to an anatomical abnormality.

THE USE OF RADIUM IN WAR-TIME

WITH APPENDIX ON RADIUM POISONING

BY

L. H. GRAY, M.A., Ph.D.

AND

J. READ, B.Sc., Ph.D.

RADIUM UNDER WAR-TIME CONDITIONS

In response to inquiries concerning the necessity or otherwise for rendering radium permanently out of commission under war-time conditions, we submit the following statement of the position as it seems to us.

The Danger Inherent in Use of Radium in War Time

The danger to life lies in the possibility that through a direct hit by high explosive on a building in which the radium is in use the radium containers might be broken and the naked radium liberated, since radium element which has entered the body is only slowly eliminated and may produce severe injuries and ultimately death.[1] If naked radium is lying about in the open air there will be serious risk that some will be breathed as radium dust. Even in a laboratory where radium is handled under comparatively carefully controlled conditions it is possible to detect radium dust in a sample of the air in the room. Further, the amount of radium which is lethal when fixed in the body is definitely known to be extremely small—namely, about one-millionth of a gramme.[1] Thus the complete destruction of a ward in which 500 mg. of radium was in use on a number of patients might liberate many thousand lethal doses of radium.

It is difficult to find data on which to base an estimate of the proportion of the radium breathed which becomes fixed in the body. By experiments with animals it has been found that of the radium which enters the blood stream 50 per cent. is fairly rapidly eliminated; but about 4 per cent. is still in the system at the end of six months, and 2 per cent. at the end of two years (Rajewsky, 1939). These figures, as might be expected, were found to be subject to wide individual variations. There can therefore scarcely be any doubt that if radium element is to be used under war-time conditions one of the following alternatives must be adopted.

---

[1] See Appendix, " Radium Poisoning."

(*a*) The radium might be used at a site where a direct hit by high explosive is a negligible risk.

(*b*) The radium might be used in such a form that it could be transferred to the bottom of the "radium well" within, say, five minutes of an air raid warning. Clearly, no interstitial radium treatment could be given in these circumstances. The most convenient form in which the radium could be used would probably be teleradium therapy. Several existing "radium beam" units are already equipped with apparatus for the pneumatic transfer of radium from the beam unit to a safe, and it would appear to be a relatively simple matter to arrange that the radium, instead of being returned to the safe, be put into a container and automatically lowered down a shaft, thus completely avoiding exposure of personnel and ensuring that the radium was stored in safety. This could probably be done within two minutes of an air raid warning. Arrangements could probably be made to transfer radium in use in the form of plaques, and perhaps radium in gynaecological use, into an ordinary "radium well" within five minutes of a warning. The difficulty here is essentially one of *organization* so as to ensure (i) that no radium is overlooked; (ii) that all plaques are taken from patients simultaneously, so as to reduce the time to a minimum; and (iii) that exposure of personnel is avoided. The details of such organization would have to be very carefully worked out, but such procedure does not appear to present any insuperable technical difficulties.

(*c*) The radium could be used under normal conditions if it were agreed that, should the site be hit while the radium is in use, either the site will be abandoned for all time, or the site will be carefully cleared of all debris by suitably protected workers, and the debris, together with a small depth of undisturbed earth, be buried elsewhere. If suitable precautions were taken the task of clearing the debris need not involve danger to personnel. Radium continually gives off the gas radon, which is injurious in quite low concentrations, but it is probable that even if 100 mg. of radium were liberated in the space of a single ward the radon concentration would not rise to dangerous levels under open-air conditions. Moreover, the concentration can easily be tested before work is started. The danger of breathing radium dust could be eliminated if the workers wore suitable masks (Leitch, 1935). The average concentration of radium element among the debris would be low compared with that in radium ore. Thus, for example, if one wing of this hospital[1] were demolished while one gramme of radium was in use the concentration of radium in the debris would only be about one-hundredth of the concentration of radium in the ore mined in the Belgian Congo. It is to be noted, however, that in removing debris contaminated with radium the latter may be encountered in small patches of high concentration in the demolished building, so that adequate precautions against the breathing of the dust would be imperative for those clearing the debris.

(*d*) *The Use of Radon*.—Although radon is injurious to health if breathed, it is not likely that the liberation of even as much as 500 millicuries by complete demolition of a building would appreciably add to the loss of life and injury caused by the high explosive itself. The site would not be permanently contaminated. The radiation from radon filtered through 0.5 mm. of platinum is identical with that from radium element of the same degree of filtration. In the case of radon irradiation the intensity of the radiation is high at first and falls away to zero (unless fresh radon is introduced), with a half-value period of three and a half days. In all other respects radium or radon may be considered to be identical sources of radiation. The radon plant could be set up either in such a position that the risk of a direct hit is negligible, or in a naturally occurring cave or tunnel or a specially constructed "bomb-proof" chamber.

APPENDIX ON RADIUM POISONING

Below are listed a number of papers dealing with this subject published during the last ten years. It is evident that during the earlier part of this period the difficulty of measuring minute quantities of radium in a living person, and tiny radon concentrations in the breath, led to much inaccuracy and conflicting results. However, in the work of Rajewsky (1936, 1939; Janitzky, Krebs, and Rajewsky, 1938) and Robley D. Evans (1933, 1937; Evans and Aub, 1937; Aub, Evans, Gallagher, and Tibbetts, 1937-8) accuracy of measurement has reached a high standard—Evans (1937) can measure down to 0.2 microgramme in a living person—and their results seem reliable and consistent. Among earlier papers a series of four in the *American Journal of Industrial Hygiene* on conditions in the watch-dial painting industry is notable (Ives, Knowles, and Britten, 1933). From a study of this literature the behaviour of radium after its introduction in the body appears to be as follows.

Most of the radium taken by mouth is rapidly eliminated—about half in a few days and 90 per cent. in a few weeks. The rate of elimination continually diminishes, however: after six months it is about 0.02 per cent. of the remaining radium per day, after one year 0.004 per cent., and after ten years 0.003 per cent. The amount of radium still in the body after one year can for practical purposes be considered as fixed there. If the radium is taken intravenously the initial rate of elimination is about half as quick, but after a few weeks the rate becomes the same. However, owing to the slower start a given quantity of radium taken intravenously will always show a higher residuum than if it is taken by mouth. Rajewsky (1936) says that about 0.5 to 1 per cent. of radium taken by mouth and from 2 to 5 per cent. of radium taken either intravenously or by breathing becomes fixed in the body. Evans (private communication) has found that the fractional retention of radium taken by mouth is from 1 to 5 per cent., and he believes that for intravenously injected or breathed radium the retention is about 10 per cent.

In the first week or so radium is distributed throughout all the tissues; it then becomes concentrated in bone trabeculae and finally in the bone cortex. However, the concentration is by no means uniform throughout the skeleton. The distribution found by Rajewsky (1936) in a woman poisoned by breathing radium dust, who died three years after her last exposure, is given in the table:

	Per cent.		Per cent.
Lung	9	Thigh bone	21
Heart	0.0007	Rib	32
Liver	3	Vertebrae	34
Spleen	0.007		

Schlundt and Failla give the following radium concentrations in various bones:

Humerus	2.7×10^{-9}	grammes radium per gramme dry bone
Rib	3.4	
Vertebra	5.2	

During the early part of the history, radon in the breath is about 50 per cent. of that produced by the radium, but after some years, when the radium is fixed in the bones, this drops to from 3 to 10 per cent. (Rajewsky, 1936). Elimination of radium at this stage is 90 per cent. in the faeces and 10 per cent. in the urine (Evans, 1937).

The fatal dose is usually stated in terms of the residual radium at the time of death. However, as death may be as long as ten years after the radium intake, the actual damage to which death is due may have been caused by the much larger quantities originally present. Evans describes the case of a watch-dial painter who was examined for radium once a year for eight years with negative results, presumably by a crude method. He developed necrosis of the jaw, and just before he died Evans (1937) measured a total content of 1.2 microgrammes. Rajewsky (1936) describes the case of a woman whose death resulted from the breathing of radium dust (lung carcinoma) five years after starting employment in a radium laboratory. After her death 6 microgrammes of radium were measured in the body; the lung, which was the site of the immediate cause of death, contained less than 1 microgramme. Several similar cases can be quoted, but in contrast to these are two women described by Evans (1937). The first had intravenous injections of radium chloride ten years back and still contains 8.5 microgrammes. Her weight is 160 lb. and height 5 ft. 8 in. The second took radium by brush-licking while watch-dial painting during 1922 to 1929, and in 1937 was still so employed, except that a glass pen technique was used. She then contained 9.7 microgrammes, and her weight was 116 lb. and her height 5 ft. 5 in.

---

[1] The Mount Vernon Hospital—a solidly built two-story building with subway. The wing measures about 35 feet by 150 feet.

Evidence of harmful effects of radium less serious than death is contained in the *American Journal of Industrial Hygiene* reports (Ives, Knowles, and Britten, 1933). An investigation was made from June, 1929, to March, 1930, on two groups of watch-dial workers: Group A, seventy persons, all having started work after brush-licking had been abolished on January 1, 1927; Group B had worked before that date. Group A contained persons who had from 0.1 to 2.4 microgrammes of radium due to breathing radium dust. They showed a tendency to a lower red cell and haemoglobin determination than in a group of controls. Bone changes for Groups A and B, classified against radium content of the individuals, are shown in the table:

Microgrammes	Per cent. with bone changes
1	5
1 to 1.9	12
2 to 2.9	17
3 to 4	40
4 and more	100

These measurements were made during exposure to radium intake and within relatively few years of the first exposure, in contradistinction to the earlier cases mentioned, which had all the radium fixed in the skeleton for some years.

According to Martland (1931; McClelland, 1933), for several centuries the underground workers in the cobalt mines of the Schneeberg district and in the pitchblende mines of Joachimsthal have been subject to a pulmonary disease resulting in death in middle life. An official investigation extending over three and a quarter years resulted in a diagnosis of carcinoma of the lungs in 62 per cent. of the deaths among miners. During the same period examination of 362 persons in the same districts, not working in the mines, discovered no indication of malignancy in the lungs. These deaths have been variously ascribed to rock dust, dampness, volatile arsenical compounds, chrome and arsenic dust, but, as the air of the mines is distinctly radio-active and as breathing radium dust in laboratories has been shown to produce lung carcinoma, the radio-activity of the air must be regarded as a likely cause.

From a consideration of these papers it seems probable that, though there is a considerable variation from one person to another, an ingestion of about 500 microgrammes will lead to a fixed quantity of about 5 microgrammes, causing ultimate death. In some cases as little as 50 microgrammes might produce this result. These quantities are roughly halved if radium is taken intravenously; but it is difficult to deduce from this the fatal dose which must be inhaled, as we have no data on what proportion of dust inhaled is retained in the body.

BIBLIOGRAPHY

Radium Poisoning

Aub, Evans, Gallagher, and Tibbetts (1937–8). Effects of Treatment on Radium and Calcium Metabolism in the Human Body. *Ann. intern. Med.*, 11, 1443.

Report on an attempt to treat three cases of radium poisoning by dietary methods, aimed at increasing the rate of elimination. The three cases of poisoning occurred (*a*) by deliberate intravenous injection, (*b*) by brush-licking on the part of an operative in the luminous-watch-dial industry, (*c*) an explosion in which radium was scattered and some dust particles fell on the face of a physicist and were probably breathed. Detailed case histories, measurement of radium content, and rate of elimination are given, but these were begun many years after the radium entered the system in the first two cases and about four weeks after the accident in the third case.

⁂ A more complete discussion of radium poisoning, written by Dr. J. Read, will appear shortly in the *British Journal of Radiology*.

Dislocation of Hip.—In about 5 per cent. of all patients with congenital dislocation of the hip the deformity is combined with other malformations. In such cases the dislocation of the hip appears to be caused by mechanical factors and should be regarded as a secondary deformity. Twenty-eight illustrative cases are described by the author and the previous literature is reviewed.—Significance of Dislocation of Hip combined with Other Malformations for Problem of Dislocation of Hip.—W. Müller.—*Z. Orthop.*, May 30, 1939, **69**, 293.

THE EMERGENCY HOSPITALS' OPPORTUNITY

"Somewhere in England,"—in one of the London sectors, in fact—an emergency hospital has been prepared, like hundreds of others, for the reception of air raid casualties. Part of this hospital is a workhouse building, one hundred years old, which has been adapted for the purpose; the other part consists of more modern buildings, together with some recently constructed hutments. Altogether the hospital will accommodate between 800 and 1,000 patients. The staff includes fifteen specialists.

It is regarded as important that the hospital should provide in-patient facilities for London patients who have been deprived of hospital service in their partly evacuated city. It is true that the Ministry of Health arranged for patients actually occupying beds in in-town hospitals, and not fit to be sent home, to be accommodated elsewhere; but provision for the constant accession of fresh cases was limited. This hospital, thirty or forty miles from London, is in effect functioning as a London hospital, to which patients are brought twice a week in motor coaches converted to ambulance use.

The medical superintendent and his staff are keen on making some local contribution to the emergency. The hospital is situated in a town whose normal population has been increased by 30 per cent. since war began owing to the presence of evacuated persons from London. There is only one other small general hospital, which even before the war was always filled to capacity. Accordingly the emergency hospital is proposing to start various clinics to which local practitioners may send patients for consultation. The specialist units will deal with both local and transferred cases. The ophthalmological unit, for example, will take cases from Moorfields and from the ophthalmological departments of other London hospitals as well as cases arising at its own doors. The same is true of the dermatological unit, the maternity unit, and the projected dental unit, which last will also deal with facial injuries. A first-class pathological department has also been established, half of its equipment coming from one London hospital and half from another. In addition the hospital service has a training school for student nurses, fifty of whom have been transferred from a school in London with their sister-tutor. Again, the hospital expects to receive military casualties from the front.

The trouble, almost inevitable in any scheme of emergency organization, is that while those on the spot take a long-range view and are eager to grasp new opportunities, a more remote officialdom insists on regarding all such hospitals only as improvisations to meet a temporary emergency. This has the unfortunate result that, whereas the provision is in many respects on generous and enlightened lines, in others it is wholly inadequate to the situation, at least to the situation as those on the spot appreciate it.

Experience of an Up-graded Hospital

The hospital consists of an old workhouse building, newer infirmary and casual blocks, and a number of recently constructed hutments. A wing of the old workhouse has been transformed into a psychiatric unit, for which it offers advantages, consisting as it does of a number of small wards, each with four or five beds. The unit, which is self-contained, thus ensuring the quiet which is essential, is in charge of two London psychiatrists who will from the beginning be able to deal with the more difficult cases of neurosis. Its sister-in-charge was trained at the Cassel Hospital. The unit will take in not only shell-shock cases but civil cases of nervous collapse. One of the old day rooms has been turned into a room for occupational therapy, another into a dispensary, and a third into a dental clinic. What was formerly a school room for the Poor Law children, and was afterwards used as a chapel, though not consecrated, has also been turned into a ward. The old reception wards have become first-aid posts. A part of the building is still appropriated to the use of the workhouse inmates.

The infirmary part of the institution, which is of more modern construction, has been arranged to take 150 beds, which are fully occupied by local and transferred cases. The maternity unit also has been established in this part of the building. In the former casuals' block the dormitories have been made into wards for ambulatory cases, fitted with bathrooms and sinks, and afford accommodation for seventy or eighty patients. The room where the tramps had their meals is now a receiving room for local air raid casualties, for it has to be remembered that in the unpredictable course of air warfare even a country hospital may have casualties at its doors. Provision is made for urgent operations, and sisters, nurses, and orderlies are in attendance. Twelve cell-like cubicles in which the former inmates were sometimes isolated for various reasons have been transformed into individual consulting rooms. In this part of the building arrangements are made for the care and treatment of school children, cleansing facilities being provided and examinations made for conditions such as scabies and impetigo. It should be added that the old associations of the place are so far as possible eliminated by the cheerful scheme of decoration employed. Even the frames which have been put up to darken the windows have their monotony relieved by designs by local artists.

Hutments: Advantages and Some Criticisms

In the garden of the institution there have been set up eleven ward huts, each equipped for forty-two patients. The dimensions of the huts are 108 feet long by 25 feet wide. One hut of the same size is assigned solely for the purpose of an operation theatre and *x*-ray department, and another for that of kitchen to serve the whole establishment. The huts are built of breeze blocks on a frame, and a concrete wash gives them the appearance of concrete houses. The roofs are of corrugated iron. There is a great deal to be said for the way in which this construction has been managed. The planning is good, with plenty of window space. A sufficiently wide gangway runs down each hut between the rows of beds, and the beds seem to be spaced adequately. Each of the wards is heated by three Canadian stoves down the middle, and hot water is supplied by a separate boiler for each hut. The only hut to be centrally heated is the operation block. Each hut has its own service kitchen, bathrooms, lavatories and sluice room, and dressing room.

The operation block includes a sterilizing room, a room for dressings, surgeons' and nurses' changing rooms, and space for the storage of theatre linen. The theatre has four tables, lighted by shadow-proof lamps, but only two sinks or washing places, and these located together at one corner. The *x*-ray room is large, and rooms are provided for developing and viewing.

While there is much that is admirable in the hutment arrangement, certain disadvantages, each relatively small but in their cumulative effect likely to prove a severe handicap in times of pressure, make themselves obvious. For example, in each ward only one sink has been provided. There are no chairs, ward tables or cabinets, or bedside lights, so that injections and examinations will have to be done either by the light of a torch or of the pendant lamps from the ceiling. Again, there are no means of keeping food hot after it comes from the central kitchen, which is in another hut at some distance from many of the wards. A more serious complaint relates to the construction of the beds, which are of a light collapsible type and without castors. Yet another criticism is that the space between the huts has merely been dug over and left, so that it is impracticable—even if the beds had castors—to wheel patients out into the open air as it would be if the space were gravelled; yet french doors have been provided.

The hut where operations are done is under the disadvantage of being approached by a pathway which certainly is roofed over but is otherwise open to the weather, so that patients carried in and out must be exposed to the cold air. The anaesthetics room also is not happily placed, and in the absence of partitions the anaesthetizing of patients takes place in what is practically a public thoroughfare. Similarly, the approach to the x-ray room compels the patients to be taken either through the operating theatre or out into the open right round the building.

The staff at this hospital are billeted out, with the exception of forty nurses, for whom there is a nurses' home in the old infirmary block. A skeleton staff is always in attendance, while others are at call.

SULPHONAMIDES FOR INFECTED WOUNDS

PROPHYLAXIS AND TREATMENT

In our issue of October 21 (p. 834) we published a War Office memorandum concerning the use of sulphonamide derivatives for prophylaxis and treatment of wound infections. Supplementary Memorandum No. 1 is now being distributed from the War Office to all officers of the Royal Army Medical Corps.

War Office Supplementary Memorandum

In the above-mentioned memorandum (A.M.D. 7, dated October 11, 1939) it was emphasized that there is no evidence yet available for assessing the reaction to these drugs of persons suffering from shock. The fact that they may stand the drugs badly is probable. It is therefore advisable that the first batch of cases to which sulphonamide derivatives are administered for the purpose of prophylaxis or treatment should be carefully observed. If patients are severely shocked, treatment with these drugs would be better suspended until the circulation, temperature, and urinary excretion have been re-established to reasonable levels by treatment of the shock *per se.* Should there be evidence which indicates that the drugs, in the doses suggested, are not well tolerated, administration should be suspended or the dose reduced.

If experience shows that the dosage given in the original memorandum is too high, it is suggested that the undermentioned modified course of prophylaxis and treatment should be tried on a further batch of cases.

Modified Course for Prophylaxis and Treatment

SULPHANILAMIDE AND M & B 693

Prophylaxis.—Total of 3 gm. per diem to extend over a period of four days, administered as follows: 1 tablet every four hours for four days.

Treatment.—First twenty-four hours: Total dosage 4 to 6 gm., according to severity, but in extreme cases, such as septicaemias, up to 9 gm. Spacing of dosage: Four-hourly, so that half the total dose is given during the first two administrations, and the balance equally divided between the remaining four administrations. Second twenty-four hours: Total dosage and spacing similar to the first day. Subsequent days: Dosage to be guided by the condition of the patient, reducing the administration of the drug to 2 to 3 gm. per diem. Total period of administration not to exceed nine days.

IMPORTANT INSTRUCTION

It is extremely important that when patients who have received prophylactic or curative treatment with these drugs are transferred from one medical unit to another, clear indication should be given in the transfer documents as to treatment, and, in particular, which drug has been employed, as well as the *total* dosage given. If this is neglected there may be a grave danger of overdosage, with the consequent risk of agranulocytosis. Individuals who have been found to be unduly susceptible to sulphonamide derivatives should have this fact clearly stated on their documents, in order that the drugs may not again be administered at some future date. Susceptible persons inevitably suffer a recurrence of complications when a fresh course of the drug is instituted.

Reports of Societies

LATENT VIRUS INFECTIONS: THEIR BEARING ON THE CANCER PROBLEM

At a meeting of the Section of Comparative Medicine of the Royal Society of Medicine on November 1, Dr. C. H. **Andrewes** of the National Institute for Medical Research delivered his presidential address on the subject of latent virus infections and their possible relevance to the cancer problem. He said that animals and plants might harbour viruses within their cells though showing no evidence of disease; bacteria, too, might carry a bacteriophage which did not materially affect them. Such phenomena might be called "latent virus infections."

Transient and Persisting Infections

Dr. Andrewes spoke in the first place of transient latent infections—namely, those diseases in which an animal became infected with a parasite, the infection ran its course, and the parasite ordinarily ceased after a time to be recognizable, but at no stage did overt symptoms of disease occur. A small quantity of residual virus might be very hard to demonstrate in a recovered animal, and therefore it would be more accurate to call this group "apparently transient latent infections." The natural subclinical immunization of many human beings against diphtheria might be ascribed to transient latent infection. Many inhabitants of the yellow fever regions of America and Africa had neutralizing antibodies in their serum though they had never suffered from classical yellow fever. During the course of influenza epidemics the serum of many persons showed substantial rises in neutralizing antibodies against the virus, though the people concerned remained in perfect health. The majority of adults had antibodies against poliomyelitis virus in their blood, probably indicating part contact with, and even inapparent infection with, the virus of infantile paralysis. He also mentioned a bird disease, psittacosis, saying that it was a normal course of events for budgerigars nesting in aviaries in California to develop a symptomless infection, associated with enlargement of the spleen, with psittacosis virus.

His second group consisted of persisting infections with virus as a sequel to overt disease. After an overt attack of a virus disease the virus might continue to be harboured by the host after the disease symptoms had long since disappeared. Poliomyelitis virus had been recovered from nasal washings of man during convalescence, and the very similar virus of mouse paralysis had been found in the spinal cords of recovered mice for as long as a year after infection. Fowls infected with the virus of fowl-pox continued to carry it for long periods, particularly in the liver. The virus of foot-and-mouth disease had been, according to some workers, detected in the urine of hyper-immunized cattle 246 days after infection. Other examples were lymphocytic choriomeningitis and equine infectious anaemia. Virus might be masked by antibody and therefore hard to demonstrate. Some workers believed that persistence of virus after a disease was the rule, life-long immunity being explicable as an infection immunity, an immunity which persisted only because the virus has never completely died out of the body, but Dr. Andrewes thought that caution was needed before accepting that hypothesis.

Indigenous Virus Infections

A third group consisted of indigenous virus infections, which were symptomless like the first group, persistent like the second, and in addition usually infected their host very early in life, possibly making their entry in infancy or even *in utero*, or being handed down from the parent in the germ plasm. This type of host–parasite relationship had been described as perfect parasitism, an association in which the two partners were perfectly adapted to one another, neither causing the other inconvenience, and with admirable arrangements for perpetuating the partnership from one generation to the next. Dr. Andrewes discussed a number of examples such as lysogenic bacteria, viruses carried by normal potatoes, lymphocytic choriomeningitis, herpes simplex, virus III of rabbits, and mouse-pneumonia viruses.

His final class was complicated latent infections. Evidence had recently been brought forward to suggest that the virus of swine influenza might pass through an intermediate host in lung-worms. The ova of such worms might be passed in an infected pig's faeces, be ingested by earthworms, in which some stages of the life cycle might be passed, and then these earthworms might be eaten by other pigs and the lung-worms find their way through the intestinal walls back to the susceptible tissues in the pig's lungs. But this was not enough to make a pig go down forthwith with swine influenza. The virus would lie harmlessly in the worms until some provoking stimulus lit up the infection.

Latent Viruses and Cancer

Three important features kept recurring in many of the instances he had mentioned—namely, ubiquitous occurrence, infection from early life onwards, and possibility of upsetting the host–virus equilibrium with production of disease. Theories about cancer which claimed a role for virus in the aetiology must postulate that such viruses were very widely distributed in the animal kingdom and that they were normally latent infections but could be lit up by some stimulus such as the application of a carcinogenic hydrocarbon. Admittedly there was little direct evidence that cancer was caused in the manner suggested, but some facts in experimental research seemed to point in that direction.

In considering certain neoplastic diseases in the light of this knowledge about virus infections, he began with fowl paralysis (neurolymphatosis), an obscure disease which was certainly related to neoplasms. Dalling had stated recently that there were three theories of the nature of fowl paralysis—that it was an infection, that it was a tumour, and that it was a virus disease. While "reluctant to introduce the Athanasian Creed into pathology," Dr. Andrewes suggested that here there were not three explanations but one explanation—an infection with a tumour virus would serve as a theory to cover all the facts. Evidence in some recent work by Blakemore had been obtained suggesting that fowl paralysis was the chronic stage of an acute disease which might naturally be wholly or largely symptomless. There was as yet no proof that the agent was a virus, but analogy with similar conditions in fowls, such as leukaemia and sarcoma, made it very probable. There was also evidence that environmental factors might determine whether or not a latent infection would blossom out into declared disease.

Another neoplastic disease which might be considered in the light of this knowledge about virus infections was tar sarcomata in fowls. Most normal fowls as they grew older developed neutralizing antibodies active against filtrates of Rous sarcoma virus; the antibodies were, however, usually low in titre compared with those found in birds bearing slow-growing tumours. Their presence suggested, although it did not prove, that many normal fowls might carry or had had contact with a virus serologically related to tumour viruses such as described by Rous. There was evidence that tumours induced in fowls by injections of tar or other carcinogens might generally owe their continuing malignant character to the action of a tumour virus within the cells, such a virus having been liberated from some restraint by the poisoning of the cells by the tar.

The Heredity Factor

Yet another piece of work of interest in this connexion was Bittner's experiments with breast carcinoma in mice. Some strains of mice used in cancer research work had an incidence of breast cancer in breeding females of 80 to 90 per cent., whereas in others the incidence was almost *nil*. In hybrids between two such strains it had been found that the incidence of breast cancer in the offspring depended not upon Mendelian rules but wholly upon whether the mother came from a high- or a low-cancer family. Only the mouse born from a "high-cancer mother" developed breast cancer in later life. Bittner had found that mice from the low-cancer strain would develop a high proportion of cancer if suckled from birth by high-cancer-strain mothers; conversely, mice from high-cancer mothers showed quite a low tumour incidence if fostered by mothers of low-cancer strain. It looked as though something affecting the occurrence of cancer in later life were transferred to the young in mothers' milk. But there were still stranger findings. If young mice of the low-cancer stock were suckled by high-cancer mothers and developed cancer later despite their hitherto unstained "family escutcheon," then, on inbreeding them, their children and grandchildren were also very liable to breast cancer. On the other hand, the young of the high-cancer stock which escaped the disease through being fostered by low-cancer mothers were able to pass on their freedom from cancer to their descendants. Dr. Andrewes added that Bittner had considered whether the agent transmitted in the milk might not be a hormone. "I can swallow some things, but it is hard to swallow a hormone which, when taken in infancy, will condemn your grandchildren to the development of cancer in their years of maturity." But on casting one's mind back to some instances of indigenous virus infections it was not too difficult to believe that Bittner's high-cancer mice were infected with an indigenous virus which normally remained quite latent, and ultimately a series of stimuli, perhaps acting over a long period, revealed its role as a causative agent of breast carcinoma.

Theory of "Toothless" Viruses

After mentioning other work Dr. Andrewes suggested that a virus might depend for its power to infect normal cells on some, possibly haptene-like, aggressive mechanism—"teeth," as it were—permitting an entry into the new cell. In certain circumstances a virus might perhaps lose its "teeth" by disuse atrophy, as armadillos and ant-eaters had done. One might imagine that this could happen most readily in the environment of the cancer cell, where virus could be carried on from cell to daughter and granddaughter cell as division was stimulated, and the need to come out of the cell to look for fresh prey would disappear. The virus which had become "toothless" by some such process could thus act as a proximate cause of cancer, and yet one would never be able to demonstrate its presence by injecting tumour extracts into fresh hosts. Roundabout methods of revealing them would always be necessary.

It was not very easy to reconcile the conception of a "toothless" virus in the cancer cell with the need for visualizing some possible means of carrying the virus over from one generation to the next. Complete "toothlessness" seemed to involve transmission through the germ plasm: relative "toothlessness" would allow a little more latitude. "Toothless" viruses need not be found only in cancers. Might not the viruses which, as some thought, must persist after infections and be responsible for keeping up a lifelong immunity be capable of being modified or made relatively "edentulous" instead of merely being masked by antibody?

He disagreed with the recent suggestion by Green that a cancer virus in a cancer cell was the highest conceivable form of parasitism, virus and cell having their division exactly synchronized—almost a virus–host hybridization. The perfect parasitism was rather the association of a latent indigenous virus and its host, neither doing any harm to the other. Such a compromise had probably evolved in more instances than were suspected. Cancer, when it occurred in animals, would then be due to the incursion of some unexpected factor—a *tertium quid*, which broke up the happy association; a disease affecting both partners, of advantage to neither. Instead of human cancer being considered as a disease of man caused by a virus it would then be necessary to consider it as a disease of the man–virus partnership. To sum up, the association of hosts and parasites, particularly viruses, might lead not to violent disease but to a certain "balance of power," which might at times be upset with the result that the disease occurred after all.

Discussion

In some discussion following the address, Dr. T. W. **Lumsden**, taking up one remark regarding breast carcinoma in mice, said that he did not gather when he saw Bittner, whose work Dr. Andrewes had quoted, that he claimed that if the mice with a low-cancer strain were suckled by a mother with a high-cancer strain there was any constant increase of cancer incidence in the young. He thought everyone agreed that the reverse was the case—there was no regularity at all.

Dr. **Andrewes** remarked that his own statements had been made on the basis of Bittner's published figures.

Dr. G. W. M. **Findlay** recalled a book by Dr. W. O. Stapledon, *Last and First Men*, in which he pictured the human race some millions of years hence being attacked by the Martians with masses of various particles which had the property of receiving and transmitting short- and long-wave radiations. A large part of the human population was thus killed off, and it was only when man managed to incorporate the various particles into himself, thus converting himself into a receiving and transmitting station, that he overcame the forces arrayed against him. That seemed an analogy on the physical plane for Dr. Andrewes's argument on the biological. Latent infection in yellow fever was extremely well seen in the African wild monkey; many of these animals were found to have immune bodies to yellow fever. It was well known that man could form reservoirs of latent herpes virus in very peculiar situations. A friend of his always got genital herpes on taking a Turkish bath. A girl now 8 years old, when she was 2½ fell down and grazed her palm; a bullous eruption formed, and ever since then, at intervals of three or four months, she had the same type of eruption, from which the herpes virus could be obtained. Psittacosis in parrots and budgerigars had been mentioned. This infection could apparently continue latent for a long time. Some years ago the wife of a well-known American became possessed of a parrot of which she was very fond. The bird was apparently in good health, but after eighteen months or two years the lady developed psittacosis, and it was then found that the parrot was excreting psittacosis virus in considerable amounts.

Mr. J. T. **Edwards** said that the conception which Dr. Andrewes had brought forward was not very difficult for those who practised veterinary medicine on domestic animals. It had long been recognized that neoplasms in fowls might be caused by filter-passers. Rinderpest in cattle could be transmitted to rabbits, causing merely a transient latent infection. Dr. Andrewes had quoted German workers (Waldmann, Trautwein, and Pyl) to the effect that the virus of foot-and-mouth disease could be detected in the urine of hyperimmunized cattle more than 200 days after recovery. The speaker was very sceptical about that statement. The fact was that the virus would not survive in the urine. The observation was more likely to be explained by an accidental infection. He referred in conclusion to the great difference between viruses; some were extremely difficult to kill, persisting for years in the laboratory, whereas others were very fragile. What was the cause of this difference? Was it not possible that in the case of mammalian cancers the virus was extremely fragile, and when released, perhaps by adsorption on the proteins of the host cells, it immediately became inactivated and not able to persist independently as in the case of avian agents?

Dr. Tom **Hare** was not sure whether Dr. Andrewes had suggested that in fowl paralysis (neurolymphatosis) the causative agent was a virus. Perhaps he had merely claimed that from the results obtained by certain workers it appeared that a virus was present. That view was certainly held by a number of workers in America and on the Continent as well as at Cambridge. But from his own work during the last five years he found it very difficult to recognize fowl paralysis other than as inherited as a Mendelian recessive. It might be possible that a virus had passed through the germ plasm, but it was extremely difficult to visualize that it would so pass in almost strictly Mendelian proportions. Again, where fowl paralysis was firmly established on a farm year after year one would expect some increased virulence of the virus so that there would be transmission to other "healthy" strains if in close contact—not solely in adult life, but from hatching onwards—with the fowl-paralysis-bearing strains.

Dr. J. H. Douglas **Webster** said that from a clinician's point of view one of the most striking characteristics of an established tumour was that it often showed periods of quiescence which alternated with periods of activity. The late Sir John Bland-Sutton used to say that in speaking of the progress of a growth "recurrence" was not the right term; it should be called "incomplete operation." But it was a question whether he was right. The operation might have been complete as regards the cell but not as regards the virus infection. He had found after a certain amount of study of the subject that cancer recurrences showed a certain periodicity almost exactly similar to that shown by influenza. The periodicity of influenza, which was a known virus disease, resembled closely that of malignant disease and of a number of benign tumours and leukaemia. There was no necessity to accept Dr. Andrewes's suggestion of a *tertium quid*. Here was a virus infection which went into hibernation, and then the virus, from some unknown intrinsic cause, started reproduction, and the patient had recurrences which, in his belief, came in periodical cycles. The only thing that he could say with regard to the *tertium quid* was that in one series of patients a few weeks after an influenza attack he had seen cancer recurrences and cancer primaries occur. The influenza was possibly the *tertium quid* which had stimulated the appearance of malignancy. In a few other instances he had found malignancy, primary and secondary, immediately after the cessation of menstruation, which suggested the possibility of a hormonal *tertium quid*.

Dr. **Andrewes** said that Dr. Hare had asked for an explanation of how a virus could be transmitted as a Mendelian character, particularly as a recessive character. He would prefer not to have to produce a hypothesis until he was confronted with the evidence. He thought that there was need for caution in accepting any suggestion that a cancer had a purely hereditary character, although it had undoubtedly hereditary characteristics.

Local News

ENGLAND AND WALES

Tuberculosis in Wales

Special interest attaches to the annual report of the King Edward VII Welsh National Memorial Association because it includes an excellent summary of the recommendations (which more particularly affect the association) of the Committee of Inquiry into the Anti-Tuberculosis Service in Wales and Monmouthshire. The report of this committee, which covered a much wider field than that originally fixed by the terms of reference, attracted considerable attention, and has already been noticed in these columns (*Journal*, March 18, 1939, p. 577). Those who find the original report too long for study would do well to read and digest Dr. D. A. Powell's summary. Commenting on the committee's findings, Dr. Powell points out that they confirmed the contention of the association that the failure of local authorities in many areas to carry out their statutory duties in the prevention of the disease was chiefly responsible for the fact that since 1915 the death rate from tuberculosis in Wales had not fallen as rapidly as in England and Scotland. "Because the patient (and naturally he looms large in the public eye) is the responsibility of the county," states Dr. Powell, "many sanitary authorities seem to assume that tuberculosis (a much bigger issue than the tuberculous) has very little, if anything, to do with them. The county council, on the other hand, has been too ready to act on the assumption that it is not quite the thing even to take an active interest in, and still less to interfere with, the work of the smaller authorities within its administrative area." This is all the more deplorable since "in virtue of their joint responsibility the county council and the Minister of Health have the power to supervise, augment, compel, financially penalize, or *supersede* the efforts of local authorities." Dr. Powell discusses the remedies, and emphasizes that the committee completely vindicated the association. The greater part of his report contains the usual statistical tables and references to the different dispensary areas and institutions, and illustrates the expanding work of the association limited by the special difficulties in Wales.

Tribute to a Yorkshire Doctor

Residents of South Milford, Yorkshire, on October 18 assembled at St. Mary's Church to pay tribute to the memory of Dr. A. H. Radcliffe, who lived in the village and died on February 7 after thirty-six years in practice there. A memorial tablet was unveiled by Mr. Harold Collinson, consulting surgeon to the General Infirmary at Leeds, who in a short address commemorated the life and qualities of Dr. Radcliffe. He said that in spite of all the activities of the Ministry of Health and of the public authorities the family practitioner still carried out the major proportion of the medical work of the nation—work which brought him into every household and made him not only an adviser but a valued friend. "He is the standard by which we doctors are measured, and the estimate of the profession in the eyes of the public is their estimate of him. The best doctor is often one of whom the public hears the least. He belongs to the great army of quiet workers, physicians and priests, sisters and nurses, of whom little is heard but to whom is given the ministry of consolation in sorrow, need, and sickness."

Correspondence

Gas Injuries to the Eye

SIR,—Mr. Arnold Sorsby (*Journal*, November 4, p. 927) does not know of experimental work to test whether irrigation with oil is efficient in treating damage to the cornea from liquid mustard gas. I can tell him that much research has been done for the German Army Medical Service, and the treatment is by means of a mixture of cod-liver oil and glucose. The cod-liver oil is emulsified with a little alkali (1 per cent. sodium carbonate). To 100 c.cm. of the mixture is added 4 c.cm. of pituitary (posterior lobe) extract. I do not know the proportion of glucose which is employed.

The use of cod-liver oil rather than olive oil is interesting in view of the value of cod-liver oil as a dressing for burns or infected skin wounds.

This formula for eye treatment has never been published.—I am, etc.,

J. H. BURN,
Oxford, Nov. 4. Professor of Pharmacology.

SIR,—The leading article in your issue of November 4 on the above subject rightly stresses mustard gas as the most important of the chemical warfare agents in producing eye injuries. There are, however, certain points in the consideration of the subject in this leading article which require comment.

First, the suggestion that the use of chlorinating agents will minimize the effect of a mustard-gas burn of the eye is not in accordance with experimental findings in my experience. The effect brought about by contamination of the eye is immediate, and no amelioration of the injury can result from irrigating with chlorinating agents or any other liquid. The mustard gas remains only momentarily in the eye; it is squeezed out by the lids and washed away by the tears. Irrigation will remove any unabsorbed liquid mustard gas which may be on the surrounding tissues, and will allay irritation, cleanse and relieve spasm, but it will not influence the damage which has already occurred to the tissues of the eye. Irrigation, it is suggested in the article in question, has some value by minimizing the cumulative action of the agent. While this contention is true in so far as skin lesions are concerned owing to the greater resistance of the integument, the argument is fallacious when applied to the ocular tissues. The damage to the delicate membrane of the eye is so rapid that even the immediate rush of tears, Nature's method of irrigation, will do no more than remove unabsorbed mustard gas.

Secondly, there would appear to be some confusion regarding the reason for the instillation of drops of castor oil or liquid paraffin. This procedure is criticized on the grounds that as these substances are solvents for this chemical warfare agent, the action of the gas will be disseminated. In actual practice this does not take place, as unabsorbed mustard gas will have been washed out of the eye by the tears before liquid paraffin or castor oil is introduced. It is argued that as greasy preparations in the treatment of mustard-gas injuries of the skin have not been found beneficial, a similar objection exists with regard to their application to the margins of the lids. While to a certain extent this may apply, the advantage gained by permitting free drainage from the eye, which follows their use, more than outweighs the possible intensification of the established injury to the margins of the lids.—I am, etc.,

War Office (A.M.D.7), Nov. 4. L. T. POOLE.

SIR,—Will you permit me to suggest the use of dielectric oil (which can be obtained from J. Bury, Ltd., 5, St. Ann Street, Manchester) in injuries to the eyes from liquid mustard or other poisonous gases. This oil is simply de-ionized petroleum, but it has some strange properties.

The late Mr. F. H. Bowman, D.Sc., the originator of this form of oil, explained that being dielectric it was absorbed very rapidly, and by surrounding the damaged nerve filaments with an insulating material it prevented the escape of the "neuro-electricity" which he said was responsible for inflammation and pain. Be this as it may, the fact remains that in burns, contusions of any kind, and even in acute pleurisy, the effect of the oil is little short of miraculous. I have used it in various eye troubles and have had some personal experience. Once when painting a fence with creosote a great splash of the creosote flew back into my right eye. I rushed into the house and thought my eye was destroyed, because in a mirror the only thing to be seen was a red ball unrecognizable as an eye. My first intention was to use a soda solution, but seeing a bottle of dielectric I filled my hand with the oil and inverted it over my eye. The pain, which had been intense, was relieved almost at once, and within a quarter of an hour the only sign of trouble left was some redness of the conjunctiva. Some years later I had an acute inflammation of one eye, due to a Koch-Weeks infection. As after some days of expert irrigation, it showed little sign of improvement, I had resort to dielectric oil and the trouble cleared up very rapidly.

As liquid mustard gas is oil-soluble, there is a greater probability that the dielectric would prove of use. At all events I am sure that it would remove pain more quickly and permanently than either cocaine or dionine.—I am, etc.,

London, W.1, Nov. 4. ALEXANDER FRANCIS.

Choice and Preparation of Blood Grouping Sera for Emergency Purposes

SIR,—I have read with interest the article by Drs. S. W. Challinor, J. C. J. Ives, and C. E. van Rooyen (*Journal*, October 28, p. 850), and would supplement the information given by them with certain observations that have been made on the large number of sera of Group A and Group B that have been studied since the formation of the Army Blood Transfusion Service.

The authors rightly draw attention to the fact that the size of agglutinated clumps is of value as a preliminary selective test, but the speed with which the agglutination occurs is of equal importance. The two features may be described as "avidity," and it is only those sera with marked avidity that are worthy of titration. Avidity and high titre are roughly parallel. The article mentions, but does not emphasize, that the titre is influenced by the agglutinogen content of the corpuscles under test. Fallacies arise if titrations are carried out with corpuscles whose sensitivity to agglutination is unknown. All difficulties are avoided if the titration test is expanded to include a control consisting of a standard reliable serum of known titre; this will indicate whether the test corpuscles are suitable.

The authors make no mention of the simple freezing method for concentrating serum which was described by O'Meara (*J. Path. Bact.*, 1933, **37**, 166). With this procedure sera which are reasonably avid and yet have a titre below 1 in 100 can be made use of.—I am, etc.,

Army Blood Supply Depot, Bristol, Nov. 2.
L. E. H. WHITBY, Colonel.

Storage and Use of Grouping Sera

SIR,—I expect others have thought of the following technique, but I have not seen it published.

The sera are stored in sterile vaccine bottles which are closed with a rubber cap. (The usual practice is to employ white glass for Group A and amber glass for Group B serum.) Each bottle is accompanied by the *shaft* of a serum needle, conveniently attached by two rubber bands; the shaft may be obtained by breaking off the shoulder, or when quantities are wanted the needle-tubing may be purchased and cut up. When a test is to be performed the needle-shaft is removed from under the rubber bands, sterilized in a flame, and allowed to cool, and the pointed end is plunged through the rubber cap for a few millimetres. The bottle is inverted, and gentle pressure is applied with the finger to the rubber cap to eject a drop of serum from the needle-shaft. This technique is equally useful whether one or a series of tests is to be performed. At the end of the sitting the needle-shaft is removed, washed through with water, and replaced under the rubber bands.

This simple procedure has a number of advantages. With ordinary care the bottles of serum remain uncontaminated for weeks or months. Packing of a complete outfit is reduced to a minimum. The manipulation required is no greater than in the case of sera sealed in glass capillaries, and it avoids the laborious process of filling and sealing dozens of capillaries. Teat pipettes are often used for delivering the sera from the bottles when many tests are to be done, but are clumsy; it is only too easy to knock over the little bottle when the pipette is in it, and there is always the risk of interchanging the A and B pipettes; the present method removes these difficulties. The wire loop used for adding the donor's blood to the grouping sera, and the needle for pricking the skin, may also be kept under the rubber bands.—I am, etc.,

Emergency Blood Supply Depot, Luton, Nov. 4.
G. A. HARRISON.

Treatment of Gas Gangrene

SIR,—The leading article on chemotherapy and infections of war in your issue of October 28 (p. 859) states that all wounds which appear likely to become the site of infection with gas gangrene should receive a prophylactic course of sulphonamide compounds at the earliest opportunity.

The heavy mortality of this condition is due, in part, to a late diagnosis. E. Dunbar Newell, in a paper on gas gangrene (*Ann. Surg.*, 1939, **110**, No. 1, 100), points out the great value of roentgenograms in showing the presence of gas bubbles in the tissues. The film enables very early diagnosis to be made in suspected cases, and is positive hours before the physical sign of crepitus. As early treatment of gas gangrene can give a mortality as low as 5 to 15 per cent. instead of the usual mortality of 49 to 80 per cent., the value of this special method of early detection would seem to be worth emphasizing at the present time. Rinehart was the first to call attention to the value of the roentgenogram in making a diagnosis before the infection is clinically apparent. In suspected cases the roentgenograms should be repeated every four hours. If there is a steady increase in the number of air bubbles in each succeeding film it may be concluded that they are not due to the inclusion of air in the wound.

The presence of gas may be due to colon bacillus infection or to surgical emphysema, but clinical features of the sudden onset of violent pain in the wound, an increase of volume of the limb, a sudden rise of pulse rate in relation to the temperature, and a general appearance of grave illness should help one to the correct decision. On inspection of the wound there is oedema, a brownish discoloration round the wound, and a brownish serous discharge. The wound has often a peculiar mousy "sweet-sour," offensive, or putrid odour, and the nurses may be able to report the presence of this. It is a very characteristic odour. Many lives may be saved by the early detection of this physical sign. In the actual treatment of cases of gas gangrene one depends upon the decompression of the parts by splitting the deep fascia on two sides of the limb, the excision of dead muscle masses, hydrogen peroxide irrigations, large magnesium sulphate soaks, strict immobilization and elevation of the limb, the use of 10,000 to 30,000 units of polyvalent serum intravenously at six-hourly intervals, and the use of sulphonamide. In desperate cases amputation has to be considered.

There is still another method of treatment reported upon very favourably by Kelly and Dowell, who refer to forty-four cases of gas gangrene of the extremities treated with *x* rays (*J. Amer. med. Ass.*, 1936, **107**, 1114). There were twenty-nine in which amputation was not performed, and all these cases recovered. Out of fifteen cases who had amputations, five patients died. Kelly concludes that *x* rays seem to be definitely established as an aid in the treatment of gas gangrene.

The prevention of gas gangrene would seem to depend upon early well-executed surgery to excise the wound carefully. Dead and devitalized tissues must be removed, especially crushed muscles with damaged blood supply. Foreign bodies are removed. Thereafter the limb has to be efficiently splinted in the elevated position and the wound kept thoroughly at rest. Some surgeons now favour complete fixation in a plaster casing, as reported upon so successfully by Trueta. In the presence of severe involvement of the blood vessels of the limb and of much destruction of muscles an amputation may be the best primary treatment. There is evidence to support the view that the prophylactic injection of gas-gangrene serum is of value in lengthening the incubation period and in lessening the severity of the attack.—I am, etc.,

Edinburgh, Oct. 30.
W. A. COCHRANE.

Radon Supplies

SIR,—The Radon Centre at the Middlesex Hospital has been transferred to quarters in Bedfordshire by the courtesy of the management of the Barton Lime Co., and supplies of radon will be available as from November 10. The expenses involved in the transfer of radium and plant and the equipment of the new quarters are being borne at present by the Medical Research Council and the British Empire Cancer Campaign.

The accommodation is being shared by the London Hospital, who are installing their radon plant there. Radon from 1½ grammes of radium will be available from this emergency centre. Should the demand for radon exceed the supply, it is probable that other former radon centres will join in the scheme, bringing in additional quantities of radium.

It is proposed to charge a flat rate of 1s. per millicurie, but it is recognized that for some forms of treatment radon at this rate may prove too expensive for many users. For example, the treatment of uterine cancer by the Stockholm technique would involve supplying 125 mcs. on three separate occasions. The use of 125 mcs. for twenty-two hours (first treatment) would utilize less than 20 per cent. of the radon supplied. This running to waste of 80 per cent. of the supply can to some extent be minimized by arranging that several cases are treated by means of the one supply. Certainly two and possibly three patients in series could adequately be dealt with, provided we can get collaboration to this end. If institutions would bear this in mind when requisitioning radon a great saving can be effected and many more patients can be treated. Platinum radon seeds will be charged at cost, but ordinary platinum screens and applicators will be lent free of charge.

Communications should be addressed to the Radon Centre, c/o Barton (Beds) Lime Co., Barton-in-the-Clay, Beds.—I am, etc.,

London, W.1, Nov. 6. Sidney Russ.

Treatment of Venereal Disease in the Field

Sir,—I have read with interest Lieutenant-Colonel E. T. Burke's letter in the *Journal* of November 4 (p. 928) concerning the treatment of venereal disease in the field. I agree with him that V.D. cases should preferably be treated by experienced venereologists. Mobile V.D. units would be the ideal. With modern methods of treatment there is now no need to keep the average case detached from the service unit as in the last war. The suggestion of using a preparation such as stabilarsan (already in solution) or "914" dissolved in sodium thiosulphate solution is excellent. Although I myself am always an advocate of the concurrent intermittent method of treatment for the early syphilitic, I believe that the excellent unit course suggested by Lieutenant-Colonel Burke could be simplified without loss of therapeutic effect.

May I suggest the following scheme for primary or secondary syphilis in the Services:

Unit Course

Week	Intravenous As ("914") (grammes)	Intramuscular Bismuth (grammes)
1 ..	0.45 followed four days later by 0.45	+ 0.24
2 ..	One injection of 0.6	+ One injection of 0.24
3 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
4 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
5 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
6 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
7 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
8 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
9 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
10 ..	,, ,, ,, 0.6	+ ,, ,, ,, 0.24
Total..	.. 6.3	+ 2.4

Each unit course to be repeated after an interval of one month, and a total of at least four courses to be given.

Serological tests should be made every three months throughout the year following the fourth course.

Finally a cerebrospinal fluid test.

I know the results of such a scheme to be a 100 per cent. cure rate; and here the patient is not subjected to five injections a week, but receives three in the first week and two in each of the following nine weeks.—I am, etc.,

C. Hamilton Wilkie,
Director of V.D. Services, Leicester Royal Infirmary.

Nov. 6.

Immunization of School Children

Sir,—One of the endless problems connected with the evacuation of children from big towns into country districts is that of the relative suspension of the school medical service. No doubt those to whom the care of the health of the child population of this country is entrusted are fully aware of the possible consequences of this situation. It is of course essential that the progress that has been achieved in social medicine should not be allowed to deteriorate even under the stress of war, but it is also essential that urgent measures which promised to come to fruition before the outbreak of hostilities should not be altogether dropped. This is particularly important when such measures have become all the more necessary owing to the present abnormal conditions. Diphtheria immunization of children is a case in point. It has been repeatedly pointed out, and Sir John Ledingham emphasizes the issue in his survey published in the *Journal* of October 28 (p. 841), that diphtheria immunization in this country is on a lamentably low level. A diphtheria epidemic among children at the present moment would threaten a heavy toll owing to the disorganization of the ordinary routine of child life and the ordinary facilities of isolation and treatment. In a letter in your columns published a fortnight before the outbreak of the war (*Supplement*, August 19, p. 153) I urged the need for a more intensive effort towards diphtheria immunization as a preparatory measure of national defence. Now that the situation that was feared has developed it is to be hoped that the responsible authorities are not losing sight of this life-saving measure. It is sincerely to be hoped that it will not be necessary for a calamity to emphasize the obvious need for this procedure.

Another problem which may become a matter of immediate urgency before long is an epidemic of measles among children bred in town and now living under conditions abnormal to them. A measles epidemic is indeed to be expected this year, and the possibility of severe respiratory complications among the evacuated children has to be considered. It is true that immune serum is not yet a perfected method for the treatment of measles, but its value is not doubted. Is it beyond the possibility of the organization of child life in the reception areas to have facilities available for the supply of such serum at short notice should the occasion arise when it has to be used?—I am, etc.,

London, E.5, Nov. 5. Max Sorsby.

Colles's Fracture and Traumatic Oedema

Sir,—The clinical memorandum by Mr. R. Salisbury Woods in the *Journal* of October 14 (p. 767) describing a case of Colles's fracture occurring together with a dislocated elbow in the same patient once again brings before surgeons and masseuses the problem of traumatic oedema. Some years ago one used frequently to see cases of a completely stiff trophic hand following some trivial crush injury which fractured some metacarpals or phalanges. But thanks to the teaching of Böhler as regards early movement of the distal joints after a fracture such cases are fewer. Once such a condition sets in massage and stretching do more harm than good. Yet these are often carried out by masseuses who ought now to know better.

I recently dealt with a typical case of acute traumatic oedema which should never have been allowed to occur. A man sustained a simple Colles's fracture; this was correctly set and put in plaster at a hospital. During the first week he complained of tightness and swelling, but the casualty sister gave him some aspirin, and at the end of a week he was seen by a visiting surgeon. The wrist was taken out of plaster and put on a Carr's splint; massage was advised. This he had privately, and for a month the masseuse massaged and stretched the fingers and wrist. I saw him at the end of two months, when by now the fingers were practically stiff in a semi-flexed position, the wrist had no movement at all, and the circulation was poor, the skin being blue and shiny—a typical neurotrophic hand. I put the hand at rest, giving him daily wax and infra-red and contrast baths. At the end of a further fortnight the circulation was back to normal and the fingers were loosening spontaneously. Faradic arm baths and active movements such as dummy piano-playing were started. When movements were better manipulation of the wrist was carried out, after which normal recovery of the hand and wrist quickly took place. The earlier treatment indicates the abuse of massage and the failure of that masseuse to understand the physiology of the vasomotor system in fractures, and its readiness to pour out the binding traumatic oedema. This physiological problem is dealt with very lucidly by Mr. Eldon Tucker in his book on injuries.

Any patient with a Colles's fracture must be made to carry out finger exercises on the first few days after reduction of the fracture. There are, however, cases, usually in women, where the circulation appears sluggish and swelling of the fingers outside the plaster persists, even though the plaster be a split one. These cases are ones of vasomotor paralysis (see article by Turner on neurotrophic disturbances after Colles's fracture, *J. Bone Jt. Surg.*, January, 1931), and are likely to give trouble with stiffness unless special care about active movements be carried out from the first.—I am, etc.,

London, W.1, Oct. 25. G. O. Tippett.

Varicosities of Veins

SIR,—Mr. J. B. Oldham's letter (*Journal*, October 28, p. 885) gives facts of first-class importance about the risk of ligating the internal saphenous vein at the saphenous opening in the presumably ambulatory patient. The operation appears to be safe and is known to be very suitable for obliterating the superior reflux when the valves are incompetent, as in a Trendelenburg-positive case. Would that we could control the inferior or muscular reflux as easily. The anastomoses of the superficial epigastric, circumflex iliac, and external pudic veins are of no importance in the average case of varicosity. When they become thrombosed after an ascending injection, given by the empty-vein method with elevation of the limb, recurrence may still take place. The choice of operation now lies with the most certain surface marking. The difficulty of finding the vein lower down in its course in a fat subject is sometimes considerable.

The late Sir Henry Gray in 1909 introduced an important modification of Babcock's extraction operation and used to demonstrate that the saphenous vein could generally be felt in the wound in cases of difficulty if the limb were abducted. He also showed that the smallest knob used on his extractor when passed from above downwards would stick at the valves when Trendelenburg's sign was negative, and he then passed it from below. It occurs to me that the larger knob on the distal end would be useful to draw up the sclerosing fluid after the upper part of the vein had been tied. But is suction really necessary when any guidable solution, such as sodium salicylate, is employed? By utilizing the pain as a guide one can generally ensure that the solution enters any required areas (see *British Medical Journal* of November 9, 1929). When morrhuate or other nearly painless injection is used Mr. Oldham's method with a ureteric catheter is likely to be a permanent addition to the technique. As the pain caused by salicylate, saline, and some other solutions is a delayed one, the transit of the catheter would have to be fairly rapid or the pain would be too prolonged to be bearable.

It has been the experience of many that 30 per cent. salicylate in the absence of saphenous ligation is often insufficient to produce thrombosis, whereas 40 per cent. is enough. A condition of the vein refractory to thrombosis arises (see *Lancet* of August 8, 1931). A similar condition is figured in the *British Medical Journal* of July 13, 1935. For such types ligation of the saphena combined with injection is indicated. But one cannot as yet predict that this condition will arise. It seems to me that the obvious course will be to inject first from below upwards by the empty-vein method so as to flood the whole available area if possible and then to tie and divide the vein high up. Judging by former three-year results ligation will seldom be required. The variables are so numerous and classification so difficult that it is not yet possible to say that any one method or solution should have the preference.—I am, etc.,

London, W.1, Oct. 31. G. H. COLT.

Procaine or Percaine?

SIR,—As medical adviser to the manufacturers of percaine I attended the inquest reported in the *British Medical Journal* of October 28 under the heading "Procaine or Percaine?" The suggestion that "the most important factor was the similarity of the two names" is untenable, since the medical witness testified that (*a*) he knew that percaine and procaine were not the same drugs, (*b*) he read the words "Percaine 2 per cent. solution" on the bottle, (*c*) he referred to the manufacturers' price list in order to ascertain whether percaine 2 per cent. solution was suitable for injection, and read the words "exclusively for surface anaesthesia" in the specification of this solution.

There was, in fact, no suggestion that percaine was administered to the deceased in the mistaken belief that it was procaine. The alleged confusion between the two names (the doctor stated that he had verbally ordered procaine, while the dispenser stated that percaine had been ordered) is relevant only to the events preceding the opening of the package by the doctor. It was not the "vital distinction between the two names" that the doctor failed to appreciate, but the vital distinction between the appropriate concentrations of two substances known to be different.

The statements that "procaine . . . may be sold to a lay purchaser without restriction or record" and that the chemists were "within the law in dispensing percaine on a doctor's verbal order" if they made an entry in the prescription book are both incorrect. Procaine and percaine are both First Schedule poisons with the qualification that procaine solutions of less than 10 per cent. are exempted. A dispenser is not entitled to supply a First Schedule poison on a doctor's verbal order unless he is (*a*) satisfied that there is an emergency, and (*b*) secures an undertaking from the doctor that he will supply a written order or attend personally to sign the Poisons Book within twenty-four hours. The percaine solution was therefore improperly dispensed in this case, although it is plainly indicated in the manufacturers' price list that it is a First Schedule poison.

Accidents must be expected if poisons are dispensed and administered with a disregard of their conditions of sale and administration, and to attribute such accidents to a similarity of names when all parties concerned knew that the two names represented two different compounds is an argument which I cannot follow. It is evident from the fact that procaine, ethocaine, allocaine, syncaine, kerocaine, neocaine, novocain, and planocaine refer to an identical substance that no mere dissimilarity of terminology could serve to indicate a difference of dosage. Percaine was introduced and had become well known and widely used under that name during the three years before the official adoption of procaine—a name which was almost unknown in this country and has not yet attained general currency. A simultaneous change in the names of two well-known local anaesthetics might well have caused considerable confusion, and the manufacturers felt that it would be desirable that at least one of these drugs should retain the name under which it had become well established.—I am, etc.,

The Laboratories, Horsham, Nov. 2. N. HOWARD JONES.

⁂ The report might with advantage have referred to "2 per cent. procaine" instead of to "procaine" in the phrase challenged. It is, however, clear that what is referred to throughout the report is not procaine itself but a 2 per cent. solution, and it is the law that such a solution may be sold without a record having to be kept by the seller. In his principal challenge Dr. Howard Jones correctly summarizes the conditions in which—under Section 18 (2) of the Pharmacy and Poisons Act, 1933, as applied to Section 20 by Rule 7 of the Poisons Rules, 1935—poisons in the First Schedule of the Rules may be supplied to a medical practitioner. But he overlooks the alternative method provided by Section 19 of recording the supply as a prescription in the prescription book. It was to this method that the report referred and it appears to have been the method properly adopted by the chemist.—ED., *B.M.J.*

"Foreign Pharmaceutical Products"

SIR,—The schedule of pharmaceutical specialties published in your issue of October 28 was prepared as a war measure by the Association of British Chemical Manufacturers with the express object of advising the medical profession of British sources of supply for products available in replacement of preparations which were understood to be foreign products and of which supplies might prove difficult to obtain through pre-war channels. The schedule had, therefore, to be completed quickly under the stress of war conditions. The Association included in the schedule all proprietaries which it was advised were foreign products. Despite its care to have the list as accurate and complete as possible, it is regretted that a few inaccuracies have occurred, and for these the Association tenders its sincere apologies to you and to the firms concerned.

The Association is glad to be able to report that it has now been advised by the following firms—non-members of the Association—that the products shown below against their names are in fact made in this country and should therefore be deleted from the list of foreign products:

Firm	*Product*
Ciba Ltd.	Dial tablets
Denver Chemical Manufacturing Co.	Antiphlogistine
Menley and James Ltd.	Calsoid
Modern Pharmacals Ltd.	Sulfarsenol
H. R. Napp Ltd.	Fiatal Raminal Somnosal
Gedeon Richter (Great Britain) Ltd.	Aurobin Kalmopyrin
Roche Products Ltd.	Digalen Larostidin Omnopon
William R. Warner Ltd.	Anusol Veganin.

A revised edition of the schedule is now being prepared and will be available for issue (gratis), both in replacement of the copies already distributed and for new inquirers, in the week commencing November 13. This edition will take into account the above amendments and such other omissions and additions as have already been brought to our notice. You have already been good enough to indicate a number of these in the annotation in the issue of November 4. As indicated in the foreword to the present edition, the Association will at all times welcome observations and suggestions which will enhance the accuracy and scope of the publication, and any amendments which these may necessitate will be made in subsequent editions.—I am, etc.,

166, Piccadilly, W.,
Nov. 6.

J. DAVIDSON PRATT,
General Manager, Association of British Chemical Manufacturers.

Personal Hygiene in Syllabuses of Training Colleges

SIR,—In a letter which appeared in the *Journal* of October 14 (p. 785) Dr. Octavia Lewin states: "It is well known that personal hygiene is not on the syllabus of the training colleges. It is easy to understand, therefore, why it is not in the curricula of the schools." This statement is directly contrary to the facts. Hygiene is a compulsory subject in the training colleges, and the syllabuses in use at those colleges are submitted to the Board of Education for their approval. These syllabuses, of course, include personal hygiene. Moreover, the Board's *Handbook of Suggestions on Health Education*, on which indeed some of the syllabuses are based, and which deals specially with personal hygiene, is increasingly used in the training colleges by students and lecturers alike.—I am, etc.,

Board of Education, Nov. 3.

A. R. AINSWORTH.

Peter Camper

SIR,—Your interesting note on Peter Camper under "Nova et Vetera" (October 28, p. 867) would suggest that the distinguished Dutchman was primarily an exponent of "midwifery and the diseases of women," as those subjects were designated in the times in which he lived, and lived lustily, as the secrets of his diary divulge! But surely his name goes down to posterity as an anatomist at least first, and perhaps foremost. Have we not all been hard put to it to remember whether the fascia in the inguinal region which goes by his name was really the superficial or the deep sheet, both being eponymous? Garrison credits him with discovering the processus vaginalis of the peritoneum and the fibrous structure of the lens, and he certainly wrote a treatise on hernia. But in the old days the study of anatomy and the practice of obstetrics often went hand in hand, as witness the fame in both fields of James Douglas and his pouch and William Hunter and the monumental *Anatomy of the Human Gravid Uterus*.—I am, etc.,

British Postgraduate Medical School, Oct. 31.

G. GREY TURNER.

Biography of Harvey Cushing

SIR,—Mrs. Cushing has requested me to prepare a biography of her husband, and I should be most grateful to anyone who wishes to make letters, anecdotes, or other memorabilia available. Copies of all letters, no matter how brief, are desired, and if dates are omitted it is hoped that, when possible, these may be supplied (for example, from the postmark). If original letters or other documents are submitted they will be copied and returned promptly.

A new medical library building is being erected at the Yale University School of Medicine to receive Dr. Cushing's library and collections, including his letters, diaries, and manuscripts. Any of his friends who wish, now or later, to present correspondence, photographs, or other memorabilia for permanent preservation among the Cushing papers will receive the appreciative thanks of the University.—I am, etc.,

JOHN F. FULTON, M.D.

Yale University School of Medicine,
333, Cedar Street, New Haven,
Conn., Oct. 16.

R.M.B.F. Christmas Gifts

SIR,—Many members of the profession have most generously supported the appeal made each year for donations towards the Christmas Gift fund of the Royal Medical Benevolent Fund. In the years of peace this special work of ours in bringing extra comfort and pleasures on Christmas Day into the homes of old people directly connected with our profession has obviously appealed to the hearts and sympathy of many of your readers.

In this year of war may I through you, Sir, ask the question —Is the Fund to give its usual gift at Christmas, 1939, or are these old people to receive nothing at a time when they may be suffering from greater privations and difficulties? I am very confident that the reply will be that this is not the year to withhold the gift which means so much happiness and brings such pleasure to many old and infirm people. I invite those who can contribute to send donations to the Royal Medical Benevolent Fund, Christmas Gift Account, Wormingford, Essex. Although many members of our profession have been hard hit, yet I have every hope that the response will be a generous one.—I am, etc.,

THOS. BARLOW,
President.

Nov. 1.

Obituary

DR. DAVID ALEXANDER MCCURDY, formerly of Derry, died at the Derry City and County Hospital on September 27 after an illness lasting more than thirteen years. Born in County Donegal nearly eighty-three years ago, he received his medical education at Trinity College, Dublin, and the Royal College of Surgeons in Ireland. In 1891 he qualified L.R.C.P.I. and L.M., with the special certificate in gynaecology from the Rotunda Hospital. He held for some time the post of resident surgeon to the Royal City of Dublin Hospital, and was elected F.R.C.S.I. in 1899. He had a large practice in Derry, and was the Board of Trade medical officer for that city as well as the medical representative there of the American emigration authorities. He was on board the Anchor liner *Columbia* on the historic passage when it had its bows stove in by an iceberg, but nevertheless reached its destination, New York, after three days of risk and adventure. Dr. McCurdy was widely popular in Derry, being associated with social and philanthropic activities, and highly esteemed by colleagues and patients. He joined the British Medical Association in 1892, remaining a member for thirty-five years. More than thirteen years ago he was incapacitated by a stroke, and during the last five years he had been living in Sheffield with his married daughter, returning to Derry only five weeks before his death.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on October 31 Sir Farquhar Buzzard, Regius Professor of Medicine, introducing two decrees, said that Professor G. R. Girdlestone, Nuffield Professor of Orthopaedic Surgery, has felt compelled to resign from his chair because of the great pressure of his clinical work. He is also resigning from the honorary clinical directorship of the Wingfield-Morris Orthopaedic Hospital because he feels that the professor should have the supervision and control of the clinical work of that hospital. Professor Girdlestone is not resigning from his appointment of honorary surgeon to the Wingfield-Morris Orthopaedic Hospital or that of honorary orthopaedic surgeon to the Radcliffe Infirmary. A decree providing for the appointment of the Nuffield Professor of Orthopaedic Surgery at £1,200 a year was approved. Hitherto it has been an honorary appointment. The new professor will not be permitted to engage in private practice for personal gain, but as clinical director of the Wingfield-Morris Hospital he will receive an additional stipend of £600 a year.

The time-table of the examinations for the degrees of B.M. and B.Ch. in the Michaelmas term, 1939, has been revised as follows: First examination, December 11, 12, 13, 15, 16, 18, and 19; second examination, December 6, 7, 8, 9, 11, 13, 14, 15, 16, and 18.

UNIVERSITY OF CAMBRIDGE

At a Congregation on November 4 the following medical degrees were conferred:

M.D.—*G. D. Hadley.

M.B., B.CHIR.—W. H. S. St. John-Brooks, H. Curtis, J. S. H. Wade, G. C. Smith.

*By proxy.

UNIVERSITY OF EDINBURGH

Sir John Donald Pollock, Bt., M.D., LL.D.Ed., Hon. D.Sc. Oxon., has been elected Rector of Edinburgh University. Sir John Pollock controls large business interests and has made many philanthropic gifts. He is a member of the executive committee of the Carnegie Trust for the Universities of Scotland and holds the honorary ranks of Colonel R.A.O.C., Surgeon Commander R.N.V.R., and Wing-Commander R.A.F.V.R. In the last New Year's Honours List a baronetcy was conferred upon him for benefactions and services to education.

QUEEN'S UNIVERSITY, BELFAST

War Service by Graduates

Queen's O.T.C. has been active in dealing with applications for commissions in the various Forces, and the Vice-Chancellor is anxious that all Queensmen and Queenswomen who have joined any branch of the Forces or the auxiliary services, or are engaged in any form of national service, should communicate with the secretary at the University to inform him of (1) the period during which they were in residence, (2) the date of their enlistment or enrolment, and (3) the branch of the Services which they have joined. The University authorities, aware of the difficulty experienced in the last war, are anxious to take steps at the present stage to secure a complete record of the war services of graduates.

The following candidates have been approved at the examination indicated:

M.B., B.CH., B.A.O.—Patricia K. Allan, T. T. Baird, A. F. Barr, P. J. Blaney, R. Calwell, R. H. Clarke, D. T. Crozier-Ritchie, A. F. Ferguson, R. F. Forbes, R. J. A. Heron, S. M. B. Hill, W. G. Jackson, C. Kelly, T. M. Kelly, W. N. M. F. Kelly, R. H. Kennedy, T. M. Lennox, J. Lillie, J. G. McAviney, J. M. McAviney, S. J. McClatchley, J. H. McIlrath, R. A. M. McVicker, D. Mitchell, T. E. Moody, C. J. K. Orr, R. Reid, A. W. W. Robinson, F. E. Scott, W. R. D. Seymour, T. B. Smiley.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the requisite examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P. and S.Glas.:

L. Abel, J. D. Addison, M. Ashpis, Elizabeth N. G. Baker, L. A. Bornstein, R. P. Boyd, A. Bleecker, J. C. L. Cameron, C. M. Chambers, A. D. Chisholm, G. A. M. Cowie, H. Cohen, S. D. Cudjoe, R. Dalrymple, I. Diamond, C. C. B. Doherty, H. Du T. Du Toit, O. Eisert, E. Emma, Ll. G. Ermshar, A. Fink, M. C. K. Finlayson, S. Fox, L. Gitman, A. Glassman, L. L. Goldberg, M. M. Goldenkranz, S. Gudis, G. R. Jones, A. I. Kaplan, L. A. Kaplan, E. W. Langs, R. B. Lenora, I. Levinson, M. McAlley, S. N. Mandel, M. Mariaskin, R. J. Mehr, A. Michelson, Jean Middlemiss, R. A. Morrison, J. Morton, R. S. Morton, J. H. Murray, M. N. A. Nasir, W. C. Pilgrim, E. Pravda, H. M. Pretorius, M. R. Rapoport, S. W. Rubin, T. Russell, D. R. Sandison, K. S. Seal, D. McG. Simpson, L. Singer, D. R. Skudowitz, T. M. Small, G. Smith, C. B. Storch, A. M. Tawfic, M. H. Tischler, E. M. Webster, A. Weiss.

The following graduates of recognized foreign universities were also admitted licentiates:

J. Adler, E. J. Billigheimer, J. Brand, K. F. Hirsch, E. Horowitz, R. Hurwitz, E. Schleyer, W. T. Strauss, R. Treu, A. Vogl, W. Worms.

Medical Notes in Parliament

This week the House of Commons approved a resolution to authorize the introduction of a National Loans Bill. Statements were expected from Mr. Chamberlain and Mr. Churchill on conditions of peace and the progress of the war.

The Chartered and Other Bodies (Temporary Provisions) Bill was introduced by the Lord Chancellor in the House of Lords on November 1. Its purpose is to promote economy and efficiency in the carrying on under war conditions of the work of certain chartered and other bodies, and to enable certain universities and colleges to adapt themselves to war conditions. The Bill was read a second time on November 7.

Evacuation Problems

A debate on the problems of evacuation was opened in the House of Lords on November 1 by the BISHOP OF WINCHESTER. A large number of mothers had returned to the towns, but the evacuated children were happy and were gaining in health. Very often the hosts, too, were happy, but a large number of people had been prejudiced against receiving children because some of them had left the towns with skin diseases or were infected. Such children should be sent to special hostels or camps whence, after a few days, they could, with a medical certificate, be sent on to a private house. The ARCHBISHOP OF CANTERBURY said there was urgent need for the medical officers of health throughout the country to provide special hospitals or "sick bays" in separate houses to which children who were ill or infected could be removed.

LORD DAWSON said the evacuation of children could not be more than partial, but the policy of evacuation must not be abandoned. About 250,000 children had been evacuated from London and had not returned. An equal number remained in London and were drifting about the streets. Provision must be made for the education and health of the latter, although welfare and hospital services had been reduced to skeleton services, babies were not looked after as in peace, and school medical services worked at half-speed. They could not afford to keep closed any longer the big hospitals which were the key and inspiration of medical thought. Any week now they might get the winter diseases and the height of the cycle of measles, with which they might get diphtheria. If the big hospitals were closed patients with early disease would be left at home, their condition neither diagnosed nor treated. There was danger, too, in the country districts, where an outbreak of severe influenza might occur in the overcrowded communities of the reception areas. They should remember that the power of resistance of the community was lower than in peace. He would without hesitation open the big hospitals in London, reserving one-third of each for casualties. If there were special facilities for evacuating into a hospital near by—not difficult to arrange—his proposition was quite practicable. Yet they went on from week to week and nothing happened. The big hospitals were pools of silence. The effect of removing for any length of time the normal services from 8,000,000 people in London would inflict more suffering than the dangers envisaged from air attack. This did not imply criticism of the Emergency Medical Service, which, under its Director-General, had done wonderful work. Besides reopening the big hospitals, medical education should be restored and the training of nurses resumed. The harm which was being done to the institutions was continuous, ubiquitous, and certain. Each profession should do the work which belonged to it in the place where it should rightly be done.

Earl **DE LA WARR** said the evacuation scheme was prepared on the assumption that on the declaration of war London and the other great towns would be subject to heavy bombing. It was now being judged by peace standards. The Government was reopening schools in the evacuation areas because 750,000 children could not be left without education and medical care, but it appealed to parents to leave in the reception areas the children who were there.

The debate then closed.

DISCUSSION IN THE COMMONS

Evacuation was also discussed by the House of Commons on November 2. Mr. **EDE** opened the debate.

Dr. **ELLIOT** said the actual movement covered 1,400,000 persons in England and Scotland. They were: 750,000 unaccompanied children, 542,000 mothers and young children, 12,000 expectant mothers, and 77,000 others. These one and a half million people, mainly children, were entrained, moved fifty to one hundred miles, detrained, fed, and re-accommodated in the space of four days without a single casualty. Inquiries from receiving authorities and from the large cities covering nearly three-fifths of all the evacuated school children showed that, speaking broadly, about 50 per cent. of the mothers and others who were evacuated and about 78 per cent. of the unaccompanied school children were still in the reception areas. Returns of the incidence of infectious diseases in the reception areas for the first two months since the outbreak of war showed there had been no increase; indeed, the figures for the "fevers" were actually lower than for the corresponding period of 1938. It had been a sunny, healthy autumn, and these figures must be considered with due reserve.

INCIDENCE OF "FEVERS" SINCE EVACUATION

Dr. Elliot gave the following figures of the total number of cases of diphtheria, enteric fever, pneumonia, cerebrospinal fever, and poliomyelitis in Great Britain.

Disease	Seven weeks to October 21	
	1938	1939
Diphtheria	9,960	7,637
Enteric fever	284	437
Pneumonia	4,365	3,268
Cerebrospinal fever	141	177
Poliomyelitis	544	267

For enteric fever—that is, typhoid—they got a striking result. In England and Wales there were sixty-two notifications in the week before evacuation began and seventy-seven in the week in which it actually started, as against forty-seven and thirty-two in the corresponding weeks of 1938. In the last two weeks for which we had figures they were forty-two for the evacuation year and thirty-two for last year (October 14) and thirty-one for the evacuation year as against thirty-six for last year in the last week—that ending October 21. As regards maternity cases, to move nearly 12,000 expectant mothers, still more to carry through childbirth with scratch nursing personnel and improvised accommodation, was an anxious task. In the 165 or so maternity homes, comprising 4,500 beds, which were improvised in the reception areas in Great Britain, over 3,500 confinements took place in the first six weeks of war. The proportion of complicated cases was no higher than normal. The incidence of puerperal fever and puerperal pyrexia up to the week ending October 21 showed no increase over 1938.

Circulars issued at the beginning of last month authorized the provision of accommodation in separate houses for children suffering from minor illnesses or convalescent from more serious illnesses who could not properly be cared for in their billets. Where the receiving district authority agreed, the county council would provide and maintain the sick bay. In making arrangements of this kind each case of minor illness should be admitted only on the recommendation of a medical practitioner. The practitioner should continue to attend regularly at the sick bay, and the staff should include at least one trained nurse. For an evacuated population of some 383,000, about 800 beds were being provided for non-notifiable infectious diseases and another 800 beds for minor illnesses. If the same proportion applied throughout the whole country, something like 2,500 beds had been provided for non-notifiable infectious diseases and about the same number for cases of minor illness. Measles and whooping-cough had been made compulsorily notifiable. Local authorities would know at once wherever an epidemic threatened and be able to take measures promptly.

In co-operation with the Central Medical War Committee arrangements had been made for the domiciliary treatment by general practitioners of unaccompanied school children in the reception areas. The treatment would be given to every child in need of it without charge to the householder. The practitioner would look for payment to the Government and not to the local authority. The cost worked out at slightly over 2d. a week—equivalent to about £250,000. A figure of 5,000 beds for children's illnesses and £250,000 for a children's medical service showed the scale of the scheme. The beds in the emergency hospital scheme would be available if needed to deal with calls for extra beds for cases which existing infectious diseases hospitals were not capable of accommodating.

HEALTH SERVICES IN RECEPTION AREAS

Dr. **HADEN GUEST** said there was urgent need in the reception areas for improved school medical and nursing services, clinics, and inspection of children. At the outbreak of war medical officers of health became heads of the casualty medical services in their districts. Public health nurses went to first-aid posts, mobile units, and other services of that kind. In many places 80 per cent. of the nurses left their ordinary public health duties. That wasted the capacities of women trained for public health duties and specially for school work. If all these nurses were withdrawn from first-aid posts and allied services they could be replaced from the civil nursing reserve. The medical and clinic services in the towns should be reopened. For these the Ministry must take some of the nurses from their present work. There were sufficient doctors to staff the public health services in the reception areas and to do the medical work required, as well as meeting the need for doctors in the casualty services. Those not required in the towns could be lent from the evacuation authorities to the reception authorities. The Minister should give a plain instruction to this effect.

Sir **RALPH GLYN** said he knew the immobilization of the great London hospitals and of many doctors was engaging the attention of Dr. Elliot. Doctors, who now were acquainted with their war stations, should have terms offered which enabled them to get on with their ordinary work, especially as consultants Unless specialists were attracted to give part-time services the London hospitals could not do the work they should do. The number of beds which these hospitals were allowed would be inadequate if there happened to be an epidemic of influenza. In the last war doctors were enabled to continue their ordinary work once they had learnt their war stations. For the medical care of children evacuated to reception areas mobile clinics could go round and treat throat and ear ailments and the like.

Sir **FRANCIS FREMANTLE** referred to the notification of measles and whooping-cough. Notification of a disease should imply means of dealing with it by nursing or isolation. The Ministry hoped to provide isolation in the new hutment hospitals, but in Sir Francis's part of the country it would be impossible to isolate an epidemic of whooping-cough or measles. To keep the children in reception areas safe and sound during the winter months the district nurses should be given special help. More use should be made of the county nursing associations and of the Queen's Institute of District Nursing, and arrangements should be made for the evacuating authorities to send nursing relief. Mr. HERBERT MORRISON reported difficulty with hospital supplies. The Surgical Instrument Makers' Association had agreed that 90 per cent. of their output should be allocated to the War Office for military purposes. How the voluntary and municipal hospitals would get their share out of the remaining 10 per cent. he did not know. Mr. Morrison mentioned that midwives and nurses, both for school nursing work and fever nursing, had been sent from London to the reception areas. He had an impression of lack of co-ordination within the Ministry of Health. In the Hospital Branch the officers hung on to their doctors and nurses in the casualty and base hospitals. Doctors and nurses should be allowed to go to the reception areas if their services were needed there.

Sir JOHN ANDERSON replied to the debate.

Mr. KENNETH LINDSAY announced on November 1 a decision that schools in evacuation areas which could be made available should be reopened for the education of children whose parents desired them to attend.

Reservation of Medical Students

Sir ERNEST GRAHAM-LITTLE suggested on October 26 that Mr. Ernest Brown should arrange with Mr. Hore-Belisha to reserve for military service, until after qualification, all medical students at present registered, irrespective of the stage of their studies. Mr. BROWN replied that he had consulted Dr. Elliot and was satisfied that at present the reservation of medical students who had passed the first professional examination and completed two terms of study in anatomy and physiology was adequate to meet the needs of the situation.

Petrol for Doctors

Mr. GEOFFREY LLOYD replied on November 1 to a question which asked if he knew of the difficulties experienced by doctors in some areas as regards obtaining necessary supplies of petrol, and why his Department had refused to investigate individual complaints. Mr. Lloyd said special arrangements were recently made for dealing with applications from doctors for supplementary allowances of petrol. Cases of difficulty which arose were being dealt with by the Divisional Petroleum Officers in consultation with the liaison officers appointed by the British Medical Association.

Facilities for Short-wave Therapy

Sir ERNEST GRAHAM-LITTLE asked on November 1 whether attention had been drawn to the value of short-wave therapy in the relief of pain, the healing of infected wounds, and the rapid restoration of function to maimed and injured limbs, as well as in the treatment of lung affections, especially those following gas attacks. He also asked how many of the machines required for this treatment were available in the military hospitals and what provision had been made for skilled personnel to use them. Miss HORSBRUGH replied that she knew the value of this form of treatment for the types of cases mentioned. She could not give the number of machines or of skilled personnel, but full use would be made of the plant available. This was widely distributed through the general hospitals designated for the treatment of casualties. In allocating personnel to these hospitals due provision had been made for radiological staff and radiographers.

Medical Practitioners' Enlistment

Mr. GROVES put a question on November 2 alleging dissatisfaction among members of the medical profession arising from the fact that many medical men making application for commissions in the Services had been referred to a voluntary organization of medical men to which they did not belong and to which they had no desire to make application. He asked Dr. Elliot to consider consultation with the Medical Practitioners' Union in order that its view could be presented side by side with that of the British Medical Association. Dr ELLIOT said he had no reason to believe that the medical profession in general was dissatisfied with the arrangements made by the Central Medical War Committee for the supply of doctors to the Forces. He accepted a correction from Sir Francis Fremantle that the central organization was not the British Medical Association but the Central Medical War Committee, which included others beside the British Medical Association.

Part-time Service in the Emergency Medical Service

In an answer on November 2 to Sir Ernest Graham-Little Dr. ELLIOT said that the number of specialists and senior members enrolled in the Emergency Medical Service who reported for whole-time service in the London sectors and were for the most part on the visiting staffs of the London voluntary hospitals was 656. Of these seventeen were on indefinite leave without pay and five had transferred to part-time. There had been one offer of service without obligation. The whole question had been under consideration by a special committee, including the Presidents of the three Royal Colleges. This Committee had formulated its recommendations, which it would discuss with Dr. Elliot on November 3.

Sir ERNEST GRAHAM-LITTLE said the uncertainty was mischievous for these voluntary hospitals, and only 25 per cent. of the members of these staffs had applied for part-time service. Dr. ELLIOT said it was for this reason that he would give urgent consideration to the recommendations from the special committee.

Tuberculosis in Billets

Mr. EDE inquired on November 2 whether advice had been tendered to billeting authorities on the undesirability of billeting evacuated persons, especially children, in houses in which a patient recently discharged from a tuberculosis sanatorium lived. Dr. ELLIOT answered that he had recently made it clear to a conference of representatives of the voluntary organizations for the prevention and cure of tuberculosis and of medical officers of health that patients in the infective stages of tuberculosis who had been inadvertently discharged from sanatoria at the outbreak of war should be sought out and brought back for treatment. He had no reason to believe that billeting officers were not alive to the point made by Mr. Ede. The only sound way was to seek out the tuberculous patient and give him institutional treatment. The information in the possession of local authorities as to tuberculous cases was, of course, confidential.

B.M.A.'s Protection of Practices Scheme

On November 7 Mr. GROVES asked the Minister of Health whether he was aware of and had authorized the circular letter of the Central Emergency Committee that medical practices, both as regards private and National Health Insurance practice, could be adequately protected under the British Medical Association's scheme, and in no other way. He asked whether the Minister had approved the scheme and disapproved of any other scheme whether instituted by an insurance committee or otherwise. Dr. ELLIOT replied that some of the documents issued by the Central Emergency Committee of the British Medical Association were sent to him for his information, but he did not know to what particular document Mr. Groves referred. He was aware of the Association's scheme for the protection of the practices of practitioners engaged on whole-time national service, and h. l recommended insurance committees to assist in its operation so far as it related to insurance practice. He had approved a number of substantially similar schemes submitted by insurance committees and panel committees jointly, and was prepared to consider any other schemes submitted by such committees.

Medical News

In reply to numerous inquiries the Clothes Room Committee of the Ladies' Guild of the Royal Medical Benevolent Fund announces that the work is being continued throughout the present national emergency. Existing conditions make every effort much more difficult, but it is hoped that the committee may have sufficient support to help all beneficiaries. Parcels of clothing can be sent as usual to B.M.A. House, Tavistock Square, W.C.1.

The Royal Society announces that the Croonian Lecture on "Aspects of Animal Locomotion" will be delivered by Professor J. Gray, F.R.S., on Thursday, November 16, at the Zoological Department, Downing Street, Cambridge. The lecture will deal primarily with the mechanism responsible for the neuromuscular co-ordination of locomotion in a variety of animals. A cinematograph demonstration will be given of each of the main facts alluded to in the lecture. Tea at 3.45 p.m.

The twenty-eighth Long Fox Memorial Lecture will be delivered by Dr. C. C. Chesterman in the H. H. Wills (large) Lecture Theatre, Bristol University (Royal Fort), on Tuesday, November 14, at 3.40 p.m. His subject is "Forest Folk: Modern Medicine in the Congo."

The first medical congress in Bolivia will be held at Caracas from December 17 to 24. A very full programme is announced.

The British Institute of Philosophy announces a series of public addresses on "The Deeper Causes of the War and the Issues Involved in it," to be given at the Royal Empire Society at 2 p.m. on Thursdays, November 16, 30, December 7, 14, and continuing after Christmas. The first four speakers will be Professor W. G. S. Adams, Professor Gilbert Murray, Viscount Samuel, and the Dean of St. Paul's. Tickets can be obtained on application to the Director of Studies, the British Institute of Philosophy, University Hall, 14, Gordon Square, London, W.C.1.

No meeting of the Medical Society of Individual Psychology will be held this month, but it is proposed to hold the December meeting in the afternoon. Notices will be sent out to members a fortnight beforehand. Publication of pamphlets will be continued.

The Maida Vale Hospital for Nervous Diseases (Maida Vale, W.), which has maintained an uninterrupted out-patient service since the outbreak of war, announces that on and after Monday, November 13, the out-patient department will be open in the mornings at 9.30. Out-patients should therefore attend at 9.30 a.m. instead of at 1.45 p.m.

The Finney-Howell Research Foundation announces that all applications for fellowships for next year must be filed in the office of the Foundation, 1211, Cathedral Street, Baltimore, Maryland, by January 1, 1940. Applications received after that date cannot be considered for 1940 awards, which will be made on March 1. This Foundation was provided for in the will of the late Dr. George Walker of Baltimore for the support of "research work into the cause or causes and the treatment of cancer." The will directed that the surplus income from the assets of the Foundation, together with the principal sum, should be expended within a period of ten years to support a number of fellowships in cancer research, each with an annual stipend of two thousand dollars, "in such universities, laboratories, and other institutions, wherever situated, as may be approved by the Board of Directors." Fellowships carrying an annual stipend of 2,000 dollars are awarded for the period of one year, with the possibility of renewal up to three years; when deemed wise by the Board of Directors, special grants of limited sums may be made to support the work carried on under a fellowship. Applications must be made on the blank forms which will be furnished by the secretary.

The notice that the hours of the out-patient department at the National Hospital for Diseases of the Nervous System (Queen Square, W.C.) have been altered has resulted in an increased number of attendances. Patients should, if possible, come on Monday, Tuesday, Wednesday, Thursday, and Friday at 9.30 a.m. In certain circumstances some patients can be seen up to 12 noon.

The French postal authorities have issued an anti-venereal postage stamp with the motto *Pour sauver la race*, the small sum spent by the purchaser over and above the ordinary value of a postage stamp being allocated to the anti-venereal diseases organization responsible to the Minister of Public Health for propaganda.

Dr. Duncan Graham of Toronto was nominated president-elect of the Canadian Medical Association at the last annual meeting at Montreal.

A campaign against undulant fever has been organized in Denmark, and has been supported by a donation of 100,000 kroner by the Government.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

The incidence of scarlet fever declined during the week in England and Wales, but diphtheria showed a slight increase; the incidence of both diseases was below the level of 1938. In Scotland and Northern Ireland notifications of both diseases were fewer, and there was an increase in Eire, slight in scarlet fever and appreciable in diphtheria. Notifications of dysentery have recently increased in Scotland, the numbers recorded in the last four weeks being 27 (6), 69 (37), 89 (60), and 39 (22). The figures in parentheses denote the notifications in Edinburgh—more than one-half of the 224 recorded for Scotland during the four-week period; the disease appears to have been mild, as there were only five deaths, representing a case mortality of 2.2 per cent.

Notification of Measles and Whooping-cough

The Minister of Health recently made regulations, which he has communicated to county councils and local authorities in England and Wales in Circulars Nos. 1896 and 1896a, whereby measles and whooping-cough must be notified by medical practitioners to medical officers of health. The object of these regulations, which were put into effect on November 1, 1939, is to provide the Ministry of Health with data on the total incidence and geographical distribution of these diseases and the bearing thereon of the displacement of susceptible subjects by evacuation schemes. Early information might enable authorities to secure supplies of immune sera or vaccines for use in the prevention or modification of these diseases in reception areas where these specific agents have not been generally available. Hitherto measles and whooping-cough have been notifiable only in certain districts and to a limited extent. For example, in the administrative county of London notification was put into effect on October 1 last year and was confined to cases occurring in a household at an interval of two months from any previous cases; other local authorities have restricted notification to subjects under 5 years of age.

Diphtheria in Europe

The decline in the morbidity and mortality of diphtheria recorded in the post-war years was followed by an increase in most European countries in the three-year period 1934-6. Since that time the disease has declined generally, but in 1938 increases compared with 1937 were encountered in Germany, England and Wales, Scotland, and Italy. There has been less diphtheria in the first six months of 1939 than in the corresponding period of 1938 in all European countries except Denmark, Finland, and Switzerland.

No. 42

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 21, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for : (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for : (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases ; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)
Cerebrospinal fever	18	1	7	—	2	19	5	3	—	—

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The TELEGRAPHIC ADDRESSES are
EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*
SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Dochtuirí na h-Eireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Effect of Castor Oil on Epithelium

Dr. N. Z. **KHAN** (Calcutta) writes: The striking results sometimes obtained on the administration of castor oil in early and mild cases of mucoid and bloody influx of dysentery cases seems to be due to its stimulation of regenerative capacity of epithelial structures and not to the cleansing effect, as other purgatives do not help to the extent that it does. On the above assumptions is it not justified to advocate more extensive use of sterile castor oil in cases of ocular and nasopharyngeal affections, and above all in burn cases? Non-stickiness of any necessary dressing is of great significance in treating raw surfaces.

Income Tax

Staff Fund Payments

"**TAU**" explains that at the hospital with which he is connected that part of the Government fees which was to be paid to the honorary staff was placed to a staff fund from which payments were made for special purposes, and the balance was accumulated. "Tau" understands that income tax has been paid thereon. He is outside the scope of the hospital pension scheme, and received in 1938 a lump sum of £x as his share of the accumulations He is being assessed to tax on that amount as if it were a profit of the year in which it was received. Is this correct?

*** If, as we understand, income tax was paid by the treasurer of the staff fund on the whole of the fees received by that fund, it seems that "Tau" has a good claim to regard the grant made to him as his share of a taxed fund, of which he and others were beneficiaries. In other words, tax has already been paid by someone acting for him, and cannot properly be charged again. If the facts do not bear that interpretation—and a full examination of the documents and circumstances is desirable—we do not consider that "Tau" can legally claim to spread the income back over the years when it accrued *to the fund.* If his legal title to participate arose only when the grant was made in 1938, then the payment was a profit of that year. Possibly some concession might be made administratively.

LETTERS, NOTES, ETC.

"Foreign Pharmaceutical Products"

Messrs. **WILLIAM R. WARNER** and Co., Ltd., the manufacturers of the products sold under the trade marks "Anusol" and "Veganin," explain that as a result of the inclusion of these products in the list of "Foreign Products" prepared by the Association of British Chemical Manufacturers which was reproduced in our issue of October 28 they have suffered serious reactions so far as the trade and the medical profession are concerned. As already explained, this list was published in all good faith, the Association of British Chemical Manufacturers being relied upon for its accuracy, and we regret exceedingly that any ill results should have occurred as the result of the erroneous inclusion of Messrs. William R. Warner and Co.'s products. We trust, however, that this statement and the other steps which we have taken will correct any wrong impression and reassure the trade and the medical profession that the trade marks "Anusol" and "Veganin" distinguish products which are owned by a British company and which have been manufactured in this country for many years at Messrs. Warner's factory at Chiswick, and that the continued manufacture is not in any way affected by the war.

Mr. **HENRY J. W. FRANCE**, Managing Director of Roche Products Limited, Welwyn Garden City, Herts, referring to the schedule of foreign pharmaceutical products with British equivalents and alternatives, writes: By omission it [the schedule] ignores all manufacturers in this country who are not members of a particular trade association. . . . I notice that no reference is made to the Roche vitamin preparations manufactured at our works here. . . . Omnopon, which we manufacture here from opium, is stated to be a foreign product.

Mr. H. C. H. **GRAVES**, Chairman and Managing Director of Vitamins Ltd., Hammersmith, W.6, writes in reference to the list of pharmaceutical products published in our issue of October 28, under the heading of "Foreign Pharmaceutical Products: British Equivalents and Alternatives": The effect of the omission of our name from this list is to imply either that we are a foreign firm or that our products are not worthy of inclusion in the list. . . . I would like to point out that we have had a vitamin B_1 concentrate on the market in this country long before any of the vitamin B_1 products mentioned in the list were available, and, in fact, our product was advertised in the pages of your *Journal* as long ago as May 2, 1936. Since that date we have introduced other varieties of vitamin B_1 both in the pure form—namely, as aneurin tablets and ampoules—and in the form of a natural adsorption product.

The Manager of the Saccharin Corporation Limited (London, W.) writes: I notice in your issue of October 28 a list of products which it is stated "may be difficult to obtain." Among these is novocain, and as my company is the distributor of novocain I can assure you that ample supplies are available.

Treatment of the Common Cold

Dr. N. **HOWARD MUMMERY** (Jersey) writes: Your columns frequently contain alleged remedies for the common cold, most of them useless or unpleasant to use, but so far I have seen no reference to a tablet with the trade name of "caapi," marketed by Messrs. H. R. Napp, Ltd., which contains atropine, caffeine, phenacetin, quinine, and cinnamon. All these ingredients are very old remedies for "colds," but in this combination they have a remarkable effect if taken strictly in accordance with the instructions on the packet, and my own experience, and that of all to whom I have recommended the remedy, is that they seldom fail to abort an acute coryza completely within twenty-four hours. I have no interest whatever in the firm mentioned.

Slippery Floors in Hospital

"**TIMOCLES**" writes: Some features of hospital construction seem to be nobody's business, and, apparently, the condition of floor surfaces comes into that category. Few of us who have walked the floors of hospitals have escaped occasional falls on slippery patches, and in most hospitals it is quite usual to find at least one bed occupied by some old person who, when calling to see a relative, has slipped and fractured a femur or sustained some other serious injury. These injuries must frequently come under the notice of surgeons, and it amazes me, as a physician, that no effective action is taken by them. To-day I slipped twice while walking along a tiled passage in a large hospital, but being fairly nimble I was able to maintain my equilibrium; had I been old, stout, or feeble the results might have been serious. One of the house-surgeons told me that he knew of three fractures which had occurred in this hospital during the past few months among visitors and members of the staff. (One was an ambulance man who fractured his femur.) The total number of such cases in Great Britain would probably surprise most of us. This is not a time for discussing unimportant details, but, apart from their actual danger, slippery floors must impair efficiency considerably. Surely it is time that the medical staffs insisted on the obvious remedy for this ridiculous defect which exists in so many hospitals.

THE TREATMENT OF OPEN FRACTURES*

BY

WILLIAM GISSANE, M.B., Ch.M., F.R.C.S.

Surgeon Specialist to the London County Council; Surgeon in Charge of Accident Unit, St. James Hospital, London

The principles governing the treatment of open fractures hold good whether the fractures are caused by trauma common in civilian life or by the high-explosive missiles of modern warfare. Certainly war adds many more difficulties to the surgical problems presented by such fractures, as witness the extent of the problem, the severity of the injuries, the delay in bringing in the wounded—adding exposure, dehydration, and loss of blood to accentuate the shock of a painful injury—difficulties of transport and hospital facilities, and finally the especial prevalence of infection, particularly of tetanus and anaerobic infection. That the problem is immense only places it in line with the other problems this country is now facing.

Organization

The first essential to proper treatment is to place an effective organization to deal with each stage and to co-ordinate the entire period of treatment. The great increase of road accidents in recent years presented a similar problem for solution. The British Medical Association report of 1936 and the findings of the Interdepartmental Committee on Fractures formulated four guiding principles necessary for treatment. They were: (1) segregation; (2) unity of control; (3) careful after-care; (4) rehabilitation centres. The creation of a similar organization now both for civilian patients under the Emergency Medical Service and for the war-wounded would seem the first essential. There is nothing new in the problem, and it was solved successfully during the Great War. Robert Jones realized the need, and was able to produce an organization which dealt satisfactorily with the great numbers of severe fractures which came back from France to this country. He insisted on segregation, and, backed by the Advisory Council, he overcame all opposition and formed the orthopaedic centres, where, for the first time, segregation, unity of control, after-care, and rehabilitation were practised. With an organization which controlled in the end some 36,000 beds the fracture problem was solved. All that is needed is to recapture this organization, re-form these centres, and concentrate the patients and the skilled personnel. It is easily possible. It needs only the good will and foresight of those who control the Medical Services of the Fighting Forces and the Civil Medical Service to give us again what we had in 1918. It is interesting to recall Robert Jones's (1925) own words:

> "The Great War afforded the most convincing proof of the mishandling of complicated, and even of simple, fractures. In the early period these cases arrived home with appalling deformities. Excessive shortening and malunion were the rule. . . . Men with no experience in this branch of work did the best they could, while men who understood how to treat fractures found the conditions such that it was impossible to obtain satisfactory results. They deplored the fact that . . . continuity of treatment was impossible. Fractures of the femur serve as a notable example. . . . In 1916 the mortality from these [open] fractures amounted to 80 per cent., a large proportion of the deaths occurring on the way to or at the casualty clearing stations. Later, when the Thomas splint was applied almost exclusively, and as near the firing line as possible, we have it on the authority of Sir Henry Gray that the mortality in 1918 was reduced to 20 per cent. This is an astounding and inspiring fact, and led Colonel Crile of the United States Army to say that the Thomas splint did more to prevent death from shock than any other single measure.
>
> "The next great advance in the treatment of fractures at the front occurred when we were able to secure the segregation of cases. The country owes a great debt of gratitude to Major Meurice Sinclair. . . . His femurs came over with scarcely any shortening and with excellent alignment. The problems of segregation and of team work had been overcome, with very admirable results. In England, however, we were not in a position to segregate these fractures when they arrived. . . . Splints were removed too soon and often changed unnecessarily, and the good work abroad was thus sadly interfered with. . . . After a time permission to segregate the fractures was granted. . . . Let me emphasize again that the success in the treatment of fractures during the later phases of the war was due to expert supervision, simplicity of apparatus, team work, segregation, and appropriate after-care. These are the lessons the war taught us; are we going to apply them, and improve upon them, or are we to revert to the bad old way?"

In the recent evacuation of fracture cases from the London area we have, in fact, immediately returned to "the bad old way." Fractures from one segregated centre have been dissipated all over the South Coast. Continuity of treatment could have been maintained by their evacuation to a prearranged centre. Skilled personnel are available, and indeed very willing for work. In the present days the many details of necessary organizations to maintain the continuity of treatment could be worked out quietly between the evacuating hospitals (now casualty clearing stations) and their base hospitals.

First-aid Treatment

MECHANICAL TREATMENT FOR QUICK TRANSPORT

The method employed must be both efficient and simple; it must allow easy and painless access to the wound and protect the limb from harm during transport, and the splints must be easily carried by the stretcher party. For these reasons only two splints are advocated: for the arm the swivel ringed Thomas, and for the leg the Thomas knee splint. The method of application of these splints needs no explanation here. There is only one other splint required to complete the stock of first-aid splints. It is a rather cumbersome piece of apparatus, but it should be available at the casualty clearing stations; it is a modification of the Thomas hip splint known as "Jones's abduction frame," and is used for high fractures of the femoral shaft and hip regions. One simple modification of this splint allows free access to gluteal and pelvic wounds—most difficult regions to treat adequately without the frame. The patient, who lies on this splint, can be lifted and moved without pain, without disturbing the fracture, and the dressing can be changed without interfering with the mechanism of fixation. With these three splints traction is easily applied and maintained, and need not be relaxed for any purpose during the period of transport.

---

* Revised from a paper read in opening a discussion in the Section of Orthopaedics and Fractures at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

While treatment can be satisfactorily maintained on the Thomas knee splint and the abduction frame, it should be stressed that the Thomas arm splint is essentially a transport splint, and its prolonged use will give rise to permanent stiffness of the elbow, wrist, and fingers.

TREATMENT OF SHOCK

Shock is present in varying degrees in all patients with open fractures, and in its initial stage is undoubtedly due to the pain of the injury. The first-aid treatment of shock is to immobilize the fracture by an efficient splint so that the patient can be moved without further aggravating the pain and increasing the shock. To this purpose the application of the Thomas splint and fixed traction will be undertaken with great gentleness and under the injection of 1/3 grain of morphine for an adult. In those patients in whom exposure, dehydration, and loss of blood have added to the shocked state the first step again is application of the Thomas splint under morphine followed by the administration of hot fluid by the mouth, the application of heat, and, if possible, a period of rest.

WOUND DRESSING

Here our aims are twofold—to cover the wound and so prevent further infection, and to conserve the vital quality of the damaged tissues. A dressing of a non-irritating modern antiseptic such as 1 in 2,000 euflavine is adequate to both these aims. The use of strong irritating antiseptics such as iodine defeats the last aim, and consequently these substances are to be avoided.

TREATMENT BY SERA AND DRUGS

The main defence against infection of the wound is by early radical débridement. However, the prophylactic injection of tetanus antitoxin and anti-gas-gangrene serum should be made at the first available opportunity. Recent advances in drug therapy have given us sulphanilamide and its derivatives. These drugs are of the greatest value when once infection is established, but their prophylactic value against infection has yet to be proved.

Surgical Treatment of Wound

This stage of treatment should be carried out as soon as possible after receipt of the injury. Early efficient surgical treatment of open fractures is the only means by which we can prevent infection and so legislate to shorten the period of treatment and save the function of the injured limb. Hospitals for such treatment must be as near as possible to the "danger areas." The stages of surgical treatment of open fractures may be summarized as follows:

1. The preliminary treatment of shock up to the stage at which the administration of an anaesthetic is a safe procedure—this stage should be short and should rarely exceed one hour.

2. The prevention of infection by direct surgery at the earliest moment and certainly within eight hours of the injury. This includes the excision of all dead and dying tissues, ingrained dirt, and debris—the vital quality of the tissues left after débridement rather than the use of any antiseptic being the safeguard against infection.

3. The gentle reduction of the fracture. From this stage onwards the reduction is held either by the extension pieces of an orthopaedic table or by a distraction apparatus.

4. The immediate closure of all wounds treated within eight hours of receipt of the injury, either by suture or by skin graft if a skin defect is present. Wounds treated after this period are left open.

5. The application of a soft protective-pressure dressing to the area of soft-tissue damage in order to prevent oedema and death of the tissues from failure of return of fluids from the area of soft-tissue injury.

6. The final immobilization of the fracture in its reduced position. The principle hereafter to be followed is *rest*, complete and absolute. If the limb is placed in plaster-of-Paris this rest is assured—even the most inquisitive cannot remove a dressing placed under plaster! Plaster-of-Paris is used whenever it can effectively hold the reduction, incorporating, if necessary, transfixion pins through the proximal and distal fragments placed at some distance from the site of fracture. For some fractures splints are necessary—for example, in fractures of the shoulder-joint and some fractures of the shaft of the humerus the shoulder abduction splint has its place. For the pelvis, hip, and some high fractures of the femoral shaft the Jones abduction frame is indicated, while for the femoral shaft the Thomas knee splint is the splint of choice. All these splints allow the application of fixed traction, and without this additional aid it is not possible to hold the reduction of some fractures. But the governing principle should be retained—the wound dressings should be left undisturbed. I believe that it is upon the principle of rest that the success of the Winnett-Orr plaster is founded.

7. Complete rest of the injured limb for at least five weeks. The temperature and pulse rate may be somewhat raised during the early stages of this period, but if the general condition of the patient is satisfactory the plaster or dressings should not be removed. If the *x*-ray picture of the reduction is unsatisfactory it should be remembered that further manipulations undertaken before soft-tissue repair has occurred will most surely inflict additional damage to the limb. Such manipulations should be postponed until soft-tissue repair is sound enough to withstand this additional trauma.

Preparation of Limb for Operation

The undressing of the limb and the removal of the first-aid splint are parts of the surgical procedure, for in every way we must guard against inflicting additional injury. The open wounds are sometimes large and multiple; consequently it is not always possible to shave and wash the limb without further contaminating the wounds. It is safer to cover the limb with a sterile roll of gauze soaked in a suitable antiseptic or in spirit, the areas of the wounds alone being left uncovered. This technique allows us to cleanse the skin in the neighbourhood of the wounds, carry out the débridement, reduce the fracture, and close the wounds by suture, skin graft, or dressing before proceeding to the cleansing of the unaffected areas of the skin prior to the application of the plaster cast or appropriate splint. During the whole of these procedures it is essential that the limb be lifted clear of the table, and for this purpose the traction appliances of an orthopaedic table or a screw traction apparatus of the Böhler type are indispensable.

Anaesthesia

Shock is primarily caused by the pain of these injuries: to relieve the pain is to treat shock. There is no better anaesthetic agent for this purpose than brachial plexus block by 25 c.cm. of 2 per cent. novocain for the upper extremity and low spinal anaesthesia for the lower extremity, and for patients seen early there is no reason to delay treatment. When the picture of shock has been accentuated by delay, exposure, dehydration, and loss of blood, with a consequent fall of blood pressure to 90 mm. Hg or below, there should be a period of delay to treat such shock adequately followed by anaesthesia by gas-and-oxygen with ether. Spinal anaesthesia in such patients is definitely dangerous.

Débridement

This is another lesson of the last war: " The large-scale experiment of 1914–18 established the failure, relative but none the less unmistakable, of antiseptics. It showed that what determined the fate of a wound was, above all, the vital quality of the tissues exposed to infection " (Leriche, 1939).

In those wounds seen before infection has supervened it is our task to make quite sure of the " vital quality " of the tissues remaining after the débridement. This means an excision of all dead and dying tissues and the removal of all foreign matter from the wound. The main force of trauma in the civilian type of open fracture is inflicted on the skin fat and muscles, and the quantitative sacrifice of non-vital tissues will be in that order. In the injuries caused by the high-explosive missiles of war the skin injury is frequently small and the muscle injury great. In both types the surgical exposure must be adequate to explore the extent of the damage, and the excision of dead tissues must be radical. Fortunately osseous tissue has remarkable powers of recovery; it may be smashed into multiple pieces, but if given a chance it will live. Débridement of bone should never be more than a shaving of periosteum or osseous tissue. Large lengths of bone should never be removed; indeed, it is wiser to amputate than to remove large lengths of the femoral or tibial shaft.

Buried sutures should seldom be left in the wounds after débridement, nor are they necessary. Muscles are damaged almost exclusively in their fleshy bellies where suture cannot hope to repair the damage. Few blood vessels require ligature. With the exception of division of the musculo-spiral nerve in open fractures of the middle third of the shaft of the humerus, nerves are seldom divided in the civilian type of injury. I understand that in war the sciatic nerve is often divided in gunshot wounds of the thigh associated with fractures of the femur. If a divided nerve is encountered in the débridement it should be sutured by the minimum number of stitches of the finest thread or catgut after the fracture is reduced. Such approximation of the nerve ends will save a very tedious exploration at a later date.

Value of Skin Grafts

All skin flaps raised from their connective-tissue beds by the violence of injury must be carefully examined and their vitality proved by demonstrating bleeding vessels from their edges. The débridement of such flaps must be continued until this demonstration has proved satisfactory. In the extremities such excision of skin will invariably leave a defect, for under no circumstance must skin be approximated in open fractures under tension. Often patients have lost areas of skin by the violence of the injury. If such skin defects are allowed to heal by the normal processes of tissue repair, not only is the healing extremely slow, but if the wound is a large one it is associated with permanent deformity in the underlying muscles, with associated loss of function to neighbouring joints. Furthermore, the final scar, particularly if the healing has occurred under plaster-of-Paris, is of tissue-paper texture and a source of subsequent trouble; indeed, many such scars have to be excised and treated by skin grafting at a later date before sound healing has been attained.

For several years I have grafted these skin defects, and I am satisfied with the results. By skin grafting no time is allowed for fibrous-tissue changes to take place in the underlying muscles, and as a consequence the normal elasticity of the muscle is retained. The grafted area has a particularly healthy appearance; fat is often laid down under the graft, and the area stands up to normal trauma very well.

I have followed two methods of grafting: (1) immediately following the original débridement; (2) at the first change of plaster—that is, three to five weeks after the date of injury. Both methods have given excellent results. The second will be the method of choice during war, when speed is an important factor in treatment at the casualty clearing stations. The graft used is the split skin or Thiersch graft, which can be cut with a razor to quite large dimensions after practice. It must be accurately placed on the donor area and held in position by a firm pressure dressing; then it must be left undisturbed for at least a period of five days, when it will have " taken." The dressing may be kept in position for a much longer period, and can be left under plaster and the usual routine treatment for the fracture followed.

In the " delayed " grafting, the appearance of the granulating surface of the wound and the general condition of the patient are the indications whether or not the graft will be successful. If the granulations are healthy and the general condition satisfactory the graft will live. After a limb has been in plaster for a few weeks it may smell very offensively; if the wound when cleaned presents its usual healthy appearance it should be skin-grafted.

Treatment of Infected Open Fractures

In war many patients will receive their first treatment when the wound is obviously infected. The wounds in such cases should be explored and all foreign matter lying free in such wounds should be removed and adequate drainage established. The fracture should be reduced and held in the reduced position. Although I am a strong advocate of the Winnett-Orr method of treatment for such fractures, this method should be under the continuous supervision of the surgeon undertaking the treatment. Complications I have experienced have included severe secondary haemorrhage under the plaster and the development of gas gangrene under the plaster. Accordingly I believe that it is safer to transport such cases to the base hospitals in the Thomas splint and to allow the surgeon at the base full control of the Winnett-Orr method of treatment.

Open Fractures associated with Other Serious Injuries

Sometimes in civilian practice, undoubtedly more frequently in war surgery, the problem of serious abdominal injury is associated with that of open fractures of the extremities. Under one anaesthesia the immediate treatment must be completed. First the extent and nature of the more serious injury must be explored and treated before it is possible to legislate on the line of treatment to be followed for the fractured extremity. The treatment of the abdominal injury may so take charge of the situation that all that is possible for the open fracture is the application of an appropriate splint. With an ideal organization, such problems are the sphere of a surgical team, and although I remain a firm advocate of segregation of fracture patients I believe that in the "danger zones" the segregation should only be one department of a general hospital containing personnel capable of dealing efficiently with any emergency.

THE INTRA-UTERINE DEVELOPMENT OF RESPIRATORY EFFORT*

BY

SIR JOSEPH BARCROFT, F.R.S.

Late Professor of Physiology, University of Cambridge

The attempt to explore a subject so well worn as the regulation of respiration by approaching it from a new angle is admittedly a daring one; but a fresh approach seems to be the only excuse sufficient to justify the effort. In the present introduction, therefore, I shall put before you some glimmerings on the matter, as a crude attempt made to build it up from the developmental standpoint: developmental not in the philogenic but in the ontogenetic sense—that is, by studying the phenomenon as it gradually unfolds in the life of the mammalian foetus to see what sort of picture we obtain. Study of the regulation of breathing demands an understanding of the phenomenon of respiration, and as that appears to be bound up with the essence of movement itself you must bear with me if I start at the very beginning.

Stage I: The Initiation of Movement

The first neuro-muscular movements observable in the sheep foetus appear on the thirty-fourth day of foetal life—not quite a quarter of the way through pregnancy, which in the sheep is normally about 147 days. The foetus is perhaps the size of the thumb-nail, but it is large enough to admit of the appropriate stimulation of the sensory fields which correspond to the endings of individual nerves. The very first movement to take place is obtained from stimulation of the area just over the lip and under the eye: this corresponds to the position to which the maxillary branch of the trigeminal nerve has grown. The movement obtained is a slight lateral one of the head, and appears to be asymmetrical because the stimulus is asymmetrical: in the next few days the nerve grows down to the snout, at which time stimulation of that organ (involving the nerves from both sides) produces asymmetrical throwing back of the head.

It is interesting at the very outset that a nerve so intimately connected with respiration as the maxillary branch of the trigeminal should be the first to evoke movement.

Stage II: The Earliest Rhythmic Movement

Within the next week, or even the next three or four days, the capacity of the foetus for movement has advanced in quite a number of ways, of which four may be singled out: (1) the sensory area, stimulation of which can evoke movement, becomes much enlarged; (2) the adequate stimulus alters in nature; (3) the extent of the response becomes greater; (4) the response becomes rhythmic. To consider these in a little more detail:

1. Not to go further than the trigeminal nerve, the maxillary branch has now come to innervate a much greater area by, say, the fortieth day than was the case on the thirty-fourth. Moreover, the supra-orbital branch of the ophthalmic division has come into play. Thus, from considerable areas around the snout and eyes stimulation by a glass rod or a faradic current will evoke a response.

2. The repercussion of the enlargement of the sensory field means that a much less intense stimulus if applied to the enlarged area will evoke a response. Thus a drop of saline falling in the eye from no more than a centimetre will initiate movement; or, *in utero*, a current set up by the injection of warm saline into the sac, if it impinges on the face, will have a like effect.

3. As the days pass, more and more muscles become involved in the response. Starting with a simple movement of the neck muscles, it comes to involve the longitudinal muscles of the back; later those of the limbs and tail, as well as those of the throat and trunk: by the forty-second day the diaphragm is formed, and it too is involved.

4. The response has become rhythmic. No movement is sustained for any length of time, but the whole response lasts perhaps a half to three-quarters of a minute, in that it consists of a rhythmic series of individual spasms. Each spasm involves, as indicated above, a great part of the whole musculature of the living foetus. The conditions which determine its periodicity have not been defined.

This perhaps is the place for a word about the phenomenon spoken of as "spontaneous movement." Most users of this phrase, ourselves included, have safeguarded themselves by saying that it means no more from their pen than an admission of inability to ascribe any definite form of stimulus to the movements. The phenomenon is evident enough, and is that in first opening the uterus the foetus as seen in the sac is undergoing rhythmic movements similar to those described above. In view of what has just been said about the ability of currents in the amniotic fluid and slight changes of pressure to produce foetal rhythms; we are sceptical as to the spontaneous nature of these rhythms, using the word "spontaneous" in the sense of something which starts in the central nervous system without the interference of stimuli from an afferent field.

Stage III: The Individuation of the Generalized Rhythm into Somatic Movement and Respiratory Movement

If the rhythm be set up by stimulation of the snout with a glass rod at about forty days the following may be seen. The first, or the first and second, of the individual mass movements which constitute the rhythm differ from the succeeding movements as follows. The extensor element is more pronounced. The head is thrown back—a composite movement which consists of an extensor and a flexor component; in the subsequent movements the extensor component drops out and the head nods forward. During the seventh week of foetal life the two sorts of movements diverge in type, till at the forty-ninth day the initial somatic movement is a long-drawn-out spasm, while the tendency of the subsequent rhythm is for all the muscular movements to be shed except those of the diaphragm, the thorax, and the throat. Here, then, is the essence of the neuro-muscular mechanism of respiration. It consists of three components: the sensory stimulus, the immediate somatic response, and the subsequent respiratory response. I am fortunate to have Professor Adrian as my chairman: neither in his presence nor in his absence would I make any attempt to say by what chain of events in the central nervous system a foetus can start with a hit on the nose or rump and end with an effort to get up, followed by the movement of a breathless attack; I know he would not allow me to say that the stimulus is turned into the response, but I am in hope that his own contribution will help to bridge the gap.

---

* Read in opening a discussion in the Section of Physiology and Biochemistry at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

We have, then, the germ not only of the respiratory mechanism but also that of its regulation, for the three factors enumerated (the sensory stimulus, the immediate somatic response, and the subsequent respiratory response) are related to one another quantitatively: the stronger the stimulus the greater the somatic response and the greater the respiratory effort which follows it. At seven weeks the system has become very delicate. It is almost impossible to hold the foetus so quiet as to avoid the liminal stimuli required to initiate respiratory movement. Whether these stimuli are proprioceptive or whether they are due to alterations of pressure on the surface I cannot say; but the result is evident: quite a small movement initiates a respiratory rhythm in an otherwise quiescent foetus, whilst in one which already exhibits a rhythm muscular movement is associated with an alteration of the rhythm in three respects—(1) the frequency increases; (2) the movements become deeper; (3) the area of movement spreads. In short, the foetus exhibits the cardinal characteristics of forced respiration. It seems difficult to escape the conclusion that even at the seven-week stage nervous regulation of respiration—the phenomenon demonstrated by the classical experiment of Krogh and Lindhard—has been laid down. The nervous regulation of respiration, as opposed to the chemical, is, then, the first in time to be evolved, and appears to be part of the very essence of movement. Up to this date asphyxia has no effect upon bodily movement—respiratory or otherwise—except to obliterate it.

Time and space forbid a discussion of the anatomical basis of the individuation into somatic movement and respiratory movement. This much may be said: the individuation is coincident with the functional appearance of the midbrain, and demonstrates the first phase in the progressive forward development of the brain; for if the foetal brain be transected between the medulla and the red nucleus the pattern of movement reverts to a modification of the six-week stage—that is, a simple rhythm of a respiratory type.

Stage IV: Inhibition in Relation to the Asphyxia Factor of Respiration

From the end of the seventh week the foetus undergoes a remarkable change: from being on a hair-trigger it becomes increasingly inert. Stimulation elicits little movement, either somatic or respiratory. The foetus appears almost dead. That it is not may be demonstrated by three different procedures, application of any one of which will produce a reversion to the lively seven-week stage. These are: (1) transection of the central nervous system at the middle of the forebrain; (2) exposure; (3) and in the present connexion most important of all, asphyxia—that is, occlusion of the umbilical cord.

The first of the above procedures demonstrates the general nature of what is taking place. The section is made at any time after the fiftieth day, and the foetus allowed to grow on in the uterus so that there may be no question of traumatic stimulation. It then becomes clear that the alteration from the quiescent to the active stage is a matter of *release*. The lower centres are released from one in the upper part of the forebrain but below the cortex; in fact, the whole foetus after the seventh or eighth week is maintained in a condition of profound inhibition. Respiratory movement is no exception to this general condition; its existence at any time, or if it exists its degree, depends upon the issue of a battle between sensation and inhibition. The chemical factor in the regulation of respiration is in part the abolition of inhibition. Inhibition represents another phase in the forward functional development of the brain. Any circumstance which promotes sensation in the foetus will make for increased respiratory movement, the natural factor being somatic movement. Any factor which tends to reduce inhibition will have the same effect. If the two take place simultaneously their joint effects might be expected to be greater than that of either separately.

Stage V: The Onset of Birth

Such would appear to be the case at birth, for which the foetus is now fully prepared.

Increased Sensation.—The organism is at this stage introduced into a new environment, and one calculated enormously to increase the number of stimuli from sensory areas: stimuli of cold and touch from the skin; proprioceptive stimuli from the limbs, which are now able to move freely; and, not least, stimuli from the embryological origin of sensation, the maxillary division of the trigeminal nerve.

Depressed Inhibition.—At the same time the inhibition is depressed by asphyxia. This fact has two repercussions: (*a*) direct, (*b*) indirect.

(*a*) We are now in a position to give some quantitative estimate of the degree of asphyxia necessary to release the foetal respiratory mechanism. It amounts to a reduction of the percentage saturation of the blood from the brain—that is, gleaned from the sinuses—to about 20 to 10 per cent. oxygen saturation. At the level of asphyxia respirations will start.

(*b*) But release also takes place in other directions; reflexes generally become heightened, and the proprioceptive afferent stimuli resulting from the movements liberated may be an appreciable addition to the increase of sensation.

After the first breath—that is, after the chest has actually expanded and respiration has become established on a tentative basis—a whole new set of sensory stimuli come in from the respiratory area itself—the nose, the throat, the lungs, the diaphragm, and the chest wall. It will be for future research to sort these out and to determine whether or not to the end the regulation of respiration is a battle between sensation and inhibition. In the foetus, inhibition had the upper hand so completely that respiratory movements did not normally take place once it had been established; post-natally, on the other hand, sensation has the upper hand, inhibition merely damping the respiratory movements.

Some Pathological Forms of Forced Respiration

In the light of what has been said I find it interesting to review the possible cause of certain forms of hyperventilation that are associated with obvious dysfunction of the higher parts of the brain. Two which I may instance are found in coma and cerebral haemorrhages. It has always appeared difficult to me to associate these with stimulation of the respiratory centre, and therefore it seems not out of place to inquire whether they are not due to some form of release of medullary centres from an inhibition centre placed in the upper part of the forebrain. At all events, granting the existence of such a centre it would seem wholly reasonable to suppose that influences which deprived the cortex of its consciousness might extend their devastating influence to the upper part of the thalamus.

TREATMENT OF ANGINA OF EFFORT*

BY

GEOFFREY BOURNE, M.D., F.R.C.P.

Physician with Charge of Out-patients and of the Cardiographic Department, St. Bartholomew's Hospital

Cardiac pain may be founded on organic disease of the coronary vessels or it may be of a functional variety described variously under labels such as angina innocens, pseudo-angina, and left submammary pain. There are also certain well-known non-cardiac causes of chest pain which simulate cardiac pain fairly closely: fibrositis of the pectoral muscles, brachial neuritis, cholecystitis, pneumothorax, and diaphragmatic hernia are examples of this.

The first essential step is to distinguish clearly angina of effort. This is a pain generally felt centrally in the chest, but occasionally more on the left side. In a few individuals its first and chief manifestation may be in one or the other arm. Classically it is central and radiates most commonly to the left arm or to both arms. It is a quantitative pain, being exactly proportional to the amount of exercise the patient is taking. With slow walking or at rest there is no pain, but with any increase in the amount of exercise above a definite level a sensation of pressure, discomfort, or even pain arises. Should the exercise be increased the pain is quantitatively increased, and if the exercise ceases the pain immediately begins to subside. This symptom is so exact and so striking, and is supported so strongly by evidence on the point obtained electrographically and by post-mortem examination, that there can be no doubt that it results from some interference with the adequate flow of blood through a branch of the coronary arteries during exercise.

Grouping of Cases

For purposes of treatment angina of effort can be divided into two groups—the slight or moderate and the severe. Slight angina of effort need not be treated by rest in bed. There is only one real indication for putting such a patient to bed, and that is where the angina of effort is the only symptom of a small coronary thrombosis. This is a somewhat rare occurrence, but very definite in its symptoms, and suspicion of it should arise whenever angina of effort suddenly starts in a hitherto healthy person. In such cases the severity of the pain is greatest at the beginning and slowly subsides as time goes on. In the ordinary case the onset of the pain is gradual and is at first not taken great notice of by the patient, who ascribes it to flatulence or dyspepsia. Here the patient should be encouraged to take as much exercise as is comfortable, provided that it does not bring on pain. Where the pain only occurs at the starting of exercise, after which it can be walked off so that subsequent exercise produces no pain, the patient should be encouraged to do this, if necessary with the help of a tablet of nitroglycerin, which should be taken before the first pain is due to arise. The reason for encouraging such patients to take as much exercise as possible is that this measure is most likely to stimulate the development of a collateral circulation in the heart.

Patients with symptoms of angina of effort may also be subjects of adiposity. These patients may be helped considerably by a reduction in their weight. This reduction should not be made too rapidly, and if possible it should not be accelerated by the use of thyroid extract, for hyperthyroidism appears to be a factor in the sensitivity of the nervous system to cardiac pain. Another general measure to be considered is that of posture. The individual who carries most of his weight in his abdomen tends to assume automatically a position of lordosis. It has been claimed that correction of this posture by a properly fitting abdominal belt helps the thoracic movements and thus the mechanical position and function of the heart.

Prognosis

Perhaps the most necessary step in the treatment of patients with cardiac pain is an absolutely full and sympathetic physical examination. The patient should be first convinced that his cardiac condition has been made quite clear by the examination, and this examination should entail a complete history, physical examination, and investigation by electrocardiograph and screening apparatus. The next step is to explain to the patient, to an extent compatible with his understanding, that his symptoms are due to some loss of elasticity in a blood vessel, the result of which is that the heart is not receiving its full amount of blood during exertion, and to indicate to him that gradual and careful exertion is likely to help the organ to readjust itself to the new situation. The label "angina" should be omitted, for its application will only add a quite unnecessary factor of apprehension. The second point that should be stressed is that the pain is not dangerous, and that patients do not die during such attacks of pain. In an investigation into 112 successive cases of angina of effort Dr. Bodley Scott and I found only one example of death during an attack. It should also be borne in mind that patients with true angina of effort may live from ten to fifteen years after the start of the symptoms, and that although a certain proportion of them subsequently die of coronary thrombosis, yet many succumb to some quite different disease.

The above reasonably good prognosis will have to be modified and the modification explained to the patient's most responsible relative in certain circumstances; these are the presence of severe shortness of breath during exercise, of Cheyne-Stokes respiration, or of paroxysmal nocturnal dyspnoea, and electrocardiographic evidence of some serious myocardial disease, such as shown by a bundle-branch lesion, inversion of the T wave in Leads I and II, or a deep Q wave in Lead III. Another point suggesting a bad prognosis is a family history of sudden cardiac deaths during the 50's or early 60's. In one such family two brothers of the patient had died of coronary thrombosis and one had recovered from an attack, while the patient himself had suffered from coronary thrombosis two years previously and his tracing now showed evidence of gross myocardial disease.

In addition to reassuring the patient to the fullest possible extent, it should be explained that life must be lived physically and mentally in as leisurely a manner as possible. Hurry, tension, and strain should be avoided, and an attempt to cram into the day just one or two more activities than it would comfortably hold should be prohibited.

Coexisting Conditions

Certain other conditions may be present in a patient suffering from angina of effort. Disease of the stomach is particularly apt to accentuate cardiac symptoms, and the possibility of gastric ulcer, hyperchlorhydria, or even carcinoma must be considered, and, if present, they must be treated. A man who had been attending St. Bartholomew's out-patient department with a classical angina of effort was found also to be suffering from dyspepsia and loss of weight. He had a carcinoma of the stomach, which was removed surgically, after which his cardiac pain subsided. The effect of rest in bed as such could be considered here as a factor, but rest in bed alone is not usually followed by the disappearance of the symptoms of angina of effort. Disease of the thyroid gland where hyperthyroidism or hypothyroidism is present should also be kept in mind. Two cases of myxoedema with angina of effort in our follow-up clinic have been treated with thyroid extract, and both patients have lost their cardiac pain. Diabetes mellitus is often complicated by arteriosclerosis of the coronary arteries, resulting in angina of effort. Careful treatment of the diabetes generally helps these patients, but it should be remembered that the heart muscle needs a free supply of glycogen, and therefore, if it is not possible to balance the diabetes with less than 120 grammes of carbohydrate per day, it is advisable to give a freer supply of this with a proper quantity of insulin.

---

* This paper forms the basis of a lecture to the Willesden Division of the British Medical Association and to the St. Leonards Medico-Chirurgical Society.

Drug Treatment

The drug treatment of angina of effort is somewhat disappointing except for the effect of nitroglycerin. Phenobarbitone, 1/4 grain t.d.s., p.c., is probably the most useful drug; but it can be given in combination with theobromine or diuretin in some such preparation as theogardinal, 5 grains t.d.s., p.c. In a few cases theobromine alone, 3 grains t.d.s., p.c., or theobromine sodium salicylate, 10 grains t.d.s., p.c., is effective. Nitroglycerin tablets can be taken by the patient as often as they may be required for the prevention or the treatment of pain. They are generally put up in chocolate, so that the patient may be reminded to crush them in the mouth and hold them there for a few minutes before swallowing. If they are swallowed direct, pharmacological action is delayed and is sometimes less efficient.

Type of Person Affected

It has long been known that patients with angina of any kind tend to be of the highly strung, easily reacting type, and this is borne out by the fact that the symptom is said to be rare among the negroes and the Chinese, whose threshold for pain seems to be higher. A scientific basis for this observation is suggested by the work done by Dr. Wittkower and myself on the psychological make-up of patients suffering from heart disease with and without cardiac pain. The proportion of patients with some psychological abnormality is higher in the cardiac pain group. This increase is present both in angina of effort and in the functional group, but is higher in those patients with a functional type of pain. Following upon this a series of twelve cases has been treated by Dr. Wittkower psychologically, and the results seem to indicate that where a definite psychological abnormality exists the treatment of this is likely to help to diminish or to banish the cardiac pain.

Three Organic Diseases influencing Treatment

There are three organic diseases which interfere with the coronary circulation and which must be remembered in planning a course of treatment in angina of effort. These are coronary thrombosis manifested by angina of effort, angina of effort due to syphilitic aortitis, and angina of effort due to anaemia, whether pernicious or microcytic. Where angina of effort follows directly after a coronary thrombosis there is a very good chance of its disappearing completely during the subsequent twelve months or so, and the patient should be so informed. In the case of syphilitic aortitis manifesting itself by angina of effort the cardiac pain can often be cured by thorough anti-syphilitic treatment. This should consist of a six-weeks course of full doses of potassium iodide, 90 to 150 grains daily, a subsequent course of bismuth injections, and a final course of intravenous injections of neosalvarsan. This programme should be repeated, with intervals of two to three months' rest, until the Wassermann reaction becomes and remains negative. When angina of effort is due to anaemia, the pain nearly always completely disappears with the improvement of the blood count.

Thyroidectomy

The vast majority of all cases of angina of effort respond successfully to treatment on the lines described, but there remains a small group in which the cardiac pain is extremely severe and no improvement follows persistent treatment. In these cases some operative procedure may be justifiable. From a total of about 400 cases of angina of effort I have picked out fourteen as being suitable for thyroidectomy. In nearly every one of these the relief from pain has been striking, and this relief has lasted in the least successful case for a period of six months. The more successful cases have had periods of up to three years, during which time the pain has either vanished or has become so slight as to cause no serious inconvenience. The details of this procedure have been published elsewhere, but it should be remembered that so radical a measure should not be embarked upon without very serious consideration.

The chief indications for thyroidectomy would seem to be that the pain is extremely severe, that previous treatment has failed, that the pain shows no sign of decreasing, that the pain is not the result of a recent coronary thrombosis, that the patient is not adipose, and that there are no signs, clinically or electrographically, of grave disease of the heart muscle. It is possible that in the future omentopexy could be a means of successfully treating these patients, but the evidence available to date has not proved without doubt the usefulness of the measure as a method of general application.

Summary

The origin and symptoms of angina of effort are described.

Cases are classified into two groups and treatment in these is detailed, the necessity for a complete and sympathetic physical examination being stressed.

Points suggesting a good or a bad prognosis are discussed.

Concomitant conditions that accentuate the symptoms of angina of effort are subjects of survey, together with three organic diseases that influence treatment.

The indications for thyroidectomy are given.

Calcium Deficiency.—A diminished calcium content of the blood may be accompanied by normal, excessive, or diminished excretion of calcium in the urine. Treatment by calcium salts orally is rarely efficient. Injections of calcium have a transient effect only, but are useful in tetany and in similar manifestations. Treatment by irradiated ergosterol—8,000 to 10,000 rat units a day for about a month—gives good results in rickets and osteomalacia, and in tetany with calcium deficiency. A.T.10 is less valuable because it mobilizes the calcium at the expense of the bones.—Calcium Deficiency. J. Decourt.—*Ann. Méd.*, May, 1939, 45, 362.

INGUINAL HERNIA

A NEW OPERATIVE REINFORCEMENT

BY

A. SIMPSON-SMITH, M.Ch., F.R.C.S.

Surgeon to Out-patients, West London Hospital

Max Page (1934) stated that the recurrence rate in inguinal hernia was far greater than previously admitted, and in healthy metropolitan policemen, whose average age was 32, the rate amounted to 20.2 per cent. in indirect and 25.8 per cent. in direct varieties. Since this paper several carefully examined series of cases supporting Page's view have been published. Grace and Johnson (1937) record 1,032 cases, all over 50, with a recurrence rate of 25.8 per cent., Birkenfeld (1933) gives 28.49 per cent., Lyle (1928) 10.3 per cent., Fallis (1936) 8.25 per cent., and Block (1933), in 642 cases personally followed for two years, 34.8 per cent.

Fascia sutures have been of great service in repairing wide hernias, but even this method is not without defect, for Burdick *et al.* (1937) admit 29.1 per cent. of failures in a series of 975 fascial repairs. In addition, it is tedious and time-consuming to use this material. Ogilvie and Maingot (Maingot, 1937) have employed heavy floss silk loosely woven across the posterior wall of the canal to form a lattice. They claim that the minute fibres constituting the silk cords are readily absorbed, provoke little reaction, and have no tendency to encourage sepsis. Graham (1938), however, states that it is necessary to use fine silk, heavy braided silk being harmful.

Injection treatment alone, while of value in preventing hospitalization, is open to the serious disadvantage that twelve or more appropriate fluid quantities must be placed exactly in the right position. The difficulty of controlling the hernia throughout the treatment and the danger to testis, cord, or bowel by "blind" injections have compelled many surgeons to discard this procedure. What emerges from this method of treatment is the fact that experimentally and clinically selected sclerosing solutions can create a firm area of fibrous tissue.

The general disinclination of the public to accept herniorrhaphy is shown by the number of patients who are prepared to put up with the discomfort of a truss for the rest of their lives: one instrument firm in London manufactures no fewer than 3,000 spring trusses a week.

The present method aims at reinforcing a satisfactory operative repair with the adhesive barrier of the injection treatment.

Technique

The hernial sac is isolated and ligatured as high up as possible, a split salad-spoon facilitating this high excision. A Bassini repair operation is done, approximating the conjoined tendon to Poupart's ligament, either with two strips of external oblique, as in lacing up a boot and originally described by McArthur in 1901, or by the use of non-absorbable sutures. Salmon-gut, because of its lack of capillary attraction and its inability to absorb organisms, is probably safer to use than silk. Orthopaedic surgeons have preferred this material for years. A lozenge consisting of sodium psylliate in gelatin is then placed on the anterior wall superficial to the conjoined tendon but deep to the cord. The external oblique and skin are then closed in the usual manner.

Results

The first case was operated upon in March, 1938. At this time the sac was carefully isolated and, after division between double ligatures, the distal portion was filled with sclerosing fluid. The ball that resulted tended to slip about and was difficult to keep behind the cord. In the next case a slab of gelatin was used, and this proved to be much more convenient.

In all, twenty-three cases have been submitted to this operative reinforcement. Various strengths of sodium psylliate in different conveying materials have been tried. With moderate amounts of sodium psylliate a mild swelling of the wound has occurred, and has subsided in fourteen days. The distinct impression is gained that there is a plate of firm fibrous tissue around the operative site. With too strong solutions intense swelling and bruising of the skin are likely to follow, but even extensive reactions settle down within two or three weeks. Such reactions have not occurred in the later cases.

Conclusions

This is a preliminary report of a method which has not yet stood the test of time. Only the cold candour of a long series of cases will assess its utility. The small number already treated show a firm scar and encourage a further trial. A suitable conveying material that will liberate larger amounts of sclerosing fluid in minute doses over a long period of time is in preparation; this will increase the desirable fibrosis.

I am grateful to Dr. O'Neill and Dr. Shore, medical superintendents of Napsbury and Shenley Hospitals, for allowing me to select cases, and to Mr. Alex Rae, chief pharmacist of the Hospital for Sick Children, for his advice and for the preparation of the psylliate slabs.

The Economic Intelligence Service of the League of Nations has just published a study entitled *Urban and Rural Housing,* containing a comprehensive account of the methods employed in a number of countries for improving housing conditions, with special reference to the cost involved and the results obtained. It is of particular interest at the present time, since it deals largely with housing problems raised after the war of 1914–18 and the attempts made to solve those problems in various countries up to the outbreak of hostilities in 1939. It should therefore appeal to all interested in reconstruction schemes at present or in the future. The countries dealt with are Belgium, the United Kingdom, Canada, Denmark, Finland, France, the Netherlands, Norway, Sweden, and the United States of America. The author was able to visit most of these countries and to investigate on the spot the practical difficulties encountered by the housing authorities; in addition he has co-ordinated the material published by or obtained from Governmental and municipal authorities and other sources. A chapter is devoted to each country, and the information arranged in such a way as to permit the reader to compare housing problems and the efforts being made to meet them in different circumstances. A special paragraph is devoted in the case of European countries to the problem of rural housing and the measures taken to improve the housing conditions of agricultural workers or other groups of the rural population. The report is published at 3s. 6d. by George Allen and Unwin, Ltd., 40, Museum Street, W.C.1.

CONSERVATION OF THE CERVIX UTERI IN OPERATIONS FOR PROLAPSE

A NEW OPERATIVE PROCEDURE

BY

J. W. A. HUNTER, M.D., F.R.C.O.G.

Honorary Gynaecological Surgeon, Manchester Northern Hospital; Senior Gynaecological Surgeon, Withington Hospital, Manchester; Honorary Assistant Obstetric Surgeon, St. Mary's Hospitals, Manchester

In reviewing current methods in gynaecology one observes a persisting hesitation to practise the first principle of surgery—preservation of function. A distinction should ever be drawn between women of child-bearing age and those no longer capable of reproduction. In the former, preservation or restoration of function should be our aim; in the latter, certain cure of symptoms by radical means is justifiable. There is a persistent hesitation to adopt planned conservative measures lest symptomatic relief should be incomplete, and there is failure to count the cost at which a radical cure may be purchased. Avoidable hysterectomies are still being performed for "tarry cysts," pus tubes, and even fibroids in comparatively young women, although many successful pregnancies after conservative treatments have been recorded.

The early masters in gynaecology were careful to preserve this distinction between case groups. In prolapse they tended to operate only in the more severe cases usually associated with older women, while pessary treatment was employed for the minor degrees of prolapse found in younger patients. They were conservative, too, in their attitude to lacerations and diseases of the cervix. The apparent success of amputation of the cervix, with or without colporrhaphy, may have caused the pendulum to swing too far in the direction of radical surgical treatment, and it is worth while to analyse some of the harmful after-effects of this change. Modern technique has brought with it wider accomplishment and greater safety, but it has also brought new dangers and new problems.

Cervical Amputation

Cervical amputation was first widely practised by the French surgeons. Huguier, stimulated by the work of Lisfranc, adopted amputation as a routine measure in all cases of procidentia. Marion Sims in 1866 advocated the operation not only for prolapse but also for hypertrophy and disease of the cervix. Sims believed that the operation did not interfere with child-bearing, and quoted two cases of normal pregnancy and labour after his operation. T. A. Emmet in 1869 reported his operation of trachelorrhaphy which he had devised in 1862. Twenty years later, however, he advocated amputation after the manner of Sims for many cases in preference to repair, partly because it was an easier operation and partly because of its more curative effect on symptoms. He then stated that amputation had no effect on fertility, pregnancy, or labour. J. D. Emmet in 1895 advocated a return to trachelorrhaphy in view of the ill effects sometimes found after amputation, a view contradicted by T. A. Emmet in 1897. Meanwhile Schroeder in 1878 and 1880 had devised and reported on 220 cases operated on by his method of circular amputation with every appearance of success.

About this time amputation of the cervix came to be associated with colporrhaphy as an operation for prolapse. In 1888 Cohn reported 105 cases of prolapse so treated by Olshausen and Schroeder, and about the same time Donald independently devised a similar treatment. In 1914 Fothergill modified the operation by combining amputation of the cervix with the anterior colporrhaphy, and his publication (Fothergill, 1921) of the excellent results obtained led to widespread adoption of his method for all types of prolapse.

Criticisms of Cervical Amputation

Audebert in 1898 was one of the first to draw attention to the ill effects of Schroeder's operation. In a comparison between pregnancies in the same women before and after amputation of the cervix he found this marked difference: before operation these women had twenty-two labours at term and five abortions or premature labours, whereas after operation they shared five labours at term, nine premature labours, and ten abortions. In addition he reported a high incidence of dystocia, often involving incision or dilatation of a stenosed canal. Leonard (1913, 1914), in an extensive analysis of the after-effects of cervical amputation on 128 cases at the Johns Hopkins Hospital, found that four-fifths of the women who might have been expected to become pregnant remained sterile. Of those who became pregnant 50 per cent. had premature interruption of pregnancy, and of those proceeding to term an even larger percentage had difficult and prolonged labours.

Sturmdorf (1916), having noted Leonard's findings, devised his new method of amputation of the cervix, which aimed at complete excision of the cervical mucosa to the internal os with preservation of the cervical muscle. Sturmdorf maintained that by this method disease could be eradicated without any interference with the polarity of the uterus.

Rawls (1921), analysing the same subject, found sterility in 58 per cent. of women after trachelorrhaphy, as compared with 72.6 per cent. after amputation of the cervix. Further, he found that amputation carried a disadvantage in that there were 18 per cent. fewer full-term labours, and 6.2 per cent. more spontaneous abortions occurred after amputation than after trachelorrhaphy. Rawls also noted that three Caesarean sections were necessary in 100 labours after cervical operations, and that relaceration occurred in 40 per cent. of this series.

Brandt (1933) described three cases of abnormal labour following amputation of the cervix—one by Sturmdorf's method and two by circular amputation. One patient died of rupture of the uterus, one developed a large vesico-cervical fistula as the result of rupture of a cervical scar, with extension into the bladder, while in the third Caesarean section was performed as no os uteri could be detected.

Hesseltine (1934) reported a case of labour at term following cervical amputation. After eighteen hours in labour there was no dilatation and no os could be found. Caesarean section was performed as rupture of the uterus seemed imminent, and actual spontaneous rupture of the lower segment occurred while the operation was in progress. Davis (1929) reported a similar case. Gonnet and Mermet (1933) reported another case of obstructed labour, with fatal termination. Many other cases could also be quoted from the literature.

Zoefgen (1936) had found high amputation so inimical to conception that he recommended the operation as a sterilizing measure. Novak (1936) criticized this statement, and quoted two cases of repeated abortion after the operation. He stressed the need for a careful statistical review of the results of amputation in women of child-bearing age.

Repeated Abortion following Amputation

My attention was first drawn to the possibility of repeated abortion as a sequel to cervical amputation by my late chief, Dr. Haig Ferguson. He had the care of a patient whose cervix had been amputated by T. A. Emmet, and who had seven subsequent abortions. Anxiety for an heir made her consent to remain in bed from the very start of a pregnancy, and in this way she had her first and only living child at seven and a half months. Sfameni (1925) recorded a case of amputation of the cervix for leucorrhoea after a normal confinement. This was followed by four successive abortions.

Recent Cases of Abortion

During the past eighteen months several cases of repeated abortion following amputation of the cervix have reported at my out-patient department.

Case 1.—Para 3. Colporrhaphy with amputation of the cervix at the age of 30. During the following six years she had five miscarriages, all necessitating curettage. Sterilization was performed owing to the disability resulting from the repeated abortions.

Case 2.—Para 3. Colporrhaphy with amputation of the cervix at the age of 26. She had four miscarriages in the four years following the operation.

Case 3.—Para 2. Amputation of the cervix at the age of 26. During the following seven years she had three miscarriages, at the sixth, fifth, and sixth months respectively, and came under my charge during the third abortion.

Case 4.—Para 2. Amputation of the cervix at the age of 30. Since operation she has had three miscarriages—one at four and a half months, one at the third month, and one at the fourth month.

Case 5.—Para 1. Colporrhaphy and amputation of the cervix at the age of 26 after one confinement. During the next seven years she had four miscarriages, at times varying from the second to the sixth month. Her only child died recently, and she was desperately anxious to have another. During her last pregnancy she was kept in bed in hospital from the eighth week, but in spite of this she miscarried at the fifth month.

Case 6.—Para 1. Amputation of the cervix at the age of 25. Patient was sterile for five years following the operation and then became pregnant. Before pregnancy the cervical stump had been found flush with the fornices and the uterine cavity only two inches long. At the fifth month the membranes ruptured while she was asleep. Two days later evacuation of the uterus had to be performed, as the cervix remained closed and the uterine content was becoming fetid. Considerable difficulty was experienced in dilating the cicatricial cervix.

Case 7.—Para 1. Amputation of the cervix six months after confinement. During the next eight years she had four miscarriages between the third and fifth months.

In these seven women twenty-four abortions had occurred, and practically every one was incomplete and required curettage. Previous to amputation only one abortion had happened in this series.

Recent Cases of Dystocia

I have also been able to collect a number of cases of dystocia after amputation of the cervix. In the past ten years I have had occasion to perform Caesarean section on five women, at or near term, for pronounced stenosis of the cervix. In three of these cases long and tedious labour failed to produce any dilatation and it was difficult to define a cervical canal. In one case a patient had complete suppression of lochia and developed pyometra. On the tenth day graduated probes were passed with difficulty and a pint of pus was evacuated from the uterus. A rubber tube was stitched into the cervical canal, and adequate drainage and a good recovery followed.

In collecting hospital statistics over a period of eleven years I have been able to find records of eighteen labours at or near term after amputation of the cervix, with or without colporrhaphy. In ten cases the delivery was normal. The other eight cases had serious dystocia: three were delivered by Caesarean section for cervical atresia, three had vaginal Caesarean section, and two had manual dilatation of the cervix with version and extraction. There were three maternal deaths, in each case due to extension of a cervical rupture into the lower uterine segment. One followed vaginal hysterotomy with forceps extraction, one after manual dilatation with version and extraction, and the third after breech extraction. All three deaths occurred in emergency cases—in one complete rupture had taken place, and the child was in the abdominal cavity on admission.

Operative Treatment of the Cervix

A study of the literature and the account of these recent cases force us to the conclusion that amputation of the cervix in a woman of child-bearing age may have one of these unfortunate results—namely, sterility, repeated abortion, premature labour, or serious dystocia. Leonard's figures for sterility, quoted above, are worthy of serious consideration, and large statistical follow-ups are urgently needed. The wastage and dangers involved in these repeated and often incomplete abortions require us to make a careful review of the whole question of cervical function and surgical procedure.

Cervical Repair

In regard to lacerations of the cervix we might at any rate consider a more extended use of Emmet's original operation of trachelorrhaphy. It is often possible, by excising two or more deep lacerations and carefully suturing the edges of the tears, to restore an extremely distorted cervix to an almost normal contour. During recent years I have employed this method on women of child-bearing age with increasing frequency, and have found the results extremely satisfactory, both as regards relief of symptoms and subsequent childbirth. True, the operation scars in the cervix not infrequently split open during delivery, but these can be resutured at the time; even if this is not done the operation has fulfilled its purpose in enabling the woman to carry her pregnancy to term. A more detailed study of statistics in relation to trachelorrhaphy will be the subject of a further paper.

Cauterization

In cases of cervicitis with wide erosion and numerous Nabothian follicles the use of cauterization in preference to amputation might be advocated. Brunet and Salberg (1938) report 538 cases treated in this way by the "nasal loop" cautery with excellent results. In studying over 1,000 cases of cervicitis in the Mayo Clinic, Masson and Parsons (1928) state that the cautery is as effective as amputation in the cure of leucorrhoea; that pregnancy occurs more often, miscarriages are less frequent, labour is more often normal, and subsequent lacerations less liable to occur. Roblee (1931) advocates a combination of cautery and electrocoagulation, and maintains that this procedure entirely supersedes amputation and is never followed by stenosis. Harriman (1929) reports a comparison of cases treated by cautery and electrocoagulation, and is strongly in favour of the latter method, and maintains that hypertrophied cervical lips may by this treatment be reduced to normal size. Ende (1929) criticizes cauterization by thermocautery because of the danger of subsequent cervical stenosis, but has obtained excellent results in 200 cases treated by diathermy.

During the past ten years I have treated a large number of cases of cervicitis by diathermy cauterization, and more recently by electrocoagulation. The results, which I hope to publish in detail later, have been extremely satisfactory. Cervical stenosis has been recorded after deep linear and radial cauterization, and I prefer superficial cauterization of the whole eroded area by diathermy followed by multiple stab cauterization at about a dozen points in the cervix, dependent on the extent of the disease. This is followed in a few months by a return of the hypertrophied lips to normal size, disappearance of the erosion, and disappearance or amelioration of the systemic and local symptoms.

In cases where there is gross hypertrophy, and where trachelorrhaphy or cauterization is unsuitable, amputation should be as shallow as possible, and high circular amputation should at all costs be avoided.

A New Operative Procedure for Prolapse

(*Figs.* 1 *to* 12)

In the case of prolapse in women of child-bearing age the problem is more difficult. The operation devised by Donald and perfected by Fothergill stands supreme in the surgical cure of prolapse, and for women past the menopause is unequalled in its perfect results. For women

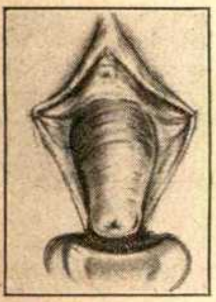

FIG. 1.

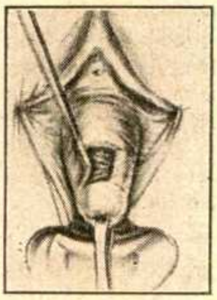

FIG. 2.

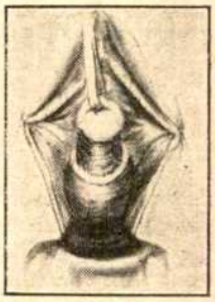

FIG. 3.

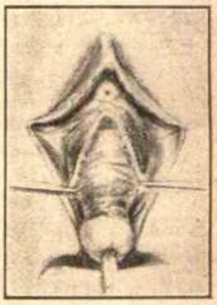

FIG. 4.

FIG. 2.—Two circular incisions are made round the cervix, about one inch apart, and a cuff of vaginal wall is dissected off.
FIG. 3.—A complete cuff of vaginal wall has been removed from the cervix.
FIG. 4.—A triangular flap is removed from the vaginal wall as in the Fothergill colporrhaphy. The apex starts just below the urethra, and the lateral incisions are carried downwards and outwards to the widest part of the upper circular incision round the cervix.

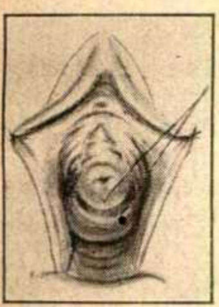

FIG. 5.

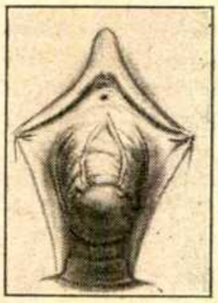

FIG. 6.

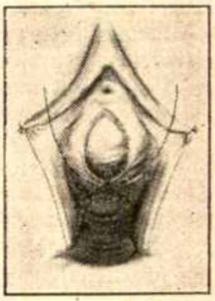

FIG. 7.

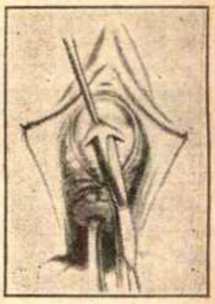

FIG. 8.

FIG. 5.—Starting posteriorly, interrupted sutures fix the cervix to the upper incision.
FIG. 6.—This shows the cervix almost completely sutured to the upper incision. The cervix and uterus are thus carried up to a higher level.
FIG. 7.—The cervix completely sutured to the upper flaps. The lateral angles of the vaginal flaps are joined together and to the cervix by a mattress suture.
FIG. 8.—If the uterus is displaced backwards the peritoneum of the utero-vesical pouch below the bladder is opened

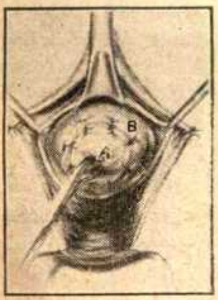

FIG. 9.

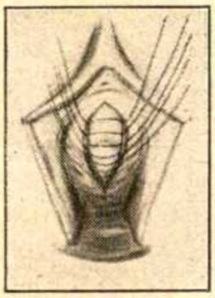

FIG. 10.

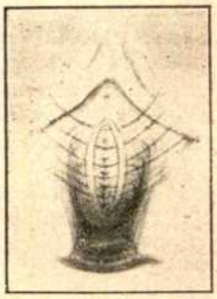

FIG. 11.

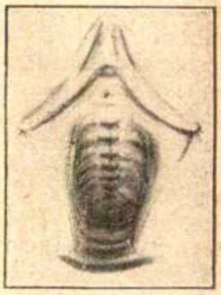

FIG 12.

FIG. 9.—The bladder is dissected upwards, and that part of the fundus uteri between the round ligaments, A, is fixed by interrupted catgut sutures to the peritoneum of the utero-vesical pouch, B.
FIG. 10.—Deep interrupted sutures are used to bring the pubo-coccygeus muscles and parametrium together on each side.
FIG. 11.—The anterior vaginal flaps are brought together by interrupted sutures and the anterior colporrhaphy completed.
FIG. 12.—The completed anterior colporrhaphy. The posterior colporrhaphy is then performed in the usual way: no illustrations of this are shown.

liable to further pregnancies, however, the amputation of the cervix, which is an integral part of the operation, may be disadvantageous for reasons we have seen, and because of this I have attempted to devise a modification suitable for young women which, while preserving the essentials of the Fothergill method, may yet conserve the cervix. The operation is applicable to those cases of prolapse in young women where there is no great degree of cervical hypertrophy, and where the total length of the uterine cavity to the external os does not exceed three to three and a half inches. It is applicable to that type of prolapse in which there is relaxation of all the uterine supports, the pelvic floor, and the vaginal walls, the uterus being at a low level in the vagina.

Technique.—Briefly the steps are these. A circular incision is made about half an inch above the external os, and another an inch to one and a half inches above this, and a complete circle of superficial vaginal epithelium is stripped off (Figs. 1, 2, and 3). A V-shaped excision of vaginal epithelium, as done in the ordinary Fothergill colporrhaphy, is then made, starting from just below the external urinary meatus and extending downwards and outwards to join at the lateral aspect of the upper circular incision (Fig. 4). The cervix is then stitched to the vaginal epithelium, starting posteriorly and working round to the front on each side, and thus the Fothergill principle of sliding the uterus up is maintained but with conservation of the cervix (Figs. 5, 6, and 7). The anterior colporrhaphy is then finished in the ordinary way (Figs. 10, 11, and 12), and the operation completed by posterior colporrhaphy and perineorrhaphy.

Unfortunately one finds in practice that in this operation the uterus tends to remain in the pelvic axis, and as at the same time in a young woman one has to be careful not to cause undue narrowing of the vagina, there may for this reason be some possibility of recurrence. One of the greatest advantages of the Fothergill operation is that the uterus tends to be brought into anteversion and so to be at right angles to the vagina, thus preventing any possible descent of the uterus; and, even if this anteversion does not always result, the scar tissue consequent on amputation of the cervix will almost certainly help to prevent any future tendency for the uterus to come down. For this reason a modification of the anterior colporrhaphy in the new operative procedure may be useful to antevert the uterus, and so lessen the chance of recurrence. This may be done by opening the anterior peritoneal pouch below the bladder, and stitching the anterior portion of the uterus at the level of the round ligaments to the peritoneum of the utero-vesical pouch as a step before performance of the anterior colporrhaphy (Figs. 8 and 9). This gives a more satisfactory result, and one case in which it was performed was followed by pregnancy and labour without any tendency to recurrence of the prolapse or retroversion. Perhaps an even better result can be obtained by anteverting the uterus, using the Alexander Adams method of suspension; but this involves a second incision, is a tricky operation, and adds somewhat to the time taken. May I stress that the object of bringing the uterus forward is not to cure the symptomless retroversion but to place the uterus at right angles to the vagina and so help to prevent recurrence of the prolapse.

I have performed this operation in nineteen cases during the past three years. This is a small number, but the severer degrees of prolapse are not common in young women, and in the minor degrees operation was not advised until after the menopause. The ages varied between 23 and 32; in ten of the cases vaginal fixation was combined with the anterior colporrhaphy, in one the colporrhaphy was supplemented by the Alexander Adams method of suspension, and in the remainder there was no associated backward displacement of the uterus requiring correction. The results have been uniformly satisfactory: there has been complete relief from symptoms, without any evidence of recurrence. One patient treated by the modified colporrhaphy with vaginal fixation has subsequently been delivered normally at term with no complications and no recurrence of the prolapse.

It seems presumptuous to suggest any improvement on that superb operation devised by Donald and Fothergill. Perhaps, however, its very success has led to its employment in cases for which it was scarcely devised, and, in view of its one limitation, the maintenance of the essential principles of the operation, but without its one possible disadvantage, may be worth consideration.

In conclusion it would appear that there is a very definite risk in pregnancy and labour after amputation of the cervix, and therefore, in the event of its being necessary to perform this operation on a woman liable to further pregnancies, she should be given instructions regarding the necessity for supervision during a subsequent confinement.

Summary

In gynaecology the necessity is stressed for subdividing cases undergoing surgical treatment into two groups—women of child-bearing age and those no longer capable of reproduction.

The literature of cervical amputation is reviewed, and various complications and harmful sequels of the operation are discussed.

A series of recent cases of repeated abortion following amputation of the cervix is reported.

A series of recent cases of dystocia following amputation of the cervix is recorded.

Methods of curing lacerated or diseased cervix, and prolapse, are suggested.

The technique of a new operative procedure for prolapse is given, with the results obtained.

Clinical Memoranda

Pyloric Obstruction as a Sequel to Rammstedt's Operation

The following case seems of sufficient rarity and interest to be worthy of record.

CASE REPORT

A male infant, which I had delivered by Caesarean section six weeks previously, was admitted to the Fermanagh County Hospital on June 23, 1938, with a history of vomiting during the previous ten days. Its weight was then only 7 lb., whereas at delivery it weighed 7½ lb. The diagnosis of congenital pyloric stenosis was easily made because of the presence of visible gastric peristalsis and a palpable epigastric tumour, together with the characteristic regurgitant vomiting.

A Rammstedt operation was done under local anaesthesia. The pyloric tumour was noted to be rather large, an incision of about one and a quarter inches being necessary. There were no post-operative complications and the vomiting ceased at once, while the weight steadily increased to 9 lb. 6 oz. by August 13, 1938, seven weeks after the operation. At this point vomiting was again reported, at first once daily but later twice a day. Alteration in the diet did not have any effect, and the general condition of the infant progressively deteriorated. On August 25 gastric distension and peristalsis were observed after a feed, followed shortly by vomiting, and recurrent pyloric obstruction was diagnosed.

The abdomen was reopened under a local anaesthetic, and it was seen that the pyloric tumour had completely disappeared, the pylorus had narrowed down to the size of a lead pencil, and the scar was now only about half an inch long. There was no kinking at the pylorus, neither were there any adhesions. A small amount of ether was found necessary before a posterior gastro-jejunostomy could be performed, and again, fortunately, there were no post-operative complications. The vomiting ceased, and the weight had risen to 11 lb. 12 oz. on October 13, when the child was discharged home. He is now nearly 18 months old and weighs 25 lb.

HORACE T. FLEMING, F.R.C.S., F.R.C.S.I.,
Surgeon, Fermanagh County Hospital.

Pneumococcal Meningitis treated with Sulphapyridine

The successful use of sulphapyridine (M & B 693) in a case of pneumococcal meningitis is here recorded.

CASE REPORT

A young man aged 23 was admitted to the Royal Infirmary, Edinburgh, about 8 p.m. on June 7, 1939, with a twenty-four-hour history of headache, vomiting, semiconsciousness, and finally delirium. On admission his temperature was 102°, pulse 90, and respirations 36.

On examination the pupils were contracted, but were equal and reacted sluggishly to light; there was marked neck rigidity; abdominal reflexes were absent; there was bilateral exaggeration of knee-jerks and ankle-jerks. Babinski's and Kernig's signs were also present bilaterally. The patient was delirious and very restless, so that he was under constant observation by two nurses for the first eighteen hours. Lumbar puncture was performed. The cerebrospinal fluid was under a pressure of more than 300 mm.; it was very turbid, and contained Gram-positive cocci, mostly in pairs. As the organism appeared to be a pneumococcus, an intramuscular injection of 1 gramme of soluble sulphapyridine was at once given, but it was not repeated during the night owing to the restlessness of the patient, which continued in spite of 1½ grains of morphine and 1/25 grain of hyoscine in the first twenty-four hours.

The next day the organism was verified as being a pneumococcus, Type XIX. Lumbar puncture was performed the morning following admission, and after his bowels had moved the patient became less restless and was able to take 1 gramme of sulphapyridine orally, four-hourly. This dosage was continued for six days with no toxic effects, each dose being administered in milk in conjunction with 30 grains of sodium bicarbonate. The temperature fell to normal in forty-eight hours, and subsequently remained subnormal. The patient suffered from retention of urine during the first three days, but this was relieved by the administration of doryl hypodermically. On the second day after admission he was practically normal mentally and could give a clear history. By the tenth day neck rigidity had disappeared completely, and convalescence was uneventful save for persistent slight left-sided earache.

An interesting fact in this case is that the patient sustained concussion five years ago, resulting in the loss of hearing in his left ear. He has had attacks of left-sided earache since, and when examined on June 19 there were signs of an inner ear disease, which were suggestive of a direct intracranial spread of infection by way of the sheath of the eighth nerve. The accompanying table shows the course of the illness:

Day of Illness	No. of Lumbar Punctures	Quantity of C.S.F. Withdrawn	Appearance of C.S.F.	Cell Count per c.mm.	Total Protein mg. per 100 c.cm.	Chlorides mg. per 100 c.cm.	Globulin	Pneumococci Type XIX
1st	1 therapeutic	c.cm. 20	Very turbid					Present
2nd	3 „	70	„	10,000	400	662	+++	„
3rd	2 „	45	Turbid					
4th	1 „	30	Slight turbidity	250			+	Not present
5th	1 „	20	Faint trace of clot formation					
6th	1 „	10	Colourless	195	30	695	Slight increase	„
7th	1 „	5	„					
10th	1 diagnostic		„	30			No increase	„
20th	1 „		„	25			„	„

I am indebted to Dr. J. D. Comrie for permission to publish this case.

FRED. J. ROBERTSON, M.B., Ch.B.,
House-physician, Royal Infirmary, Edinburgh.

Pneumococcal Meningitis treated with Sulphapyridine

The following case of primary pneumococcal (Group IV) meningitis may be considered of sufficient interest to be placed on record.

CASE REPORT

On June 6, 1939, a healthy man aged 38 began to feel out of sorts, with headache and backache predominating. The headache was both frontal and occipital, and soon increased in intensity, causing loss of sleep. On the 8th he had diarrhoea and vomiting. He saw a doctor for the first time on the 9th, when the symptoms were thought to be those of an influenzal cold; his temperature was 103° and pulse 106. There were no physical signs in the chest.

On June 10 neck rigidity and a positive Kernig sign were observed. When I saw him on June 11 he was drowsy and looked toxic; his tongue was heavily coated with brown fur;

there was marked neck rigidity; Kernig's sign was positive on both sides; knee-jerks and ankle-jerks were absent; the blood pressure was 106/86, temperature 101°, and pulse 116. There were no physical signs in the chest, and the ear drums were normal. He had herpes at the inner end of the right eyebrow. A leucocyte count showed 15,400 cells per c.mm., 80 per cent. being polymorphs. A lumbar puncture was performed and turbid cerebrospinal fluid, under slightly increased pressure, was withdrawn. This showed 624 cells per c.mm., all polymorphs, and Group IV pneumococci were cultured. During the next twenty-four hours he took 9 grammes of sulphapyridine (M & B 693) by mouth; there was no vomiting. On June 12 the temperature was 100.6° and the pulse 100. The patient was still very drowsy and the tongue was dry and furred. Cerebrospinal fluid showed 4,200 polymorphs per c.mm.; pneumococci were present. During the next twenty-four hours 8 grammes of sulphapyridine were given by mouth.

On June 13 his temperature was normal and the general condition much improved. Cerebrospinal fluid showed 360 polymorphs per c.mm.; pneumococci were present. During the next twenty-four hours a further 5 grammes was given. On the 14th he was again drowsy and his tongue was still very dirty. The temperature was normal and the pulse 90. The cerebrospinal fluid was under very low pressure and contained a purulent clot; pneumococci were present. A leucocyte count showed 15,000 per c.mm. During the next twenty-four hours 5 grammes of sulphapyridine was given orally. On the 15th the temperature remained normal; the general condition again improved; the neck rigidity was less; knee-jerks and ankle-jerks were just obtained. The cerebrospinal fluid contained 104 polymorphs per c.mm.—culture was sterile. Altogether 27 grammes of sulphapyridine had been administered; the drug was now discontinued. Daily improvement was maintained and the temperature remained normal. The cerebrospinal fluid continued to be sterile and the cells gradually became fewer. On June 16 there were 108 polymorphs, and on the 18th 72 cells per c.mm.; lymphocytes were now reappearing. A leucocyte count on the 19th showed 11,400 cells per c.mm. On the 21st the cerebrospinal fluid was quite clear; pressure normal; 20 cells per c.mm., lymphocytes predominating. On the 23rd the patient looked and felt perfectly well; there was no neck rigidity and Kernig's sign was absent. On the 24th the cerebrospinal fluid was quite clear and the pressure normal; there were 8 cells per c.mm., all lymphocytes. A leucocyte count showed 8,600 per c.mm. Convalescence was uneventful.

COMMENTARY

A case of primary pneumococcal (Group IV) meningitis is described. Treatment was not begun until the fifth day of the illness: it consisted of repeated lumbar punctures and the administration of sulphapyridine by mouth, a total of 27 grammes being given. There was rapid response to treatment; in four days the cerebrospinal fluid was sterile, and within a fortnight it had returned to a normal cytology.

I am indebted to Surgeon Commander R. L. G. Proctor for the laboratory investigations.

J. G. HOLMES, M.D.,
Royal Naval Hospital, Haslar. Surgeon Commander R.N.

Prognosis in Neuroses.—Schou finds that the prognosis in neurotic patients who apply for compensation or pension is much worse than in patients not so economically interested. In the two groups followed up from three to eight years afterwards the recovery rate in the former was only about 50 per cent., as compared with 88 per cent. in the latter. Though this may to some extent be due to the fact that those who apply for pension are more severely ill than those who do not, a more important factor is the unfavourable influence of a pecuniary interest in illness.—Laboratory and Catamnestic Investigations into So-called Neuroses. H. I. Schou.—*Acta Psychiat.*, Kbh., 1938, 13, Fasc. 4, 383.

Reviews

WAR WOUNDS AND AIR RAID CASUALTIES

War Wounds and Air Raid Casualties. Articles republished from the *British Medical Journal.* With illustrations. Foreword by Lieut.-General Sir William MacArthur, K.C.B. (Pp. 256. 10s. 6d. net.) London: H. K. Lewis and Co. 1939.

The *British Medical Journal* has rendered a notable service in gathering together in a series of twenty-three articles a wealth of information upon war injuries gained in the last war. Only those who were engaged in that war from its earliest weeks to its conclusion can realize what a vast revolution in technique and in outlook is revealed in these articles, or by what slow and painful processes these methods were evolved. It is a necessary feature of all wars that their conditions should be altogether new, for surprise is the very essence of military strategy, but it means that the doctor as well as the soldier must be prepared to meet new problems and to face conditions which it is impossible entirely to foresee. In the present war it was the universal opinion that in its very first weeks we must be prepared to deal with many thousand casualties, and these not among the soldiers but among the civilian population. This terrible forecast has so far not come true, but no one can say what the future has in store. It would, however, seem certain that whatever happens we shall have to deal with large numbers of civilian casualties in addition to those which must inevitably occur in the field. Moreover, these casualties will for the most part be due not to gunshot wounds but to the effect of exploding bombs and falling masonry. We shall in fact be faced with conditions which in our experience are without precedent, although perhaps the war in Spain may give us some clue as to what to expect. It is, therefore, all the more important that we should have before us the experience of those who took part in the last war and who slowly evolved methods which we may use as a starting-point.

There are two things which impress one in reading these articles. The first is the astounding power of recovery of the human body if it is only given a chance. Wounds of the limbs which in former days would have meant immediate amputation, wounds of the abdomen which even to the boldest surgeon might well have seemed impossible, are handled as a matter of everyday routine and with complete success. The second thing which strikes one is the variety of methods adopted, each plainly depending upon the special skill of the surgeon who writes. Yet all these methods have but one aim in view: to remove all infection and all damaged tissue and place the part at rest. To one surgeon splints and extension are the whole secret of handling compound fractures, while to another a plaster case is omnipotent. To those, however, for whom these papers are intended such differences are not perplexing but are rather inspiring, for they surely point the way towards a success in the future still greater than that obtained in the past.

The articles deal not only with wounds but with the emergency medical services, psychological aspects of war, chemical warfare, and the effects of high-explosive shells and CO poisoning as one result. No one engaged in war service in any field can fail to gather from them information of vital importance to his patients, and we hope that no one will lose the opportunity.

H. S. SOUTTAR.

HEPARIN

Heparin: Its Chemistry, Physiology, and Application in Medicine. By J. Erik Jorpes, M.D. (Pp. 87; 16 tables; 12 figures. 7s. 6d. net.) London: Oxford University Press. 1939.

For a good many years after the discovery of heparin by Howell most investigators were doubtful whether it had any such physiological function as an anticoagulant as had been suggested for it by its discoverer. It was regarded rather as an artefact with useful properties than as a naturally occurring anticoagulant which might play a part in preventing intravascular clotting. In recent years much attention has been given to its study, especially in Best's laboratory in Toronto and in Jorpes's laboratory in Stockholm, and the result of these studies has been largely to confirm most of Howell's original views. Heparin seems to prevent the conversion of prothrombin into thrombin, by acting either on the prothrombin itself or on the kinase. Chemically it is interesting, as it is a polysulphuric ester of mucoidin and so related to some other polysaccharide substances with anticoagulant properties—that is, lignine sulphonic acids, chondroitin sulphuric acids, etc. All these have in common a high molecular weight and strong acidic groups. Owing to this property heparin is thrown out of aqueous solutions by such basic substances as toluidine-blue.

Heparin occurs not only in liver but in lungs, spleen, kidneys, and especially in the intima of the blood vessels, which stains purple with toluidine-blue in consequence. It is located in the Ehrlich mast cells which lie along the intima and which probably secrete heparin into the circulating blood. Injection of peptone into the blood stream causes a release of this heparin and so renders the blood incoagulable. Heparin is now obtainable in pure form and is highly active. It produces no general physiological effects, even on intravenous injection, and has many applications both in the laboratory and in the clinic. Among the latter the chief are its use as an anticoagulant in blood transfusion, either by heparinization *in vitro* or by heparinization of the donor, and its undoubted value in the prevention or treatment of thrombosis. Very striking are the results of intravenous heparin injections in thrombosis of the central vein of the retina; in some cases normal vision was restored, whereas most untreated cases progressed to blindness.

The book is well prepared, and, although rather academic, should serve to attract attention to a subject which has been somewhat neglected in this country.

CARE OF CANCER PATIENTS

Cancer Handbook of the Tumor Clinic, Stanford University School of Medicine. Edited by Eric Liljencrantz, M.D. (Pp. 114; 50 figures. 14s. net., 3.00 dollars.) London: Oxford University Press; Stanford University, California: Stanford University Press. 1939.

This book consists of material assembled for postgraduate instruction at Stanford University School of Medicine. Its aim is to present essential facts briefly and uncontroversially but in sufficient detail to equip practitioners for the efficient care of cancer patients through the stages of suspicion, diagnosis, consultation, and treatment. It is remarked, wisely, that educational drives to instruct the public are useless unless the family doctor, who usually first sees the patient, is prepared to act decisively when consulted. His efforts should be directed to the recognition of early cancer and the avoidance of all acts of commission or omission which might worsen the prognosis. The statements that the specialists likely to be called should be consulted before the course of treatment is decided and that hastily selected treatment often spells the doom of the cancer patient will receive approval. After short introductory discussions of the production of cancer, its habits of spread, methods of diagnosis, and the principles of radiation therapy, the book describes the diagnosis, treatment, and prognosis of the forms of cancer most commonly encountered. For the most part the advice given is in accordance with current practice in this country. The insistence on the desirability of, and indeed necessity for, biopsy will not meet with universal approval, but the authors carry out biopsy under conditions which permit immediate operation when necessary.

In some respects the book scarcely reaches the standard which might be desired for postgraduate instruction; some of the sections contain no more information than should be in the possession of senior students; others, while helping the practitioner to understand the rationale of treatment, should not be allowed to obscure the desirability of obtaining the most expert aid available.

MANAGING THE BABY

The Single-Handed Mother. By Lindsey W. Batten, M.B., M.R.C.P. With a preface by H. G. Wells. (Pp. 186. 5s. net.) London: George Allen and Unwin. 1939.

Dr. Lindsey W. Batten has hit on a new idea, and has found a novel way of helping *The Single-Handed Mother* by writing a book of this name, introduced and rightly praised by Mr. H. G. Wells, who confesses that this role is one he has not played in his not uneventful career. "No book can be a substitute for a doctor," states Dr. Batten, but this is the type of volume which the practitioner can confidently advise his maternity patients to buy and study before and after the arrival of the baby. The sections on breast-feeding are particularly good, and it is a happy feature that nearly double the space is given to natural methods of feeding than to the use of the bottle. A chapter on management is full of wise hints and sound advice. Two concluding sections called respectively "Bad Habits" and "Problems and Anxieties" will help many a mother to solve worrying puzzles of child development which are alarming rather than serious.

Dr. Batten's style is clear, his teaching definite and rational, and throughout the volume it is obvious that not only has the author a wide experience of children in health and disease, but he has lived in close contact with a nursery of his own, and he has a real appreciation of the difficulties which face the young mother who has no help and no expert nursing advice ready to hand. The volume deserves a wide circulation, and medical practitioners would themselves learn something from its contents.

AN EXPOSITION OF GENERAL PHYSIOLOGY AND BIOLOGY

Man the Slave and Master. By Mark Graubard. (Pp. 366. 10s. 6d. net.) London: J. M. Dent. 1939.

The "jacket" of Dr. Mark Graubard's book prints three enthusiastic testimonials—from Professor Lancelot Hogben, Dr. Paul De Kruif, and Sir Arthur Keith, who writes that the book is "worthy of Mr. J. B. S. Haldane at his best." Whether Professor Haldane would feel flattered by this comparison is a delicate question, but it may certainly be said that more than half of the book is an admirably clear exposition of the present state of knowledge of general physiology and biology; Professor Haldane himself could hardly write a better elementary account of modern genetics. The chapters on anthropology and the history of culture also deserve praise. Of the remainder of the book we cannot speak so enthusiastically; it too frequently illustrates the truth of a remark made on page 343: " Saddening indeed is the remarkable intensification of arrogant intellectual cocksureness and ensuing intolerance in recent years." According to Dr. Graubard, scientific thinkers in biology, sociology, and anthropology first appeared in the second half of the nineteenth century. " Scientific thinking means in brief that if we desire to study any aspect of reality, information can be obtained only from a careful study of relevant facts " (p. 287). " Reality," we are informed (p. 68), is something of which man becomes aware " by means of sensations," and " sensations," according to page 67, are " arbitrary biological and psychological phenomena, products of our central nervous system." A few pages earlier Dr. Graubard wrote with some pity of the philosophers who had tried to answer such questions as—What is a sensation? How is it created? And " not without sadness and despair " of those who still studied their attempts. One such attempt was this:

> " The general character of sensation in all its forms is to be found in seeing that sense-perception is that which is receptive of the forms of things sensible without their matter, just in the same way as wax receives the impression of the seal without the iron or the gold of which it is composed and takes the figure of the gold or bronze but at the same time not as bronze or gold." (Aristotle, *De Anima*, ii, 12.)

This may not satisfy us; we may prefer the argument of Socrates (*Theaetetus*, 12 et seq.), but why dubbing sensations arbitrary biological and psychological phenomena should be thought a more scientific or successful attempt than those of Plato and Aristotle is not clear. The prescientific philosophers, again, were interested in human temperament and classified temperaments in many ways; modern psychologists have thought them not wholly wrong. Dr. Graubard, however, has no use for these distinctions. " By temperament," he says, " we mean the threshold of an individual's sensitivity." *Simplex munditiis.* It is not surprising that Dr. Graubard's anger is deeply excited by Freud, who, it seems, " displays an ignorance of biology amazing even in non-biological writers when he asserts that all instincts are associated with a feeling of pleasure." His " method of reasoning has nothing in common with science." " Freudianism is indeed unsound from the standpoint of biology, psychology, and anthropology. It is neither an approximation to truth nor a stimulating guess, but mere gossip and folly."

The fact that Dr. Graubard is not well acquainted with some departments of knowledge relevant to his theme does not, however, diminish the value of his exposition when he writes on subjects he understands.

DIETETICS

Diet in Health and Disease. Edited by Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., M.D., F.R.C.P., and Alan A. Moncrieff, M.D., F.R.C.P. The *Practitioner* Handbooks. (Pp. 383; 2 figures. 10s. 6d. net.) London: Eyre and Spottiswoode. 1939.

In the fourth volume of the series of the *Practitioner* Handbooks entitled *Diet in Health and Disease* is collected the series of articles which have appeared in the *Practitioner* on this subject, with an appropriate introduction by Professor Cathcart. The articles themselves have been revised and new matter added, and their collective value enhanced by a masterly survey of practical dietetics contributed by Professor Mottram. This first chapter is of absorbing interest and clarity and contains a special table of the vitamin and mineral values of protective foods which will be much appreciated.

The advance in scientific knowledge on the subject of nutrition has been so rapid that the busy doctor has no easy task in keeping pace with it. There must always be periods of delay between scientific discovery and its practical application. The first lag is between the laboratory and the general body of the profession, and the second between the doctor and the public. Anything which will shorten the first will have a still greater effect on the second. The need to improve the general standard of nutrition in this country is recognized as a national problem which will not be solved until the nation through the family doctor is familiar with the fundamental principles on which good nutrition is founded.

Most of us are familiar with the demand of the patient for rules of diet. Few of us can be satisfied with the advice we give or the list of " may take " and " may not take," however well they seem to serve the occasion. Too often the opportunity for instruction of the patient on intelligent lines is lost. This book should go far to remedy this state of affairs and will fill a long-standing gap on the doctor's bookshelf.

Notes on Books

All those who are wont to express strong views on the subject of the influence of the cinematograph on the minds of children should read RICHARD FORD'S *Children in the Cinema* (George Allen and Unwin, 7s. 6d.). As a rule these views are expressed with a violence in direct proportion to the ignorance of the subject. So far as we know this is the first occasion on which a careful survey has been made of the subject from all angles; and, taking things all round, it is quite clear that the cinema does more good than harm to children as a whole. Of course, there are a few children who are better for not seeing cinemas at all, more who ought not to go too often, others who should not go at certain periods of their life, and others for whom films should be very carefully chosen. It is clear, however, that children develop very strong views on what they like and what they won't have at any price. They go to special children's matinees to be entertained, and very properly resent any attempt at moral uplift under the guise of " a nice film." The real essential from the child's point of view is action, and " musicals " and child stars come a bad last in their order of preference. Such unbiased medical opinion as is available is quoted, and it is clear that films do not put ideas into children's heads which are not there already, though they may suggest methods of action whether these are desirable or not. All who are interested in children and/or in the films should read this book, and if they do it will command a very wide public.

Jordans Income Tax Guide, 1939–40 (Jordan and Sons, 116, Chancery Lane, W.C.2; 6d., by post 7d.) represents an attempt—and on the whole a successful attempt—to compress the essential facts with regard to income-tax assessments and allowances into the limits imposed by the low price charged for it. The second Finance Act of this year has laid down the rates of tax and alterations in allowances which will apply to 1940–1, and these changes have been set out in comparison with those effected in 1939–40. We doubt, however, the advisability of using the inside of the cover for that purpose instead of a sheet in the body of the booklet. One or two points might usefully be reconsidered for another edition. For instance, it is twice stated that income tax under Schedule A is payable in one sum on January 1, whereas since the rate was raised to 5s. 6d. last year some modifications of this rule have been in force for tenants paying tax and deducting it from their rents; with the rise in the rate to 7s. this provision becomes somewhat important. In the notes on Schedule E, expenses are stated to be allowable if "necessarily" incurred in the performance of the duties; the statutory rule says "wholly, exclusively, and necessarily," which is rather more restrictive. In explaining surtax, it might be made clearer how the "income" surtaxed is arrived at—that expenses allowed for income tax are also allowable for surtax, and that such charges as interest are allowable for surtax.

John Wright and Sons, Ltd., of Bristol have published a seventeenth edition (making the 197th thousand) of Warwick and Tunstall's *First Aid to the Injured and Sick: An Advanced Ambulance Handbook.* It is edited by Dr. F. C. NICHOLS. The chief feature of this edition is the more complete account given of gas poisoning in warfare, with a new section on the civilian respirator, giving full details of the apparatus and of how to fit, use, and take care of it. The price is 2s. 6d.

That Mr. W. G. MCMINNIES'S *Signpost* is a useful guide to those seeking pleasant resting-places in the country is shown by its having reached a fifth edition. It will be all the more useful now that Continental resorts will be impossible for the present and immediate future. To a medical man such a guide is very helpful in choosing a place to which he can "evacuate" old, delicate, or nervous subjects. Helpful too for the doctor himself when he is lucky enough to obtain a holiday and sufficient petrol to reach one of these havens. A photograph of each recommended hotel is given, with a brief account of its special features, not omitting the important point of the tariff, about which so many books are coy. The index gives a list of the games and sports available at each. Altogether an attractive and practical work, illustrating the great improvements that have been made in the country hotels and inns since the dawn of the motor age. It is published by Simpkin Marshall at 3s. 6d.

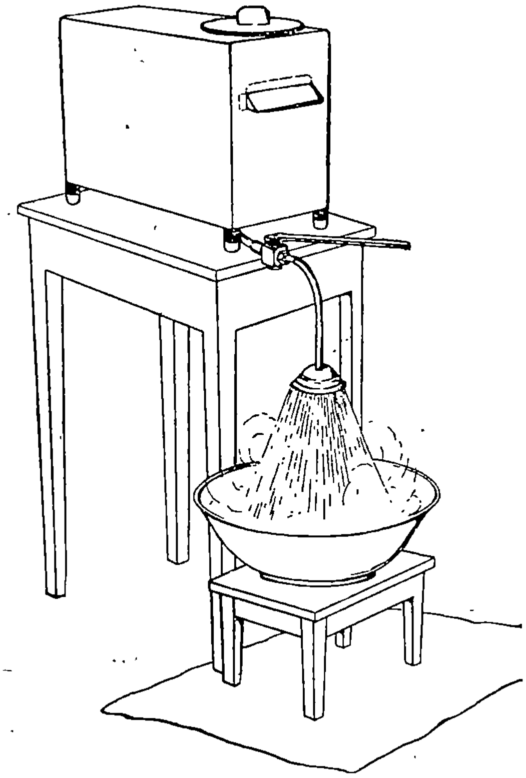
Preparations and Appliances

PORTABLE RESERVOIR WITH SPRAY

Dr. LACHLAN GRANT (Medical Officer, Ballachulish and Kinlochleven) writes:

I have been experimenting with an apparatus designed to afford in the patient's home, at the bedside, an aseptic wash somewhat comparable to that obtained at the elevated spray faucet of an operating theatre. The apparatus consists of a light rectangular-sided tank 20 inches long, 8 inches broad, and 12 inches deep, made of stainless steel or of vitreous enamelled metal, thus rendering it more impervious to corrosive lotions. The tank weighs about 10 lb., and has a capacity of four gallons. There is an opening in the upper surface large enough to admit the hand for cleansing the tank. This opening is also used for filling purposes, and is covered by an easy-fitting cap. A draw-off tap with spray outlet is fitted to the reservoir, and this tap is operated by means of a light aluminium lever handle easily detached and controlled when in use by the elbow. Another type of tap which may be fitted is an all-metal one with a hinged one-way joint. The latter is operated by raising or lowering the nozzle as required. The flow from both taps is by gravity only. The apparatus, which may be fitted into a case about the size of an ordinary midwifery bag, can easily be carried to the bedside. For use the tank should be filled with pure water at any suitable temperature. This may be done direct from a kettle or ewer. If a lotion is being employed this should be poured from a jug or may even be mixed in the reservoir. The cap having been replaced, the tank should then be elevated, to ensure the necessary gravity flow from the spray, by placing it on a small table or other support—a fairly large round or oval basin should be placed below the spray to collect the waste.

The apparatus is light, compact, and easily transportable by hand, cycle, or car. It obviates the risk always involved by washing in still water or lotion in a basin. The hands, or swabs, can be cleansed under a running supply of uncontaminated water or antiseptic lotion at the bedside. The water or lotion in the tank keeps warmer for a longer time and is less liable to aerial floral contamination than is the case with water or lotion lying exposed in an open basin. By washing under running water any gross or septic material from the skin surfaces flows away, and organisms are thus not reapplied to the cleansed surfaces. An aseptic or antiseptic wash can be achieved with a minimum expenditure of fluid. This is also an advantage where water is scarce, in areas with low annual rainfalls or in other special circumstances.



The reservoir should be part of the armamentarium of any practitioner engaged in domiciliary midwifery or surgery, whether or not water is laid on in the houses at which he attends. It should also prove as useful to veterinary surgeons and to nurses in the course of their work. It might be installed in all motor and air ambulances where surgical or obstetrical emergencies may have to be dealt with, and it should form part of the equipment of all first-aid posts under A.R.P. schemes. Its usefulness in field dressing and casualty stations will readily be appreciated, as will its advantages to practitioners in the Tropics and aboard ship, on account of its economy of water. The tank has been made for me by Messrs. Archibald Young and Sons, Ltd., of Forrest Road, Edinburgh.

EPHYNAL

Ephynal "Roche" (Roche Products, Ltd., Welwyn Garden City) is a synthetic form of vitamin E; its chemical name is α-tocopherol acetate. This synthesis was achieved by Karrer in 1938 and hence represents one of the latest of the triumphs of vitamin chemistry. Animal tests have proved that the activity of the synthetic compound is equal to that of the natural form.

The importance of vitamin E has been proved repeatedly in recent years. Observers have claimed up to 80 per cent. of successes in the prevention of abortion. It is being tried tentatively in cases of male impotence and testicular atrophy. Beneficial results are reported also in the treatment of premature infants.

Nova et Vetera

SIDELIGHTS ON ENGLISH MEDICINE IN 1677-9

RECORDS OF THE EAST INDIA COMPANY

A Calendar of the Court Minutes of the East India Company for the years 1677–9, published under the patronage of His Majesty's Secretary of State for India (Oxford, 1938), contains interesting passages throwing additional sidelights on medicine in England in the last quarter of the seventeenth century.

Some Medical Worthies of the Age

The names of the following British doctors, probably long forgotten or unknown to the present century, occur in the pages of these original records.

Doctors who stood security to candidates seeking Company's service: (1) Dr. John Micklethwaite, Doctor of Physic. He stood security for John Blunden, factor (August, 1677). The same Dr. Micklethwaite was allowed in October of the same year to ship on "expectation" to the value of 100 pieces of eight on paying freight. (2) Dr. King stood additional security to James King, writer (August, 1677). (3) William Butler, a London apothecary, acted as security for James Butler (January, 1678). (4) Dr. John Archer, security for Reuben White, writer (January, 1678). (5) Dr. Samuel Annesley for Samuel Annesley, jun., a factor (March, 1678). (6) Dr. Edward Master, security for Henry Odinden, writer (December, 1678).

Doctors mentioned as stockholders of the Company: (1) Dr. Joseph Tayler in the year 1677. (2) Dr. Peter Barwick in the year 1679. (3) Dr. Elliot in the year 1679.

Examiner of candidates for appointment as surgeons in India before February, 1677: Mr. Page, surgeon. He was paid 20 shillings for examining two surgeons who were sent to India in the service of the Company.

Apprentices: Each surgeon going out to India was permitted to take only one apprentice, "a boy of 16 years and not under."

Handbook of Medicine, provided to Company's doctors: The Court directed the Secretary on January 2, 1678, to send to Fort St. George through Mr. Orde a copy of *Culpeper's Dispensatory.* "The Pharmacopiea Londenensis was translated into English in 1649 by the famous Herbalist and quacksalver Nicholas Culpeper" (Garrison). Salmon's *New London Dispensatory* was published in 1678.

The Company and Hospitals

Bethlem Hospital: The cellars of this hospital were leased to the East India Company for twenty-one years at £100 per annum. In May, 1678, the committee for pepper warehouse were asked to negotiate with the governors of Bethlem Hospital for the cellars proposed to be let out to the Company as regards "money to be spent on fitting for use and the clamour that may arise if the scent of pepper shall annoy patients."

The Hospital at Poplar: The origin of this hospital as gleaned from old records is summarized as follows in the Court minutes of the year 1679, in the course of a statement regarding the reasons for paying the minister and schoolmaster from the funds of the hospital.

"In 1625, the Court of Committee took into consideration means of relief for wounded mariners who had been maimed or fallen into decay in the Company's service and instructed their paymasters to deduct 2d. in the pound from all seamen's wages employed by them towards the said relief and in order the sooner to raise a stock, 2d. in the pound was also to be allowed by the committee, from their gratuities and from the salaries of all officers of the Company, only very poor men to be exempted from paying the said sum. This went on well, for on March 31, 1626, £60 were given into the hands of the treasurer, to erect a hospital for the relief of mariners."

In May, 1627, a suitable house in Poplar was purchased for £360 and then fitted with conveniences at a cost of £350. Twenty poor were to be maintained there. More money accumulated as time went on, through collections and through amounts bequeathed by employees of the Company. In 1679 there was nearly £3,600 in the hospital account in the books of the Company, and the committee ordered that a book should be maintained for the accounts and concerns of the hospital.

Vizagapatam. D. V. S. REDDY.

OSLERIANA

Sir William Osler was a great humanist, a fine teacher of clinical medicine which he based on morbid anatomy, and an excellent writer. The medical faculties in the Universities of McGill in Canada, of Johns Hopkins in the United States, and of Oxford in this country bear the impress of his culture and show that he was able to get things done without apparent effort. In each he made a tradition in medicine which is lasting and growing.

The *Bibliography of Sir William Osler's Publications*[1] is a key to his manner of working and shows how he attained his ends. It is based on Miss Blogg's chronological bibliography and is edited, revised, and indexed by Dr. Maude Abbott. Dr. Henry Barton Jacobs in his foreword tells for the first time the story of the origin and distribution of the well-known Osler plaque which was executed in Paris in 1903 (although Dr. Jacobs says 1905) by Mr. F. Vernon, the sculptor. The book also contains a reproduction of Mr. Seymour Thomas's portrait of Osler, which was painted in 1908. The volume is very useful for reference and will be greatly appreciated by the numerous friends who hold Osler in affectionate remembrance.

MEDICAL ICONOGRAPHY

Iconography is the study of the work of painters, engravers, sculptors, and medallists to portray the features of those who ought to be held in remembrance. Collectors of medical portraits have been many from the days of "the princely Mead" to our own times, but few have made a scientific study of their collections. Professor Richard N. Wegner of Frankfort-on-the-Maine, therefore, has broken somewhat new ground in his recently published *Anatomenbildnis,*[2] and has produced a useful book of reference, though he has limited himself to the great anatomists who lived after Vesalius and has written in somewhat difficult German. He has gathered together portraits of men whose names and works are more familiar than their personal appearance, and considers them from the artistic side as sixteenth century woodcuts, copper-plate engravings of the seventeenth century, etchings and lithographs of the later period. He gives well-executed examples of each method, with a short account of the individual and of the artist by whom he was portrayed. The method might well be adopted for portraits of the great physicians and surgeons, but it requires a knowledge of art, a technical acquaintance with the processes employed, and literary ability. The three qualifications are not often combined as they are in the person of Professor Wegner, so medical iconographers are not common.

LYMPHOCYTIC CHORIOMENINGITIS

The five years which have elapsed since Armstrong and Lillie discovered the virus of lymphocytic choriomeningitis have seen a considerable advance in our knowledge of this virus and of its natural history. It was at first thought that this discovery had solved the problem of the aetiology of so-called acute aseptic meningitis. This belief was based on the facts that the first cases from which this virus was isolated presented the clinical picture of aseptic meningitis and that the changes evoked in experimentally infected animals were confined, so far as the central nervous system was concerned, to the meninges and choroid plexus; little or no involvement of the brain or cord occurred. It was not long, however, before doubt arose as to the validity of this assumption. Those cases from which the virus was first isolated in this country by Findlay, Alcock, and Stern[1] in 1936 had symptoms clearly indicating cord involvement. A fatal case described by Viets and Warren[2] in the following year showed definite encephalitic changes, and more recently MacCallum and Findlay[3] have recovered the virus from a patient whose clinical state might well have passed for poliomyelitis. Obviously this virus is capable of attacking both the meninges and the tissues of the central nervous system in man; acute aseptic meningitis is merely one of the forms the infection may assume. Furthermore, it seems clear from the investigations of Baird and Rivers[4] that all cases presenting the clinical picture of acute aseptic meningitis are not due to this virus, for in only a portion of the cases of this clinical type could they obtain evidence that the virus of lymphocytic choriomeningitis was the causal agent. It would appear, then, that the virus of Armstrong and Lillie can produce infections in man of varying degrees of severity, in some of which the meninges alone are involved, while in others there are deeper-seated changes in the central nervous system. And from what we know of other infectious diseases it would be expected that in addition to these clinically obvious infections milder atypical or even asymptomatic ones would occur. This, in fact, has been shown to be the case. Wooley, Armstrong, and Onstott[5] have found specific antibodies for the virus of choriomeningitis in the serum of individuals giving no history whatever of meningitis or encephalitis, and both Laigret and Durand[6] and Kreis[7] have observed that infection in human volunteers may result only in pyrexia and slight general symptoms. How widespread infection with this virus is in man we cannot say with any degree of certainty. The findings of Wooley and his co-workers certainly suggest that it is commoner than might be thought, for 11 per cent. of 1,248 sera from different parts of America were found to contain antibody for choriomeningitis virus. It is only by means of such serological surveys that a clearer idea of the extent of human infections with this virus will be obtained, and until recently the only test available for the purpose has been the neutralization test. Since this test entails the use of animals it is a relatively complicated procedure and therefore of somewhat restricted utility. But Smadel, Baird, and Wall[8] have now shown that a soluble specific antigen—separable from the virus itself—is present in the tissues of animals infected with the virus of lymphocytic choriomeningitis, and that the presence of antibody to this antigen in the serum of convalescent animals and human beings can be demonstrated by the complement-fixation test. Not only is this observation of much interest, since it parallels what has been found in some other virus infections such as rabbit myxoma and epidemic influenza, but it provides a relatively simple specific serological reaction suitable not only for the diagnosis of suspected cases but also for large-scale serological surveys.

The source of the human infections with this virus still remains unsettled; in fact, from the very outset the story has been a rather confused one. Armstrong and Lillie isolated the virus in the first instance from a monkey which had received monkey-passage material from a line of animals started with material from a human case of St. Louis encephalitis, and they also found serological evidence of infection with the virus of lymphocytic choriomeningitis in some other of their experimental monkeys, including one which had been infected with poliomyelitis. It was McNair Scott and Rivers[9] who first brought forward unquestionable evidence of having obtained the virus direct from human cases, though Armstrong and his colleagues had already shown that specific antibodies for the virus were to be found in man. Meanwhile Traub[10] had shown that this virus was responsible for a virulent epizootic in certain of his mouse stocks at Princeton. Rivers and McNair Scott[11] compared their strains of virus of human origin with those isolated by Armstrong and Lillie and by Traub, and showed that they were all serologically identical. Similar infections in laboratory mouse stocks have since been described in different parts of the world, and we know from the important investigations of Traub[12] that the virus is present in the urine and nasal secretions of the infected animals, and that infection can occur in intra-uterine life.

It would seem clear, both from the work of Traub and of others, that infection in mouse stocks due to this virus may be of varying virulence, sometimes even wholly inapparent, so that the greatest care must be taken to ensure that the mice used for experimental work are free from natural infection. The possibility that the mouse was the source of human infections was early considered. Rivers and McNair Scott[11] discussed this possibility, and inclined rather to the view that infection of laboratory mouse stocks was more probably of human origin. But recent work by Armstrong and Sweet[13] indicates that human infection from mice is far from being a remote possibility. They have demonstrated the presence of the virus of lymphocytic choriomeningitis in three out of five mice trapped in two houses, in both of which a human case of choriomeningitis had occurred. And since the interval between the patient falling ill and being removed to hospital was only four days, it seems unlikely, to say the least of it, that the mice had contracted their infection from the human cases. A rodent source of infection in some human cases is therefore more than likely, and this probability is heightened by the fact that human cases occur either singly or in small isolated groups with little or no indication of man-to-man spread. This, however, might be more apparent than real, for we do not know what percentage of the infected develop clinical disease, and the possibility that man-to-man infection does occur can by no means be ruled out. Recent observations by MacCallum and Findlay do, in fact, support this possibility. They have isolated the virus from the nasopharynx in one case even some weeks after recovery, and if the virus is commonly to be found in the nasopharynx, persisting in that situation in some cases after recovery, spread by droplet infection will almost certainly occur.

Reference has been made to the fact that only a proportion of the cases of acute aseptic meningitis appeared to be due to the virus of choriomeningitis. One would expect, none the less, that those not due to the Armstrong-Lillie virus would be of virus aetiology. A recent paper by MacCallum, Findlay, and McNair Scott[14] brings some confirmation of this, for from two cases of the Wallgren clinical type the authors isolated a virus which, though resembling the virus of choriomeningitis, differed from it in certain respects. This new virus had the same animal pathogenicity range as the Armstrong-Lillie virus, and it produced the same pathological picture in the animals. But it was unrelated serologically to choriomeningitis virus, and from preliminary filtration experiments appeared to be about three times as large. This latter observation suggests that the new virus is not just a new serological type of choriomeningitis virus, and the authors suggest for it the name of "pseudo-lymphocytic choriomeningitis." It is not absolutely clear from the findings, as MacCallum and his colleagues admit, that these two strains of the new virus were of human origin, but further work will no doubt clear up this question and settle its relation to the virus of Armstrong and Lillie.

FINANCIAL SURVEY OF LONDON HOSPITALS

The King Edward's Hospital Fund for London has issued a "Statistical Summary"[1] of the income and expenditure of the 146 voluntary hospitals in its area, which covers a radius of eleven miles from St. Paul's Cathedral. In ordinary times we should have seized upon these 115 tables, each table with about twelve columns of figures in which receipts and costs and work done are analysed to the accuracy of fractions, and have brought out some interesting and perhaps useful comparisons and contrasts. But as it is these figures come like an echo from a forgotten world. It seems incredible, as so many other things do, that six months ago these precise allocations and balances were matters of enormous interest to those in charge of hospital administration. A whirlwind has now scattered these statistics, and many people are wondering whether the old hospital structure, so ramshackle and yet so easy to find one's way about in when one got the clue, so full of anomalies and yet so manifestly working to the public good, will ever be reassembled. To vary the figure of speech, the lights have changed at the crossing, and before they come back to green the road ahead may be very different from what it was before. Some are even asking whether voluntary hospitals as we have known them can survive. Take, for example, the last table of all in this compilation, giving particulars of pay-beds, their number, description, and weekly charges. The highest charge of all—at one of the teaching hospitals—is fifteen guineas a week, but three other teaching hospitals and one non-teaching charge twelve guineas for some of their private beds. The more usual charge starts from a minimum of six guineas at the teaching hospitals and four guineas at the smaller general and special hospitals. In the economic readjustment which will follow the war one wonders whether enough people who can afford these sums will be found to occupy the 2,200 such beds which are available. On the other hand, the hospitals are making no exorbitant profits from their pay-beds. The expenditure on pay-beds in 1938, taking the whole 146 hospitals, was £389,339 as against a revenue of £464,976, a profit of about £34 per bed, which may not be unreasonable. If each bed is occupied by twelve patients in the year it means that the hospital makes only about £3 per patient.

London hospitals in this last pre-war year were not in a very comfortable financial situation. Of the teaching hospitals only the London, Charing Cross, and King's College had surpluses, and of the nine hospitals without medical schools but with a complement of 200 or more beds, all had deficits. The smaller hospitals seem to have been more prosperous. Of twenty-nine general and cottage hospitals with fewer than eighty beds eighteen had surpluses totalling to £23,000, and although the other eleven had deficits the aggregate of deficits was not more than £5,000. In voluntary gifts also the smaller hospitals on the whole seem to do better than the larger. Thus the gifts to the "big twelve," although they amounted to half a million pounds, were down by £18,000 on the amount received in 1937, whereas all the other hospitals combined managed to maintain their voluntary gifts at practically the same level for 1938 as for the year before.

But the service which the voluntary hospitals render stands out impressively from these figures. In their 19,000 beds they gave treatment last year to 300,000 in-patients, while their out-patients numbered two million. To-day they are playing, or have made themselves ready to play, an important part in the war emergency scheme. Buildings have been adapted, equipment overhauled, staff enlisted and trained. Although the Government is contributing towards the cost of beds reserved for casualties, the hospitals are still, as they were before the war, largely dependent on voluntary contributions for the maintenance of adequate provision for the civilian sick. Their restoration to normal activity with the declaration of peace will again call for large expenditures, and in the meantime the national purse will have been impoverished, and the appeals for those actually suffering in the war will be severely competitive with ordinary hospital appeals. In recent years some of the ablest brains in medicine and in the business world have been devoted to hospital organization in the belief that the voluntary principle was worth cherishing. They will be needed even more in the years ahead, if the system is to continue within a new social order.

THE HEALTH OF LONDON BUSMEN

The evidence before the Court of Inquiry appointed to examine the stoppage of the London Central Omnibus services in 1937 showed clearly that there was a widespread feeling among the busmen that the conditions of their work were injurious to health. The Court, however, concluded that no satisfactory proof of that belief had been placed before it but that there was certainly a case for investigation. Accordingly the Minister of Labour arranged for the subject to be fully reviewed by representatives of three bodies—the London Passenger Transport Board, the Transport and General Workers' Union, and the Medical Research Council (whose representatives were Sir David Munro and Dr. Bradford Hill), under the chairmanship of Sir John Forster. The results of their deliberations, now published,[1] show clearly that great pains have been taken both to assess any specific effects that the working conditions may have upon health and to suggest practicable means of ameliorating them. All the available statistical data relating to the health of drivers and conductors have been examined, the actual conditions of work have been surveyed, the present-day views of the men's representatives on those conditions have been elicited, and a considerable body of expert medical opinion has been taken upon the conditions which might be regarded as especially conducive to gastric disorders—the forms of illness to which the busmen say they are particularly liable. The statistical evidence is admittedly limited, and though the members of the committee were able to make some slight additions to it they were unable to suggest any method by which it could be placed upon a really precise basis. Figures relating to the time lost by the bus crews from illness of all kinds showed no material change in the incidence of illness between 1931 and 1938, in spite of the increasing density of traffic in this period and the men's argument that the "intensity of their work" had consequently risen. If the nervous tension involved in the busmen's duties has increased, as might well be believed, it is not reflected in the available figures relating to sickness absenteeism. On the other hand, Bradford Hill's report to the Industrial Health Research Board[2] showed some relative excess of gastric illnesses among the London bus workers compared with the tramway workers, and a similar result is shown in a comparison made in the present report between the bus drivers and conductors and the maintenance workers in the London Passenger Transport Board's employ at Chiswick. Exploring, in the light of the medical evidence given, the features of bus work that might lead to such a susceptibility to gastric illness, the report lays particular stress upon two factors —namely, the irregularity of the hours of work and meal times, and the nervous tension that may be involved. With regard to the first, the irregularity is indeed marked. The men's shifts of duties change as frequently as every week. A more stable system unfortunately introduces other disadvantages — for example, a prolonged period of work on heavier duties —but, impressed by the medical evidence placed before it on this point, the committee suggests that the Board and the Union should consider whether less frequent changes are not in fact practicable. It also concludes that some spells of duty are definitely too long, and earlier meal reliefs in such cases should be aimed at. The times allowed for meals were not, it seems, specifically complained of by the busmen, but, in view of their statements relating to the general strain of their work and the medical evidence relating gastric illness to nervous anxiety and temperament, a reduction is suggested in the number of meal periods at present affording less than forty minutes. For similar reasons much stress is laid upon the importance of proper rest pauses between journeys, which, it is advised, should be kept habitually in view in the construction and revision of working schedules. By such means nervous and physical fatigue might well be reduced. On the more debatable question of the advisability of a reduction in the hours of work no conclusion was reached, and no evidence could be obtained to show whether any part in the production of gastric illness is played by the absorption by the men of carbon monoxide and other fumes.

[2] Report No. 79. An Investigation into the Sickness Experience of London Transport Workers, with Special Reference to Digestive Disturbances. 1937.

The omnibus services are a necessary part of London's life and give employment to a large body of men—some 20,000 drivers and conductors alone. Their health is an important problem in industrial medicine. Although highly abnormal conditions of work unfortunately prevail now—some of which will probably decrease and some increase the demands made upon the men—it is to be hoped that the parties to the industry may still be able to take cognizance of the proposals made in this report and to act upon them so far as is possible.

PERURETHRAL PROSTATIC RESECTION

Twenty-nine valuable papers by American and British writers[1] throw much helpful light on the question of perurethral resection of the prostate, often less correctly called transurethral resection—less correctly because the resection is done through, not across, the urethra. The perurethral route for attacking the prostate is originally European and over 100 years old, but the modern method of removing prostatic strips by means of an electric current passed through a wire loop is American and but ten years old. To American enthusiasm also is due the credit for popularizing this operation. The almost irresistible force of this enthusiasm met an almost immovable object in Europe's perhaps too stolid conservatism. The result was generally beneficial, for, on the one hand, unprogressive complacency was stirred, and, on the other, to reverse and revise Canning's dictum, the Old World was called in to redress the prostatic balance of the New. However, several articles in this excellent symposium show that criticism of perurethral resection is by no means confined to this side of the Atlantic. For instance, the uninitiated might conclude from the fact that one large American clinic employs the perurethral route almost exclusively that this route is the best, or that this particular clinic considers it the best. Actually, an illuminating American comment provides an alternative explanation of this apparent preference: "The urological department has hitherto been purely a diagnostic clinic, with its members neither trained nor allowed to perform surgical operations. It is easily seen, therefore, why this clinic does only transurethral procedures." Further shrewd comment, referring to the average stay in hospital after perurethral resection as being from three to seven days, contrasts this period with that of healing, which takes at least three weeks, and, in partial explanation of the fantastically low mortality reported from some quarters, points out the natural tendency of statistical mortality rates to be low in proportion to the shortness of the stay in hospital. Thus, deaths from cardiac failure, sepsis, pneumonia, embolism, etc., which are included in the mortality statistics of suprapubic prostatectomy, are not included in those of perurethral resection owing to the patients' previous departure from hospital. Again, transatlantic authors quote the statistics of life insurance companies, which show that "of 100 men at the age of 60, about thirty will die before they reach 70 years of age. In other words, the average mortality will be 3 per cent. each year, though less of course in the early sixties and greater in the late sixties. Between the ages of 70 and 80 the mortality will average 5 per cent. each year." These figures are intended "to give heart to those who have a mortality from any surgical procedure and to warn those whose mortality rate for transurethral resection is soon going to be less than the expected unmolested death rate." Two further criticisms are that whereas perurethral resection has not eliminated any of the previous complications of prostatic surgery it has added one—urinary extravasation from a ruptured bladder—and that the new operation has been followed by a greatly increased sale of penile clamps for incontinence. Such refreshing candour does much to counterbalance the extravagant claims made for perurethral resection, which nevertheless has won for itself an undeniable place in prostatic surgery, more especially in the treatment of the smaller enlargements of the prostate, particularly those of the "middle lobe"; of the various fibrotic affections of the bladder neck, including the so-called median bar; and of certain prostatic carcinomata.

CONSERVATIVE TREATMENT OF GAS GANGRENE

Hitherto radical surgery, chiefly in the form of early amputation and the provision of widespread drainage, has been considered essential in the treatment of gas gangrene, but it now appears that a change in this viewpoint may be desirable. It has been claimed that combined irradiation with x rays combined with sulphanilamide therapy may so control the infection as to render amputation or even surgical measures of any kind unnecessary. The most recent support for this claim is made in a paper by R. L. Sewell[1] of Rochester, New York, who states that J. F. Kelly in 1933 was the first to advocate irradiation in gas gangrene and that Kelly's and other collected cases which have been treated by irradiation now number 160 with fourteen deaths (8.8 per cent.). There are obvious difficulties in making a comparison between radical and conservative treatment, inasmuch as amputations are performed only in the fulminant case, whereas in any particular instance infection is not always proven, as positive cultures of *Clostridium welchii* may be the result of contamination of wound exudate. Moreover, where several measures—such as injections of serum and irradiation and sulphanilamide—are used, it is not possible to decide how effective any single one of these is. It is quite likely that the effect of sulphanilamide on the secondary streptococcal infection plays an important part. Further work on the conservative treatment of gas gangrene is needed.

"THE BEST PHYSIC"

The organized public health services of the present day safeguard the citizen of any modern well-directed community against many bodily ills which would otherwise beset him. This security, though good, is not all, for it still depends upon the manner in which the individual orders his life whether he attains to that degree of health which makes life worth living. It is thus the fate and duty of every man to be to some extent his own doctor. This theme is developed by Dr. V. Heiser in his most recent work.[1] He aptly expounds his doctrine both by precept and by the example of his own experience, for, as he quotes from Bacon, "a man's own observation, what he finds good of, and what he finds hurt of, is the best physic to preserve health." Yet in the case of food, even where a man finds hurt, he may be slow to change. Age-long racial food habits, no matter how injurious, have a tendency to persist. Immigrants to the United States, Italian, Chinese, Spanish, or Russian, learn a new language more quickly than a new diet. In the matter of beverages too there may be the same unreasoned tenacity. England is a tea-drinking country not because she thinks that tea is best but in consequence of the early tea monopoly of the East India Company. Her daughters, Canada, Australia, and New Zealand, have dutifully followed her example. The people of the United States, who prefer coffee, do so not because coffee is essentially better but because the Boston tea-party turned them against tea. As regards exercise it is Dr. Heiser's view that most people do not get enough of it mainly because their daily work does not compel them to take it. He himself, when in New York, goes for a half-mile swim at his club before breakfast, and in the country he plays tennis. He admits that golf has a longer outdoor season than either tennis or swimming, and that it possesses the merit of drawing a man from drinking and smoking in the clubhouse into the air and sunshine, but he accounts it an old man's game. Bicycling and horse-riding win his approval. Of fishing, the tarpon and the trout excepted, he has no great opinion. He favours the practice of skating, and recalls with pleasure—as who would not?—the charm of ice-waltzing in Canada on gala nights of winter. The author rightly claims credit for American air-conditioning with its finely adjusted thermostatic and other controls. He cites as its crowning achievement—or last straw—that in a Chicago theatre, when a bouquet of roses is thrown upon the stage, a charge of essence of rose is simultaneously injected into the main air-intake duct, so enabling the entire audience to share the fragrance! As Dr. Heiser lives robustly so also he writes robustly, bringing to his task that *mens hilaris* which, according to the mediaeval adage, is one of the three basic requirements for self-doctoring.

VITAMIN E

A booklet entitled *Vitamin E* gives the record of a symposium held last April under the auspices of the Food Group (Nutrition Panel) of the Society of Chemical Industry. This is a collection of papers on vitamin E given by workers who are themselves engaged on the researches reported. The chemical structure and properties of tocopherol were dealt with by Professor A. R. Todd, Professor P. Karrer, Dr. A. Emmerie, Dr. Lester Smith, and Mr. R. Bailey. The physiological action of vitamin E and the consequences of vitamin E deficiency were dealt with by Professor J. C. Drummond, Dr. Karl E. Mason, Dr. S. W. F. Underhill, Dr. T. Moore, Miss A. M. Copping, and Mr. A. L. Bacharach. The clinical and veterinary uses of wheat-germ oil and vitamin E preparations were dealt with by Dr. P. Vogt-Möller, Dr. E. Shute, Dr. D. W. Currie, Dr. C. Macdonald, and Professor F. J. Browne. The academic work on vitamin E is proceeding rapidly, but it is greatly to be regretted that so little controlled work on the clinical use of vitamin E has been carried out. In spite of the claims of some clinicians to have obtained good results from the treatment of habitual abortion and threatened abortion (what exactly is the stage of threatened abortion that yields to a dose of vitamin E?) by prescribing vitamin E, it remains to be shown how many women after one or two abortions have produced a living child without any vitamin E therapy—only then can it be determined whether vitamin E is essential for the human mother as it is for the rat. The booklet is obtainable from the general secretary of the Society of Chemical Industry, Clifton House, Euston Road, N.W.1, at the price of 5s., post free.

We are asked by the Medical Research Council to point out that the pamphlet *Blood Transfusion Outfit*, to which reference has been made in several recent communications to the medical journals, is not a publication in the ordinary sense and has not been placed on sale. It is merely a memorandum of instructions relating to the particular forms of apparatus for taking and giving blood which have been supplied to the four Emergency Blood Transfusions Depots in the Home Counties and to various hospitals in the London sectors. It has been printed as a matter of convenience for distribution to blood transfusion officers at the centres to which its applicability is limited.

The Thomas Vicary Lecture will be given at the Royal College of Surgeons of England by Sir Walter Langdon-Brown on Thursday, November 30, at 3 p.m., and the Bradshaw Lecture by Sir James Walton on Thursday, December 14, at 3.30 p.m.

The next session of the General Medical Council will open on Tuesday, November 28, at 10 a.m., when the President, Sir Norman Walker, M.D., will take the chair and deliver an address.

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation

BURSITIS

BY

L. R. BROSTER, O.B.E., M.Ch., F.R.C.S.

A bursa may be defined as a cavity lined by serous membrane. Bursae are formed either by dilatation of the lymphatic spaces or as a result of a localized effusion into the tissues. They contain a small quantity of serum. Their primary function is to permit of free movement and lessen friction between the hard and soft tissues of the body, especially where such movement is subjected to pressure. They exist as normal structures in many parts of the body —in the subcutaneous tissues over freely moving parts, over such bones as the patella or olecranon, or in the region of joints under the tendinous insertions of strong muscles. In the latter position a bursa may be formed by a hernial protrusion of the synovial membrane of the joint, and will then be in free communication with the joint cavity. It is important, therefore, to determine whether such a bursa has been involved either primarily, or secondarily by direct extension from the joint, by any pathological lesion.

Normal bursae occur at certain places with fairly regular anatomical accuracy, such as the prepatellar bursa and the olecranon bursa. On the other hand, where the soft tissues overlying bony prominences are subjected to exceptional and intermittent pressure secondary or adventitious bursae are formed. Structurally these bursae are similar to normal bursae except that their walls become thick and fibrous from prolonged irritation of the soft tissues, and the lining becomes shaggy and polypoid, especially from deposits of fibrin and unabsorbed blood clot. Adventitious bursae may occur in unexpected parts of the body, and are more constantly found among workers in special occupations. Thus large subaponeurotic bursae may be found under the scalp of Billingsgate porters and those who are accustomed to carrying baskets on their heads.

The so-called Covent Garden " hummy " is a bursa over the vertebra prominens. Tailors acquire bursae over their external malleoli from sitting with their legs crossed. Deal runners develop a bursa over their shoulder. Among non-occupational bursae the most numerous are those of the feet resulting from pressure by badly fitting shoes. The best example of this is the adventitious bursa which develops in association with hallux valgus. Here a bunion results from pressure by the shoe on the exposed head of the first metatarsal, and a bursa forms between the hardened skin and the calloused bone. Similar bursae occur over all bony prominences arising from malformations or displacements. For instance, a bursa may develop over the cuboid in talipes equinovarus. A particularly painful type of bursa is the one which forms under a hard corn. The typical position is over the head of the first phalanx in hammer toe or over the corresponding points of the three outer toes when these are in a flexed position. These little bursae are liable to infection, which may spread to the joint or bone. Unless the pressure is removed recurrent bursitis ensues.

The treatment is to pare off the corn, expose the bursa, and cauterize the bursal endothelium with carbolic on a sterile tapered match-stick, or excise the corn and bursa under local or gas-and-oxygen anaesthesia. Perhaps the classic example of an adventitious bursa due to a friction of soft tissues over bone is the one which forms over the cartilaginous cap of a cancellous exostosis. This should be removed at the same time as the exostosis. A small bursa sometimes appears over the head of the radius, and results in pain. It is mentioned as one of the causes of the so-called " tennis elbow." Bursa formation may also take place when hard structures such as cartilage or bone move over soft parts. Examples of this type occur under the hyoid. A bursa here may be mistaken for a midline dermoid or a thyroglossal cyst. A bursa may also form under the movable scapula, between it and the chest wall. The bursa is apt to become very large and to give difficulty in diagnosis.

Diagnosis

As a result of continued irritation and trauma a bursa becomes distended with fluid ; it is hot to the touch, and tender and painful when the part is moved. The skin covering it assumes a dusky red colour, and is movable over the bursa. On palpation there is fluctuation, and when situated superficially it transilluminates. When grasped between the fingers it is not freely movable owing to attachment to the underlying bony prominence. When bursitis is recurrent the walls of the sac become thick and fibrous, the lining membrane shaggy and polypoid. This perhaps is the most common condition. It is not unusual for haemorrhage to take place in a bursa, and deposits of fibrin and old blood clot adhere to its walls and cause obliteration of the cavity. In these circumstances the bursa becomes more solid to the touch, and fluctuation and transillumination will not be obtained. Haemorrhage is more likely to take place in the blood diseases and in haemophilia. When bursae are deep-seated and large their diagnosis may be doubtful. In these cases a needle of fairly large bore should be inserted and the typical fluid aspirated.

The Principal Bursae

The following is an account of the more important bursae which are encountered in the various parts of the body. In the region of the knee-joint, a particularly movable part, they are numerous.

Prepatellar Bursa.—Normally two or three sacs lie in front of the patella. When exposed to irritation by friction, fluid is secreted and the bursa becomes distended. It presents itself as a globular swelling over the patella about the size of half a tennis ball. The skin covering it is warm and red ; it fluctuates and transilluminates. It is fixed to the patella, and if the quadriceps is relaxed the patella will move from side to side when the bursa is moved. If the swelling forms over the proximal portion of the patella the condition is known as " housemaid's knee " ; if the swelling appears over the distal portion of the patella or over the patellar ligament, it is commonly known as " parson's knee." These bursae arise over that part which is most exposed in kneeling. Old charwomen from their occupation are particularly apt to develop the chronic fibroid form of prepatellar bursitis: as this bursa is liable to gummatous infiltration a Wassermann test should be done to differentiate the two.

The subpatellar bursa lies under the patellar ligament, and partly over the head of the tibia and the knee-joint, with which it does not communicate. It shows as a bulging on either side of the patellar ligament with the knee in full extension, and the patient cannot stand with the leg fully extended. It may push the ligamenta alaria backwards into the joint and simulate the condition of an internal derangement of the internal cartilage or a loose body in the joint.

The subcrureus bursa, when present, communicates with the suprapatellar synovial pouch and really forms part of the knee-joint. Its secretion of fluid will therefore run *pari passu* with that of the joint, and its presence is determined by an exaggerated fullness in the region of the suprapatellar pouch.

The semimembranosus bursa lies between the insertion of the semimembranosus tendon and the inner head of the gastrocnemius. It presents as an oval fluctuating swelling limited on its outer aspect but more free and less defined towards the inner aspect of the popliteal space. As in the majority of these periarticular swellings, it becomes tense in extension and flaccid on flexion of the knee. Enlargement of this bursa is often secondary to an intra-articular lesion, such as osteo-arthritis or tuberculous disease, and the condition of the joint should be ascertained before treatment is undertaken. Owing to its proximity to the popliteal vessels it may push the artery superficially, but the pulsation is not expansile in character as in aneurysm.

The popliteal bursa is a bursa arising from the synovial membrane of the knee-joint surrounding the intra-articular portion of the popliteal tendon. It gives rise to a rounded swelling behind the external condyle of the femur deep to the biceps tendon and the ilio-tibial band. It has to be differentiated from a bicipital bursa, which lies lower down between the biceps tendon and the external lateral ligament. Both these swellings may be mistaken for a cyst of the external cartilage.

A bursa is sometimes found beneath the insertion of the semitendinosus and gracilis, and produces a swelling over the upper and inner surface of the shaft of the tibia.

The psoas bursa lies between the tendon of insertion of the psoas muscle and the hip-joint, with which it usually communicates. Distension of this bursa gives rise to a deep-seated swelling presenting on the inner side of Scarpa's triangle. It is tense on extension of the hip-joint and flaccid on flexion. When painful it is the cause of flexion of the thigh, one of the symptoms associated with psoas abscess and hip-joint disease. Before any question of aspiration is entertained it must be remembered that an obturator hernia produces a swelling in this region. An enlarged psoas bursa may be found in association with osteo-arthritis of the hip-joint and tuberculous disease.

Subgluteal Bursa.—This bursa lies between the tendon of insertion of the gluteus maximus and the great trochanter of the femur. It is present in the condition known as clicking or snapping hip. When painful it causes abduction and eversion of the lower limb, a symptom seen in the first stage of tuberculous disease of the hip-joint, from which it should be differentiated. Indeed, the bursa itself is apt to be the seat of tuberculous disease quite independently of this infection within the joint. Owing to the lax muscular planes in this region the bursa may become enlarged, and if abscess formation takes place it burrows extensively among the lax tissues.

Ischial bursae when painful must be removed, and the chronic form of bursitis here must be differentiated from a gummatous bursitis, as this is one of the bursae liable to specific infection.

In the region of the *tendo Achillis* two bursae resulting from shoe pressure may be found. There is a bursa between the skin and the Achilles tendon, which is liable to infection from continued rubbing and excoriation of the skin over the heel. The other bursa is deeper and lies between the insertion of the Achilles tendon and the upper part of the posterior of the os calcis. It gives rise to a soft swelling on either side of the tendon. It is prone to tuberculous infection. It does not communicate with the ankle-joint, but may simulate an arthritis of this type in that region. The swelling, however, remains localized. In the upper limb there are only two bursae of any consequence.

The olecranon bursa is commonly found among miners and students. It forms a red, painful, fluctuating, and translucent swelling over the olecranon process, and does not communicate with the elbow-joint. It is particularly exposed to trauma. Septic infection may cause superficial necrosis of the bone, but it is unlikely to spread to the joint.

The subdeltoid bursa is situated between the deltoid muscle or the acromion process and the great tuberosity of the humerus, and does not communicate with the shoulder-joint. It causes an increased fullness to the rounded contour of the deltoid, but does not transilluminate, because of the thickness of this muscle. When painful it restricts the movement of abduction. It is liable to gonococcal and tuberculous infection.

Treatment of Simple Bursitis

In treatment the first consideration is to obviate or prevent any cause of irritation or pressure that has given rise to the bursitis, with the object of preventing a recurrence, which leads to chronic bursitis. In superficial bursae particular attention should be paid to the condition of the skin. If chapped and dirty or cracked it should be thoroughly cleaned with ether soap and disinfected with spirit or iodine for at least twenty-four hours. Neglect of this simple precaution may be fraught with serious consequences. Bursae have a rich supply of lymphatic vessels, which become dilated in simple bursitis. Organisms from a hidden focus in the skin reaching these vessels will spread exceedingly rapidly, either obtaining access into the blood stream, with consequent septicaemia, or spreading locally, involving the underlying bone or joint. Apart from these minute skin abrasions, infection may take place from lymphatics draining any area of local sepsis which may be present at the same time as the bursitis. By taking precautions against these, simple bursitis will subside with rest and fomentations or some form of counter-irritation such as blistering or painting with iodine or strapping over Scott's ointment. If the effusion is clear and painful, and it persists, aspiration with a wide-bore needle or small-sized trocar and cannula under strict antiseptic precautions may be employed.

The same treatment may be followed in dealing with chronic bursitis. For recurrent and troublesome bursitis the only satisfactory treatment is complete excision of the sac, making sure that the endothelial lining has been entirely removed. When a bursa, such as the semimembranosus bursa, communicates with a joint the neck leading to the joint should be closed by ligature. The incision should be planned so as not to leave the scar over the points of pressure. For example, in the removal of prepatellar bursa it should be made at the side of the bone.

Complications of Bursae and their Treatment

Subcutaneous injuries result in haemorrhage into the cavity of the bursa, constituting a haematoma, which may either suppurate or absorb, leaving the cavity full of adhesions from fibrinous deposits and polypoid fringes from the organization of blood clot. The skin over the bursa will be bruised and transillumination will be lost; the edges of the bursa will feel thickened, and fluctuation will only be obtained over the centre of the swelling. This part must be kept at rest and the skin be cleaned and sterilized. Threatened suppuration, as evidenced by throbbing pain, heat, and pitting on pressure from oedema, must be treated by prompt incision and drainage, and the wound left to heal by granulation tissue. In haematoma of the prepatellar or olecranon bursa it is advisable to make sure that there is no underlying fracture of the bone.

Wounds may be caused by splitting of the tissues over the bursa through a direct fall on the underlying bone, or by penetrating injuries from without. The result is the escape of bursal fluid, which may prevent adequate healing. This will necessitate removing the bursa entirely, or opening up the cavity freely, scraping out the lining tissue, and allowing it to heal by second intention.

Acute suppurative bursitis may originate in the above way, especially if the skin is allowed to heal over a small wound. More commonly this condition arises as the result of subcutaneous injury to a chronically inflamed bursa which becomes filled with blood clot. Pus forms and may track to the surface, or sepsis may become diffused into the tissues around it. There is swelling and induration round the bursa, and in these circumstances the original site of infection may be overlooked. It is important not to mistake this condition for an acute arthritis of a neighbouring joint, and to make an incision and provide drainage from the bursa as soon as possible. Neglect to do this may lead to infection into the joint or underlying bone, which may become carious and necrose.

Tuberculous bursitis occurs in two forms. There is either a fluid bursitis—characterized by the formation of melon-seed bodies, which can often be felt as a soft crepitus in the swelling—or the dry type, in which the lining membrane becomes transformed into a mass of tuberculous granulation tissue that may lead to the formation of a cold abscess. In those bursae which communicate with joints the infection will be common to both cavities. Secondary infection should be guarded against. Tuberculous disease most commonly attacks the subdeltoid, subgluteal, Achilles, and semimembranosus bursae. Treatment should follow the rules laid down for tuberculosis in general, with rest to the affected part in particular. Scott's strapping may be applied to the part, and any form of passive hyperaemia if it is practicable. Softening when it occurs is dealt with by aspiration, but if distension becomes excessive, incision, washing out the melon-seed bodies, bipping, and closing the cavity may be used: it is undesirable, however, that any extensive operative treatment should be performed. In burrowing bursae which become secondarily infected, such as the subgluteal, it may be necessary to open the area and scrape out the granulation tissue, pack with bipp, and allow it to heal from the bottom.

In *syphilis* a symmetrical bursitis with effusion may appear during the secondary stage, or, later, a gummatous infiltration of the bursa. The walls of the bursa become thick, presenting as a hard fibrous tumour with a small cavity in the centre. This variety occurs in the prepatellar or ischial bursa. In the secondary stage antisyphilitic remedies will clear up the condition, and may help in the gummatous condition, but the gummy material tends to break down with involvement of the skin, giving rise to sinuses. Under these conditions removal of the whole mass is necessary for cure.

Gouty deposits sometimes occur and often involve the olecranon bursa. They consist of chalky masses of biurate of soda, which can be seen under the skin. As a rule gouty bursitis calls for no local treatment, but the overlying skin tends to break down and the mass should be excised before infection takes place.

In *gonorrhoea* a sudden bursitis may occur as a septicaemic manifestation of that disease. It is uncommon, and treatment should be directed towards the cause of the condition.

OPHTHALMIC MALINGERING

BY

SYDNEY TIBBLES, L.R.C.P., L.R.C.S.Ed.

Formerly Honorary Eye Surgeon to the War Office, Central Recruiting Authorities, Ministry of Pensions, etc.

Claims for injuries to sight after motor accidents and injuries at work are frequent, and are generally referred to an eye surgeon for examination and report.

Having first heard the history and seen all relevant documents, make a note of any visible defects or injuries, judging their possible effects on the sight. A small nebula at the edge of the cornea can have little or no effect on the vision, whatever the claimant may say. Should he obviously be malingering, do not let him know he is suspected, as that only raises opposition on his side, while it is so easy to find out whether he can or cannot see. Examine the front parts of the eye through a loupe, using a good light and noting the pupillary reactions. Generally speaking, the older the patient the smaller the pupils; while short-sighted people have larger pupils than normal. It is the reverse with the long-sighted; the latter have more focusing to do. Excluding tabes, in which there is no direct reaction to light, if a light from a small torch is shone on a healthy eye the pupil contracts with that of the other eye. Should the eye be blind or partly so, there is no reaction in the former and very little in the latter case. Adhesions, too, may affect contraction of the pupil. Take the distant and near vision of each eye, then by means of retinoscopy the effect of any error of refraction can be settled.

Methods of Testing

Should the patient claim loss of sight in one eye, ask him to read small print, held a foot away, then hold a ruler a few inches from his eyes, between them and the print. If he reads without hesitation, he is doing so with both eyes. Next take a strong prism, say 16 degrees, holding it base up or down in front of his bad eye. Ask him to pick up a pin, a penny, or a pen and to write with the last. If he sees with both eyes, objects appear about three inches apart, and he has the utmost difficulty in doing these things, while his attempts to do so give him away at once. Care must be taken that both eyes are kept open.

In the Friend test letters alternately red and green are looked at through a red and a green lens. The red glass lets only red rays through and the green only green rays, so if he reads all the letters he sees with both eyes. If the refraction and other things appear normal but he only admits seeing the top letter at twenty feet, he should see the second row at half the distance, and other rows in proportion. Place a plus 3 lens in front of the good eye and a weak minus, say −0.25, which will make no appreciable difference to the sight, in front of the bad eye. If he reads the letters at the end of the room he is doing so with the bad eye, as the plus 3 will prevent a normal eye seeing more than the top letter. Any number of variations can be worked with lenses.

It is possible by retinoscopy to tell pretty well what a patient should see. Roughly one dioptre of short sight cuts vision down to a half, two dioptres to a quarter, and other amounts in proportion. By holding a plus 1, 2, or 3 in front of one's eye, if the refraction is normal, short sight to these degrees is produced, so that one can tell what these myopes see. Near at hand they see reading type up to their far point, which depends on the degree of short sight; minus 10 being able to read near type at four inches, minus 2 at twenty inches, and so on in proportion. If he is presbyopic one must calculate accordingly. Should we find minus 3 of short sight, a minus 3 lens should let this eye improve from a tenth to full vision. This is fairly easy with myopes, but as long-sighted people focus to overcome what they can of their defect, an amount which varies with their age and vitality, it is not quite so easy to tell what lens they require, as that needs the co-operation of the patient. At 20, if there is plus 3 of long sight, the eye may get normal distant vision, which as the accommodation fails may drop to a half at 40 and a tenth at 60 years of age, although an appropriate lens will give him normal sight again.

Some Personal Experiences

Examining hundreds of thousands of eyes at the Central Recruiting Office at Whitehall, I found that the bulk of the refractive errors were cases of long sight or long-sighted astigmatism, then came similar short-sighted conditions, and lastly cases of mixed astigmatism. In those days there were many malingerers, whereas nowadays the men are quite hurt if they are a little short-sighted and think they may be rejected. Many men had glasses that could be improved upon; others had certificates saying that they had all sorts of eye conditions. There were many cases of artificial conjunctivitis, tobacco ash, soap, and other irritants being used. When at Devonport I saw two men who had used somebody else's atropine ointment, which had a bad effect on their sight for a few days. Many aliens swore they had trachoma and produced certificates to that effect. Some had nothing more than a slight stippling of the conjunctiva, like blotting-paper seen through a strong lens. There were plenty of genuine cases in every stage which we rejected because of the contagiousness of trachoma.

On my return from the front a man consulted me, saying his doctor told him he had trachoma. On everting his lids it was evident they had been burned with probably lunar caustic stick. The authorities were informed at once, and he turned up a week later, at a board, escorted by the police as an absentee. He gave a different name and address, denied having seen me before, and as the lid condition was getting better he was marked as fit so far as the eyes were concerned, although he had a certificate from an eminent senior saying he had trachoma.

Night-blindness used to be a good excuse for missing duty. Lack of vitamins is a supposed factor, though it is a symptom of retinitis pigmentosa, which, with its gradually diminishing visual field, has fundus changes so characteristic that once seen they are never forgotten. Hysterical disturbances occur both in the forces and among civilians. The visual fields vary greatly; there is nothing abnormal to see in the eye, in this latter respect resembling toxic amblyopias, which are generally due to tobacco and alcohol. The latter, however, have a definite scotoma for red in the centre of the field, while the history of the case helps.

One young girl recently seen had a partly blind eye, because her father, having to return to South America, had put her in a convent, which she resented. As there was no doubt about the diagnosis, he was told she would get better if he went, and in a little over a week she saw properly again. Another girl quarrelled with her mother and would not see. She soon got better. In both cases only one eye was affected, and the visual fields varied greatly from day to day.

In 1915 somebody wrote to the Press in reply to a letter of mine, when in the Army, in which I deplored the fact that men were being "boarded" out of the Army when all they wanted was a pair of glasses. He suggested that ordering glasses for soldiers would produce a nation of troglodytes. Recently I saw four American sailors, two of whom were wearing glasses; this, of course, applies to men of every nation nowadays. Happier cases where the men could have escaped duty to their country come to mind. Just before the last war one saw me about his eyes, with glaucoma of both. They were operated on; he was at the front throughout the war, winning a D.S.O. and bar. Another highly short-sighted patient served throughout at the front without bad effect upon his eyes, and the same is true of many more seen at Pension Boards for other reasons.

LUNACY AND MENTAL DEFICIENCY

THE BOARD OF CONTROL'S REPORT

The annual report of the Board of Control[1]—the twenty-fifth—carries the story of mental hospitals and institutions for mental deficiency down only to the end of 1938. Since then many things have happened. The war emergency scheme provided for the total evacuation of four mental hospitals and the partial evacuation of one mental deficiency colony, while the remaining mental hospitals (with a few exceptions) and twenty selected mental deficiency institutions were to allocate for civilian casualties about one-quarter of their normal accommodation. The scheme which the Board of Control has had in hand, including the provision of certain additional beds at hutments to be erected in the grounds of a number of institutions, is designed to furnish 41,000 casualty beds for emergency use. The consequence has been the re-allocation and some, though not undue, crowding of the customary inmates. It is not inappropriate, perhaps, that war, the supreme lunacy, should have turned the mental hospitals inside out.

But the period covered by the present report was one of undisturbed progress. Overcrowding was somewhat reduced, the death rate in mental institutions fell, the increase in direct admissions was more than counterbalanced by the increase in absolute discharges and departures, and voluntary admissions as contrasted with admissions under certificate were on the upgrade. At the same time an aggregate deficiency in bed space of nearly 3,000 had to be acknowledged, and even at the beginning of the present year the war was casting its shadows before it and armament work was delaying new hospital construction. The building of proposed new hospitals for Essex and for Lancashire was not able to be started, a site provisionally selected for a mental hospital in Kent had to be abandoned, and although sites have been acquired for new hospitals in Surrey and in the West Riding, the buildings are not likely to be completed for a considerable time to come. There is therefore no prospect of any substantial increase in bed accommodation in the near future and overcrowding is likely to increase.

Out-patient Centres and Part-time Psychotherapists

An encouraging feature of the report is the steady increase in the number of out-patient centres. Such centres conducted by or in conjunction with staffs of mental hospitals now number 177, the number of patients presenting themselves for treatment last year exceeded 19,000, and the number of attendances 74,000. In addition, an unspecified number of out-patient centres are conducted independently of mental hospitals—at least twenty-five in connexion with other hospitals in the London area, and thirty-two in different parts of the country. Only three public mental hospitals in England have no such centres associated with them.

---

[1] *Twenty-fifth Annual Report of the Board of Control for the Year 1938.* Part I. H.M. Stationery Office. (1s. 6d. net.)

Concerning part-time psychotherapists, about which a good deal has been said, the Board notes with satisfaction that a medical psychotherapist engaged on a sessional basis has been added by the London County Council to the staff of one of its hospitals to deal with those patients who appear likely to benefit by psychotherapeutic treatment. Some doubt is expressed over the terms of the recommendation by the Mental Hospitals Committee to the Council, in which it was stated that it was preferable for psychological reasons that this form of treatment should be given by a practitioner who was not open, as a member of the whole-time staff might be, to the suggestion that he was responsible in some way for the patient's continued detention. The Board points out that this in any case could not apply to the voluntary patients, and it cannot agree that it correctly represents the attitude of the average patient to the whole-time medical staff. There may be patients to whom visiting doctors are more acceptable, but the argument must not be pressed too far, because if it were carried to its logical conclusion it would limit the whole-time staff to the care of the patient's physical condition, which would be absurd.

Voluntary Patients

The increasing proportion of voluntary patients is generally satisfactory, but there is still far too wide a margin between the more and the less progressive hospitals in this respect. The tendency to restrict voluntary admissions is not entirely to be explained by the fact of overcrowding, in which conditions those under certificate would have preference. In a previous report the Board estimated that when the Mental Treatment Act was in full operation admissions under certificate would not exceed one-third of the total. This forecast has already been realized in a few areas. The percentage of voluntary admissions last year at Swansea was 73, at Cardiff 72, at Croydon 71, and at Portsmouth 70. But at the other end of the scale there are seven hospitals where the proportion of voluntary admissions is under 15 per cent., and twenty-seven others where it is between 15 and 25 per cent.

Some medical men take the view that if a patient has to enter a mental hospital the fact of entry cannot be concealed and it is relatively unimportant to what legal category he belongs. It is true that the legal classification bears no relation to the medical. A voluntary patient is not necessarily a mild case, nor is a certified case necessarily more serious or likely to require a longer period of treatment. But it must not be assumed, says the Board, that the legal classification is unimportant. If the patient recovers it makes an enormous difference to his peace of mind that he can console himself with the thought that he has never been certified, and even if there is no recovery the avoidance of certification saves the relatives from distress. At the same time the subterfuges sometimes adopted with the kindest intention to treat on a voluntary basis patients who have no volition are deprecated.

Statistics of Mental Hospitals

The main body of the report as usual consists of statistics, most of which are routine, but some throw an interesting light on the subject. Of the 158,723 persons suffering from mental disorder and notified as under care in England and Wales at the beginning of the present year, 142,897 were rate-aided, 14,972 were private, and 854 were criminal (the number of patients in the Criminal Lunatic Asylum, Broadmoor, was 779—599 men and 180 women—but there were also 77 criminal patients in local authorities' institutions). Of the total number of mentally disordered patients, 133,827 were in institutions provided by local authorities, only 275 were in private single care, and 3,560 were on outdoor relief, the remainder being in registered hospitals, licensed houses, approved nursing homes, and public assistance institutions. Voluntary patients numbered 10,297, and temporary patients 630.

The death rate in mental hospitals was 6.57 per cent. of the average daily number resident, as compared with an average of 6.94 for the preceding quinquennium. Pneumonia and diseases of the myocardium were the principal causes of death. Violent deaths, including suicide, accounted for just under 1 per cent. The cases of infectious disease among patients numbered only 128, with five deaths. The tuberculosis prevalence was equivalent to 8.3 cases per thousand patients. Typhoid and paratyphoid fever accounted for 38 cases in twenty-two hospitals. The number of cases of dysentery (565) was higher than at any time during the last ten years. It is clearly established that the recent rise in incidence is due to a large increase in infection by the Sonne organism. It is known that during the last few years Sonne dysentery has become increasingly prevalent in the general community.

Treatment by Insulin and Cardiazol

A summary is given of the results obtained from a questionary circulated to the various hospitals on the results of treatment by insulin and cardiazol. The returns relate to 3,531 completed cases, almost equally divided between males and females. The treatment has been employed at ninety-two institutions as follows: insulin only, 3; cardiazol only, 61; insulin and cardiazol combined, 16; insulin and cardiazol not given together but at different times, 12. The results in those cases in which three or more months had elapsed since treatment ended can be best furnished in a table extracted from the fuller tables published in the report. By the term "complete remission" is meant that the patient was apparently well; by "incomplete remission," that he was fit for work but with one symptom left; and by "partial remission," that he was still fit for work but with several symptoms left.

	Cases which have left Hospital			Cases which have not left Hospital		
	Complete Remission	Incomplete Remission	Partial Remission	Ameliorated	Unchanged	Worse
Insulin ..	138	36	34	50	114	9
Cardiazol ..	542	134	152	594	1,220	110
Both ..	27	16	12	30	88	3

In 363 other cases treated details were not furnished or the cases did not fall under precise headings. Nineteen deaths occurred—namely, six patients who were under insulin treatment, ten under cardiazol, and three under both, a proportion of deaths to completed cases of 0.5 per cent. It is obvious that the matter does not lend itself to exact statistical statement, but there was some remission in about 31 per cent. of cases leaving hospital subsequently to treatment, and amelioration in just over 19 per cent. of those who were treated but did not improve enough to leave hospital. The clinical opinion with regard to triazol, which had only been tried in fewer than a hundred cases, was that it gave results broadly analogous to those obtained with cardiazol.

Mental Deficiency

Good progress was made last year in institutional accommodation for mental deficiency, and practically all the larger authorities in England now have a number of beds which at least meets their most pressing needs; similar progress in Wales cannot be reported. Occupation centres continue to increase in number, though not so rapidly as had been hoped. The warning is repeated that such centres should be regarded primarily as intended for tractable and ineducable lower-grade defectives living in good surroundings. Circumstances may sometimes compel the admission of higher-grade feeble-minded patients, but the result in mixture of grades adds greatly to the difficulties of organization and teaching. The question of training supervisors for occupation centres has not received the attention it deserves. The salaries offered by certain authorities, says the Board, "would hardly attract a charwoman." The occupation centre has proved its value and emerged from an experimental stage, and the Board feels that the time has come to establish some recognized training scheme for those who will be in charge of such centres.

The number of mentally defective persons in institutions and under statutory care in the community at the beginning of the present year was 89,904. Whereas there are fewer males than females subject to mental disorder (44.2 as compared with 55.8 per cent.), in mental deficiency the sex ratio is reversed, males accounting for 51.2 per cent. of the cases and females for 48.8 per cent. About 46,000 defectives were in institutions and homes provided under the Mental Deficiency Act and 39,000 were under statutory supervision. In only a few areas does the number of defectives who are in institutions or in ante-natal care closely approximate to the number ascertained as subject to be dealt with. In some areas large numbers of the ascertained persons still remain in receipt of poor relief, and in others, although there has been a large ascertainment, action has not been taken in many cases. In one Welsh county, for example, the proportion ascertained is 1.46 per thousand of the population, and the proportion dealt with only 0.23. On the other hand, in the county of London the proportion ascertained as subject to be dealt with is 2.83 per thousand, and the number in institutions or in other care is 2.80.

At twenty certified institutions provided by local authorities or combinations of authorities and at five certified institutions provided by other bodies resident medical superintendents had been appointed. There is a decrease in the number of persons on licence from institutions (3,107), due to the anti-social behaviour of certain defectives on licence, to which prominence was given in legal proceedings. The scrutiny which local authorities have consequently made has led to the recall to institutions of a number of defectives and to a revision of policy and methods which it is hoped will eventually help rather than hinder the development of licence on safe and progressive lines.

TRANSPORT OF MILITARY SICK AND WOUNDED

BRITISH AMBULANCE TRAINS AND BOATS

The Channel port which serves as the headquarters in England for the reception and distribution of military sick and wounded from the Expeditionary Force was visited a few days ago by representatives of the Press, who were afforded an opportunity of inspecting an ambulance train and boat. The railway companies have set aside a number of their trains for this purpose, and their staffs, working to Army specifications, have fitted them up as travelling hospitals. The equipment and supplies have been provided by the Army Medical Service.

The trains are painted dark green, with the Red Cross prominently displayed on the sides of each coach and on the white roofs. Each train consists of nine coaches, five of which have been transformed into wards. The first coach is reserved for the two medical officers and the two nursing sisters who are attached to each train. Four compartments have been made into bedrooms and two into messrooms. The second coach is for the twenty N.C.O.s and men who serve as nursing orderlies, stretcher-bearers, and kitchen staff. Bunks have been arranged in two tiers along one side of the coach, and on the other side tables for meals. The men are also allowed to use, for recreative purposes, the compartments reserved for officer sitting cases when these are not otherwise in use.

The third coach accommodates kitchen and stores. The kitchen is equipped with cooking range, a large sink with drying racks, and plentiful cupboards. In the fourth coach is an orderly room and a well-fitted dispensary with all the drugs and appliances likely to be needed in transit. The nursing sisters also have in their charge a store of medical comforts. In this same coach is the provision for officers who are sitting cases; they are given comfortable cushioned seats, and the tables have books, magazines, and ashtrays.

Four of the ward coaches are for men and one for officers. The officers' coach may be partitioned and a space reserved for sick nursing sisters if necessary. The beds in all the coaches have wire mattresses, and the metal sides are coated with aluminium paint. The thirty-six beds to each coach are arranged in tiers of three, and comfortably supplied with sheets, blankets, and pillows. They can be quickly converted to accommodate sitting cases, the middle tier being lowered on to the bottom tier so as to make quite a luxurious seat, while the upper tier still takes recumbent patients. At the end of each ward are cupboards, sinks, and lavatory accommodation, and in the middle of each coach is a drinking-water tank.

Stretchers are not carried into the wards. The patient is brought on the stretcher to the middle doors, and is then lifted out and carried to the bed by trained orderlies. Some of the orderlies belong to the St. John Ambulance Association and hold first-aid and home nursing certificates, and others are hospital orderlies who are carrying on their training during the waiting period. Two small padded compartments on each train are fitted for acute mental cases, but it is hoped there will be few or none of these. The trains are lit by electricity. Loading and unloading in the dark is carried out by the light of oil lamps. When the train is standing the staff compartments are heated by a coke boiler; when travelling, of course, the heat to the whole train is supplied from the engine.

Hospital Carrier Boats

In the harbour a hospital carrier was open for inspection. The hospital carriers are boats which have been used in peace time for the Channel and Irish Sea crossings. Each boat can take from 250 to 300 cases, or enough to fill two trains. The boats are white painted, with the Red Cross on the sides and funnel. Here again, as on the train, the ordinary furnishings and fixtures have been removed so that only a shell remains, and the state and other rooms have been converted into wards, giving the impression of a large open space with swinging cots. Each ward is self-contained under the charge of a hospital sister, who has R.A.M.C. orderlies to help her. Adequate provision of dressings and oxygen equipment is made in each ward. The first-class dining room has been turned into a ward for officers, but here, as also on the train, there is no distinction between the comfort afforded to officers and to men. The more serious cases are accommodated on the saloon deck, while the lower part of the boat has wards fitted for walking cases, so that the necessity for carrying stretchers up and down narrow stairways is avoided. The bar in the third-class saloon has been made into a dressing room where walking cases may have their wounds dressed and minor operations may be performed. Near each bed is a lifebelt, and all the sisters and orderlies are trained in A.R.P. and in the necessary duty in the event of fire, collision, sinking, or other disaster which may befall a ship. The hospital staff live on the boat, which has a galley for the service of meals, and on the boat, as on the train, patients are given a meal immediately on arrival on board.

At the Port

When the authorities at the port are notified that a boat is on its way across, the trains that are assigned for duty are got ready and the staff stand by. The patients on disembarking are taken into sheds, where the stretchers are placed on trestles and medical officers make a first examination, roughly dividing medical from surgical cases in order to facilitate work at the hospitals to which the cases will be distributed. Each man has an envelope containing a card with details of name, regiment, rank, nature of disability, and place of departure, and the record is completed with the destination. Patients who are very ill are not put on the train at all, but are sent to a local hospital where beds are reserved. During the port examination a benevolent lady, Miss Baxter, and her helpers have special permission and facilities for going among the men to distribute cups of tea, biscuits, and cigarettes.

Part of the warehouse accommodation at the port is in the hands of the Army authorities. This includes one large shed ordinarily occupied with merchandise and now stocked with linen of every description, drugs, and all kinds of supplies from which the boats and trains are provisioned. The average time taken from arrival of the boat to entrainment is an hour and a half. Three officers of the Army Medical Service, together with one Navy and one Air Force medical officer, receive the casualties at the port, apart from the two medical officers attached to each train. The majority of the officers engaged in this work have come from civil practice; some had retired from the Army Medical Service and have rejoined.

Up to the present the transport has been limited to sickness and accident cases; there have been no war wounded. We were informed that there had been no cases of pneumonia or of serious respiratory complaints. Most of the sickness cases are digestive disorders, and the accident cases are no more than would ordinarily occur in any large assemblage of men. The work done by all concerned in this enterprise—the railway and shipping authorities and the medical services—cannot be too highly praised. Every detail has had consideration, and every emergency seems to have been forestalled.

THE MAUDSLEY HOSPITAL AND ITS SUPERINTENDENT

[FROM A CORRESPONDENT]

The retirement on grounds of health of Professor Edward Mapother from the post of superintendent of the Maudsley Hospital recalls the offer made in 1907 by the late Dr. Henry Maudsley to give the whole of his hard-earned fortune in order to found a hospital that would meet certain special needs which his long and wide experience had taught him existed in the field of psychological medicine. The subject was, as it still is, complex, and hence how best to formulate a scheme to meet these needs was not easy. What exactly, when reduced to terms, were these special needs; what precisely were the facilities needed for treatment and research; where and under whose aegis should they be provided? Great clinical exponent though the would-be donor was, his thoughts upon the matter were confessedly inchoate; and in his retirement from active practice he welcomed talks with his friends upon the matter. In particular, he was glad to turn to Professor (later Sir Frederick) Mott, whose name, without in the least belittling the greatness of the donor's gesture, always will be linked with that of Maudsley.

Conditions of Maudsley's Gift

In the statement communicated to the London County Council on behalf of Dr. Maudsley by Sir Frederick Mott, among the suggested conditions of the gift were the following: that the hospital should be for early and acute cases only, that it should have an out-patient department, that it should be in a central position, that three-quarters of the beds should be for patients unable to pay full cost of maintenance, and that due provision should be made for clinical and pathological research. Expression, too, was given to the hope that the hospital, laboratory, and teaching side of the institute should be recognized as a School of the University of London for the study of mental disorders and neuropathology.

There followed the acceptance of the gift by the London County Council, and if the trust which it imposed was more moral than legal, the greater and more honourable is the degree to which it has been fulfilled and the more onerous has been the task which fell on those charged with evolving the development of the scheme, especially the superintendent.

"The Maudsley," 1914-23

Immediately upon the completion of the building came the war of 1914-18 and the temporary use of the hospital first as part of the 4th London Territorial General Hospital and then by the Ministry of Pensions. To the donor this interim use was a period of deep disappointment, accentuated doubtless by his advanced age. He found it hard to believe the assurances of his friends that the work which the hospital (to which his name already had been given) was performing on behalf of shell-shocked soldiers and later for pensioners was, besides its intrinsic worth and the lessons it was teaching, of signal value in helping to pave the way for changes in the law so as to enable persons suffering from nervous and mental illness to secure treatment in the earliest stages.

At last came in 1923 the use of the hospital—aided by the Central Laboratory which, moved from Claybury, had been erected jointly with it—by its owners, the London County Council, and on lines in the main as outlined by its donor. Some four years before his death he had agreed to certain changes in the conditions of his gift: changes the need for which had been felt all the more clearly in the course of the hospital's use by soldier patients; notably the need to legalize the reception of patients on a voluntary footing, for which purpose legislation had been secured by the Council in its General Powers Act of 1915.

Captain Mapother, as he then was, had been serving in France and Mesopotamia; and, besides having been officer-in-charge of the neurological section in the 2nd Western General Hospital, had been acting as superintendent during its occupancy of the Maudsley by the Ministry of Pensions, and was an active member of the team of postgraduate lecturers for the course established there in 1920 for the Diploma in Psychological Medicine. In the mental hospitals service he had reached the position of deputy superintendent at Long-Grove, the medical staff of which he had joined fourteen years previously during the period of that hospital's opening and development. With this wide background of experience his appointment by the London County Council as superintendent of the Maudsley Hospital seemed a certainty. It was shortly afterwards, consequent upon Sir Frederick Mott's retirement, that Dr. (now Professor) Golla was appointed director of laboratory and pathologist to the London County Mental Hospitals.

The Past Sixteen Years

Since that date and for the past sixteen years Dr. Mapother has provided in himself an example of enthusiastic devotion to a chargeship and to an ideal, coupled with a prodigious output of energy. This ideal has been the elimination from the patient's feelings of any notion of constraint or coercion about the treatment or that it is being applied compulsorily, and especially of any feeling of active detention. There are, and always will be, cases in which certification and detention are unavoidable; and those whose experience is greatest know, too, that there even are cases in which such procedure is of itself so beneficial as to rank it as part of treatment. Apart from the latter cases—and they are but few—the reality of the ideal is unquestionable; and, in dealing with mental disorder, it is now a truism that when treatment is carried out either with free consent or upon the patient's own voluntary application, and in an atmosphere of co-operation, in a large proportion of cases the chances of recovery are altogether better, and the chances also of getting patients in an early stage of their illness are likewise much greater. It is on these lines that "The Maudsley," the name by which the hospital is familiarly known, has been developed. It is in fact the only hospital in the country provided by a local authority under the Mental Treatment Act for voluntary patients alone.

Teaching has gone hand in hand with all Professor Mapother's clinical and administrative work, both at the Maudsley and as physician and lecturer in psychological medicine at King's College Hospital as well as the Maida Vale Hospital for Paralysis. His own position and that which the Maudsley Hospital occupies in the field of medicine have been recognized by the University of London in its appointment of him as the first occupant of the chair of psychiatry. Now, owing to the outbreak of war, he has to witness the dispersal of the fruits of his efforts at the moment of their culmination. Some of the essentials of the work will still be in operation, however, and the component parts of the institute can be reassembled with ease upon foundations well and truly laid.

REPORT ON THE CONDITION OF POLISH REFUGEES IN RUMANIA AND HUNGARY

BY

RICHARD W. B. ELLIS, M.D., F.R.C.P.

Assistant Physician for Children's Diseases, Guy's Hospital; Physician, the Infants Hospital, Vincent Square, London

DERMOD O'DONOVAN

AND

FRANCESCA M. WILSON

The following report is based on an investigation of refugee conditions carried out under the auspices of the Society of Friends and the Polish Relief Fund between October 17 and November 3. During this time some twenty-three military camps and civilian centres were inspected in Rumania and Hungary. The fullest co-operation was given by the civil and military authorities in both countries in the inspection of records and accommodation, and in permission to talk freely with Polish soldiers and civilians.

Exact figures regarding the total numbers and classification of refugees are not yet available owing to registration being incomplete, the uncontrolled movement of civilians, and the entrance of stragglers over the Russian frontier, which still continues. There appear, however, to be 30,000 to 35,000 in Rumania, of which 10,000 are civilians; 48,000 to 50,000 in Hungary, of which again some 10,000 are civilians. Women and young children form less than a fifth of the civilians, and there are very few young children without at least one parent. There are, however, some six hundred or more Polish boy scouts and other boys of from 12 to 18 who came over with the army; many of these have in Hungary been interned with the soldiers. There are also several hundred students in both countries. About half the male civilians are "functionaries"—postmen, police, civil servants, etc.—who were evacuated by the Polish Government. Only a small number of peasants appear to have crossed the frontier.

In both Rumania and Hungary we were continually impressed by the obvious desire of the authorities to do their best for the refugees, but it was equally clear that circumstances made the immediate provision of adequate accommodation and equipment completely impossible. Thus Rumania, with nearly a million men mobilized and a new class to be called this month, was short of bedding, clothing, and barracks even for her own army, while Hungary was still in the process of absorbing some thousands of her own refugees from Transylvania, and was finding the sudden influx of 50,000 Poles an almost intolerable strain on public funds. Food was in both countries available in adequate amount, but there was no question that all amenities, and in fact many necessities such as clothing and bedding, would have to be provided by outside agencies.

Refugees in Rumania

Almost all the refugees at present in Rumania, together with many other civilians with private means who have since left the country, crossed the northern frontier within forty-eight hours in the third week in September. Although the authorities were expecting a large influx, and had sent twenty-five army trains fitted with bathing and disinfecting facilities to the frontier, the numbers were so overwhelming that all attempts at orderly delousing, registration, and distribution completely broke down. The civilians found their way, largely haphazard, to Bucarest or villages throughout the country, where they were taken in by the peasants, who showed them the utmost generosity. The soldiers were disarmed and interned, according to international law, large numbers being sent to Tulcea and Babadag in the Dobrudja. This had the advantage of concentrating them in a militarily "empty" zone well away from the northern frontier, but as the Dobrudja is a marshy and highly malarious region it has resulted in a considerable amount of infection.

The Government is now allowing 100 lei a day for each civilian adult (50 lei for a child), which with the low cost of living is adequate to provide for food and lodging. In order to draw it, however, the civilians must register and remain in one of thirty-six provincial centres outside Bucarest and away from the northern frontier. Those we visited appeared to be reasonably well provided with board and lodging, but hardly any had more than the summer clothes they came away in. There is a hope that 3,000 or 4,000 of the technicians may be found work in Turkey or elsewhere, but there is little prospect of employment for the clerks and civil servants. The future of 1,200 Jewish civilians is particularly precarious, owing to recent anti-semitic legislation. Only 200 can at present obtain permits for Palestine.

The soldiers are interned with their officers in twenty-one camps in Wallachia, accommodated in old army barracks in much the same conditions, except as regards liberty and occupation, as the Rumanian soldiers. Most of the larger camps we visited were fitted with sufficient showers to give the men one bath a week, though the water supply was not always adequate and it was not clear how fully the men availed themselves of the facilities. At Targu Jiu, Polish soldiers were at work on the construction of new barracks to house 12,000 of them, the intention being to concentrate the remainder in a second new camp at Targovisti. The existing barracks were for the most part cold, ill-lighted, and overcrowded, with inadequate sanitation and a sea of mud stretching between the buildings.

Clothing and Bedding.—In every camp there was a desperate shortage of clothing, shoes, blankets, and palliasses. Relatively few of the men had overcoats, and hardly any a change of underclothes. Many had only linen summer uniforms, although the weather was already becoming bitterly cold and wet. Time after time men stripped off their uniforms to show us the filthy, ragged, and verminous shirts they had worn night and day for six weeks. Shoes were wearing out, and in only one camp we saw tools and leather for repairing them. In some cases the men had separate beds, but in many they were sleeping on loose straw. Almost universally they complained of lice, for even with regular bathing it was impossible to keep free without changing and disinfecting clothing.

Health.—The civilians and the majority of the soldiers looked well fed and in good physical condition. An increasing number of respiratory infections, however, are occurring with the onset of the cold weather, and though medical attention is available there are practically no facilities for nursing, special care, or isolation within the camps themselves. (A Polish medical orderly told us there was no thermometer between two battalions.) The more serious cases (there have been few of these) are removed to hospital.

Malaria.—This is so common in many parts of Rumania, and so many of the Rumanians have had the aestivo-autumnal type, that it is not there regarded as a serious disease. The Poles, being infected in nearly all cases for the first time, however, were suffering considerably, particularly as adequate amounts of quinine were not always available in individual camps, although there is yet no shortage of quinine preparations in the country as a whole. In one camp of a thousand men the Rumanian doctor told me he was seeing four new cases of malaria a day, confirmed by blood examination, although fortunately the season was nearly at an end.

Typhus.—This is undoubtedly the chief epidemic danger in Rumania this winter. The classical exanthematic type is endemic in Bessarabia and parts of Poland, and was responsible for an enormous mortality in Rumania during the last war. In view of the extent of the Rumanian mobilization it was regarded as a serious possibility even before the Polish soldiers were added to the number. Immunization has not been found effective against this type in Bessarabia, and its prevention appears therefore largely to resolve itself into the prompt provision of clothing and bedding, with the consequent possibility of effective delousing. So far no case has occurred.

Typhoid and Dysentery.—Extensive typhoid inoculations are being carried out both in the Rumanian army and among the Polish refugees. There are at present sufficient quantities of vaccine in the country. No case of true dysentery has occurred so far, one outbreak of gastro-enteritis in camp in the Dobrudja having been traced to the soldiers having eaten large quantities of unwashed grapes which had been sprayed with copper sulphate.

Refugees in Hungary

As in the case of the refugees entering Rumania, the main influx into Hungary happened during the third week of September, though extending over about four days. There was, however, considerable difference in the way they were distributed. Thus in order that the Polish army should not appear to be kept as military units the great majority of the officers were separated from the men and billeted together, being allowed much greater freedom. The men were also paid two filler a day, though this had to provide for certain necessities such as soap. (In Rumania the soldiers, as opposed to the officers, had no money whatever.) The soldiers were for the most part interned in barracks, but some were in derelict factories and other disused buildings. Many of the civilians were billeted privately, but many more were in separate camps, and there were even a number of women and children in some of the military camps. Among the more unfortunate were several hundred scouts and boys of scout age who were living as, and with, soldiers under particularly brutalizing conditions. The urgency of removing civilians from the military camps was, however, fully realized by the Government, and they were being withdrawn as fast as alternative accommodation could be found. It was planned to have one large camp for the women with young children, and a separate scout camp had already been started with the aid of the Hungarian scouts which would accommodate 250 boys at Somloszöllös.

In the case of both the civilians and the military, we were particularly struck with the great difference that existed between the best and the worst refugee conditions. Thus a civilian camp at Helemba was housed in what had been a newly built Czech barrack subsequently converted into a holiday home, and was admirable as regards cleanliness and equipment, although the invariable shortage of personal clothing existed. We later saw a military camp housed in a derelict vinegar factory in which 500 men were in almost complete darkness in a warehouse below ground level, sleeping on a concrete floor covered with loose straw. In another part of the same building were a number of women and children, six families inhabiting a room twenty-four feet square.

Health.—The health of the refugees in Hungary appeared better than of those in Rumania, largely owing to the absence of malaria. Similar cases of respiratory infection were occurring. In the military hospital at Kamaron, which served camps containing over 5,000 Poles, we found only a comparatively small number of sick, all minor ailments with the exception of three cases of pneumonia and six men recovering from air raid injuries. The danger of typhus, though it cannot be altogether excluded, appears much less than in Rumania, the only cases in Hungary of recent years having been traceable to nomad gipsies coming over the Rumanian border. The same difficulties with regard to vermin infestation owing to lack of clothing apply as in Rumania, though probably more of the civilians became verminous in Rumania while staying in peasant cottages.

The Morale of the Refugees

If the lot of the civilian refugee is wretched, that of an interned army with no country to return to is still more hopeless. Almost more than the material discomfort of the cold and lice, the men felt the forlorn misery of being cut off from the outside world, among strangers, however friendly these might be. A few letters were coming through from the German occupied territory, either direct or through the International Red Cross, but none from the Russian side, and there was hardly a man without constant anxiety for family or friends. Many indeed did not even know whether their wives and children were in Germany or Russia or Rumania or Hungary, and some families were even divided between the four countries.

Although sharing many of the same anxieties as the soldiers, the civilians were on the whole less dispirited, largely on account of their greater freedom and the knowledge that they could go elsewhere if opportunity arose. There were more signs of enterprise among them, some trying to find employment locally or abroad, others to make their circumstances more homelike. Thus in Ploesti, where a thousand civilians were concentrated, the president of the civilian Polish committee had drawn up plans for starting both an elementary and a commercial school, had selected the staff and curriculum, and worked out the minimum cost for essential equipment. We felt that there would be an immediate response if workshops, etc., could be established in civilian centres.

Among the military refugees there appeared to be a strikingly different spirit in different camps, which was by no means wholly dependent on material circumstances. That in which the men were clearly most contented was one which was fortunate in having both a Rumanian and a Polish colonel of exceptional qualities, but, though there was obviously thoughtfulness for the men and a general atmosphere of cleanliness and order, the basic provisions of the camp were little different from that in which the spirit was worst. Generally speaking, the men appeared dazed and apathetic, with a general sense of grievance for the march of events and their own miserable circumstances, which was apt to be visited irrationally on either their own or their foreign officers, and tended to make them uncooperative even in improving their own conditions. They were in no mood to appreciate the real sacrifices which the Rumanians and Hungarians were making to support them, and it was sad to see signs here and there that the initial friendliness with which their care had been undertaken was beginning to give way to exasperation.

In spite of such signs, however, we were repeatedly impressed by the sympathy and understanding of the Rumanian and Hungarian commandants of the various camps. The colonel in charge of five camps at Kamaron said that he felt that many of the more troublesome men were in a state of war neurosis, and that the sudden disaster within a few weeks of their being mobilized had left them with none of the *esprit de corps* and discipline developed during a long campaign. He added that, next to blankets and underclothes, footballs, equipment for workshops, and school books were the first essentials.

Relief Organizations

A number of relief organizations are already at work in both countries, and in Hungary, where much is deputed to them by the Government, a co-ordinating committee has been set up consisting of representatives of the Hungarian Red Cross, the Polish Government, the Hungarian-Polish Society (a very active organization which has been largely responsible for the billeting of civilians), and the American Commission for Polish Relief. The last operates also in Rumania, in close association with the Y.M.C.A. and Y.W.C.A., and is planning the large-scale establishment of "foyers" in the camps of both countries, to act as local centres for relief activities. The Save the Children Fund also has active representatives in Bucarest and Budapest. Other organizations such as the OSE are concentrating on special aspects of the refugee problem (for example, the fate of Jewish refugees), and much is being done by private individuals in both countries. The activities of the organizations not receiving funds from abroad are necessarily restricted.

Conclusions

1. An urgent need exists in both countries for warm clothing of all kinds, and particularly for underclothing, overcoats, blankets, shoes, and material for mattress covers. It is unlikely that any large quantity of these will be obtainable in Rumania owing to the requirements of the Rumanian army. (Sheep-skin coats, which can be obtained very cheaply in Rumania, are unfortunately too difficult to disinfect for their use to be justified.) In Hungary at least some of these requirements can be obtained within the country at rates that would make their shipment from abroad inadvisable (for example, shoes and some proportion of the blankets, overcoats, and underclothing).

2. It is most desirable that in both countries the existing facilities for regular bathing and for the disinfection of clothing of refugees should be extended as rapidly as possible. Where straw is not always immediately available, sufficient stocks should be kept to provide for the frequent changing and burning of infected straw from sleeping quarters.

3. There appears to be no immediate shortage of either drugs or vaccines, but a shortage is likely to occur if the refugee position remains unchanged. Quinine preparations in Rumania and disinfectants and soap in both countries are those of which there is most likely to be a dearth.

4. The desirability of equipping workshops and schools and concentrating older boys and students where they can continue their education is almost as great as providing physical necessities. A few textbooks in Polish (for example, for learning Rumanian and Hungarian) could be printed locally if money were available, and would be of the greatest value.

5. In view of there being many highly trained Poles and Polish-speaking Rumanians or Hungarians in both countries, it does not seem advisable to send out any extensive personnel from this country at the present time.

We wish to express our sincerest thanks for their help to the civil and military authorities and to the Red Cross in Rumania and Hungary; to the British Legation and Polish Embassy in Bucarest, and the British and Polish Legations in Budapest; to Professor Cambiescu, Professor Ciuca, and Dr. B. Johan; to Princess Caragea and Mlle Vajkai of the Save the Children Fund; to Mr. Paul Super and Mr. James Brown of the American Commission for Polish Relief; to Countess Romer of the Polish Society in Rumania; and to Princess Odescalchi-Andracsy and Countess Erzsèbet Szápáry of the Hungarian-Polish Society.

Local News

INDIA

The Campaign against Leprosy

The sixty-third annual report of the Mission to Lepers appears with the title "The Inherent Promise" and relates to the work accomplished all over the world, and especially in India, which country has always been one of the most cultivated fields of this interdenominational and international organization. It is announced that a record number of lepers is now being helped, and special progress is noted in the report in respect of the intensive treatment of the disease in young children, where the benefit is more obvious. This extension of the programme of the organization has been especially pushed in India, where also progress has been made in the care and treatment of infected children on a larger scale and to the colonization of young people from the leper homes in which infection has been prevented; provision has been made in the Central Provinces for such children and for arrested cases in which there is now a reasonable hope of no recrudescence of the disease. The provision of the new home for lepers in Fyzabad in the United Provinces was rendered possible largely by subscriptions raised locally for that specific purpose, and a co-ordinated scheme of treatment, including colonization possibilities, is now coming into being. The Chandkuri Leper Home in the Central Provinces, which celebrated its fortieth anniversary last year, has treated some five thousand lepers, and seven hundred healthy children of leper parentage have taken their place in the healthy community. The report expresses the view that hydnocarpus oil and its esters administered intramuscularly, subcutaneously, and intradermally remain the most valuable therapeutic agents. For improving and maintaining the general health of these patients the diet must be liberal, well balanced, and rich in vitamins. Occupational therapy is highly esteemed, and it is important to eliminate intercurrent diseases. This emphasis on nutrition, which, it is remarked, has sometimes been ignored with unfortunate results, dates from the beginning of the campaign against leprosy; without an adequate diet drug therapy nearly always fails to be of much value. The report contains a reference to a case of one leper home in which the patients denied themselves meat and sugar for one month in the absence of the missionary so that the considerable amount of money thus raised might go to the famine-stricken Bhils in the Indore district. Similar forms of practical gratitude shown by leper patients are not uncommon elsewhere in India, and the popularity of the campaign is growing steadily.

Obstetrics in India

The second All-India Obstetric and Gynaecological Congress, held in Bombay last year, was attended by delegates and visitors from more than fifty different localities. The proceedings have now been published. In his address of welcome Sir Mangaldas Mehta traced the origin and growth of maternity work in Bombay. The first maternity home, containing twenty beds, was opened in 1849. To-day there are eighty-three public and charitable institutions and nursing homes with a total of 1,308 beds. Of 37,795 births registered in the city during 1937, 27,758, or 73.4 per cent., took place in maternity institutions. For the same year the maternal death rate was 4.4 per 1,000, while the infant death rate had diminished by nearly a quarter from the rate of 1920, when only 20 per cent. of women were confined in maternity institutions. In his presidential address Dr. B. D. Mukherji of Calcutta, reviewing general conditions throughout the country, deplored the ignorance and superstition of the average Indian mother and the abject poverty of the masses. In most of the Indian villages the only medical help available for the mother is that of the untrained midwife or "dhai." Dr. Mukherji also maintained that even in urban areas the position was far from satisfactory, owing to the dearth of obstetric specialists in the smaller towns. Unless employed in Government service these men were obliged to congregate in large cities, such as Calcutta, Madras, or Bombay, in order to obtain adequate opportunity for remunerative work. Dr. Mukherji advocated the establishment of rural maternity centres, affiliated to special hospitals in the district and subdivisional towns; also the provision of mobile dispensaries for obstetric and gynaecological work in rural areas. The congress devoted its attention chiefly to the questions of the toxaemias of pregnancy and carcinoma of the cervix. Among other papers read that of Dr. D. M. Satur on post-puerperal neuritis appears to be of considerable interest. Dr. Satur's patients, drawn from an impoverished community in the Andhra district, near Vizagapatam, lived on a diet consisting chiefly of polished rice. The lack of essential food factors was further accentuated by a restriction of the diet during the latter half of pregnancy and a period of three months after delivery. The neuritis, bearing some resemblance to beriberi, though showing definite points of dissimilarity, was of a severe type in many of the cases. A prolonged course of treatment invariably resulted in complete recovery. Dr. Satur supplied the missing vitamin B_1 factor by a diet of bread-and-milk, spinach, tomatoes, and oranges, together with a handful of germinating green gram and half an ounce of yeast daily. Severe cases also received a course of ten injections of betaxin.

ENGLAND AND WALES

Tuberculosis in Lancashire

The principles of the Lancashire County Council's tuberculosis scheme bear repetition because, in spite of their admitted excellence, they have not been adopted by other authorities as widely as they deserve. The scheme caters for a population of nearly two millions, and its essential features are: (1) combination of dispensary with hospital and sanatorium work; and (2) supervision by a central tuberculosis officer who is directly responsible to a special county tuberculosis committee. The administrative county is divided into five large areas (average population 328,000) and three small areas. A consultant tuberculosis officer is in charge of each large area, and to help him there are two assistant tuberculosis officers, four to seven tuberculosis health visitors, and a clerical staff of two. In each area there is a chief dispensary, at which is co-ordinated all the work required in that particular area, and two or more branch dispensaries, and also a sanatorium hospital containing up to fifty-seven beds, to which the consultant tuberculosis officer acts as visiting medical superintendent. The three small dispensary areas, on the other hand, are each under the charge of the medical superintendent of the three larger Lancashire tuberculosis institutions. Each has one dispensary with one or more health visitors, the clerical work being done in the office of the institution. The report for 1938 of Dr. Lissant Cox, Lancashire County Council's central tuberculosis officer, maintains the usual high standard of these reports. The death rate from tuberculosis, which had remained at the same level since 1935, fell appreciably during 1938 to 0.52 per 1,000 of population. A comparative table of new cases of pulmonary tuberculosis notified in 1938 and pulmonary notifications in 1920 shows that whereas in males the percentage reduction in the age period 15 to 25 is 42.5, in females it is only 19.4. Dr. Cox's remarks concerning non-notified cases of the disease should be brought to the notice of all those responsible for tuberculosis administration. He states: "The efficiency of notification in England varies directly with the efficiency of the county council or county borough scheme dealing with tuberculosis. If there is no really comprehensive scheme, if there are poor and newly qualified, part-time, and badly paid tuberculosis officers, if there are insufficient means for expert diagnosis and too few beds for treatment, then a high proportion of non-notified fatal cases will be the rule and not the exception." Of the 1,096 contacts examined during the year thirty-one were diagnosed as tuberculous; this is equivalent to 28.8 per 1,000 contacts examined, as against a proportion of 3.98 tuberculous persons per 1,000 of the population known to the dispensary staff in the county. Dr. Leggat, medical superintendent of the High Carley Sanatorium, gives the following figures, which are perhaps the only ones in this country, comparable with those given by Alexander, on which the benefits of extensive use of collapse therapy can be judged. In the five-year period 1925–9 1,352 patients were admitted, of whom twenty-two had artificial pneumothorax, and the bacillary loss was 19.5 per cent. In the five-year period 1934–8 914 patients were admitted, of whom 243 had artificial pneumothorax, 184 phrenic interruption, seventy division of adhesions, thirty-three thoracoplasty, and five extrapleural pneumothorax; the bacillary loss was 51 per cent.

Treatment of War Wounds in China

SIR,—My experiences of war surgery in China do not altogether support the amazing claims made by Dr. Trueta for the "closed" method of treatment of gunshot wounds. Before the present Sino-Japanese conflict several civil wars together with the activities of bandits over a number of years had supplied us with a steady stream of gunshot wounds with fractures of the long bones, and for many of these we used Winnett Orr's treatment. Probably most of our hospitals in China used all three methods—namely, the "closed" method, the "open-window" method, and skeletal traction on Thomas splints. Since the outbreak of hostilities, over two years ago, our experience has been greatly increased by large numbers of bomb and shell wounds.

It needs to be said that our casualties were usually seen after considerable delay and sometimes even days or weeks had elapsed; the patient's condition was strained by difficulties of transport on a primitive litter over tracks that can only euphemistically be called roads; the first-aid measures which had been applied were of the worst, usually definitely harmful and invariably produced a grossly infected wound. Shrapnel from air raids and shelling often produced frightful wounds with severe mutilation of the soft tissues. Tetanus was not uncommon, but we saw very few cases of gas gangrene. Infection of the deep fascial and muscular planes was a frequent complication of the wounds, so that it was impossible entirely to eliminate the danger of burrowing channels of suppuration by the most radical excision.

We therefore formed the conclusion that compound fractures from gunshot wounds (or shrapnel) were best treated by skeletal traction and Thomas splints. Adequate control of the fragments can be ensured, facilities for the most satisfactory drainage can be provided, the comfort of the patient, without excessive smell, is assured—and these contribute to the surgeon's peace of mind. This particularly applies to fractures of the femur, with possibly infected wounds, which formed a large proportion of our cases. Further, we abandoned Carrel-Dakin irrigation in all save the foulest wounds and considered most satisfactory the use of vaseline gauze packs, changed every ten days or so. The dry gauze pack suggested by Dr. Trueta dams back pus, is painful for the patient when the dressing is changed, and tears away newly forming granulations. Loosely packed vaseline gauze has none of these disadvantages.

Careful selection of cases for the various forms of treatment seems to be necessary. I would suggest that:

(*a*) When casualties are received early (up to six hours) and adequate débridement with reasonable hope of eliminating infection can be effected, the "closed" method is probably the treatment of choice, particularly for comfort during transport.

(*b*) For casualties received later (six to twenty-four hours) in which the damage to soft tissues is only moderately severe, after excision these can best be treated by the "open-window" method. The window of plaster can be reinserted, well padded, after each change of dressing, and if tightly bandaged one does not get overgrowth of granulation tissue.

(*c*) For grossly mutilated wounds or delayed casualties, in which certain elimination of all infective channels is doubtful, the open method, skeletal traction, and Thomas splints should be relied on.

To give a true balance it is necessary to add that no group of our cases treated by these different methods produced results comparable with those obtained by Dr. Trueta.—I am, etc.,

Superintendent, Foster Hospital, Chouts'un,
Shantung, N. China.

Knaresborough, Yorks, Nov. 7.

Treatment of Gas Gangrene

SIR,—I was glad to see the letter by Mr. W. A. Cochrane in your issue of November 11 (p. 973) drawing attention to the fact that gas gangrene is often diagnosed too late. During 1914–18 I was radiologist in the Scottish Women's Hospital, Royaumont, France, where we soon learned the necessity for prompt diagnosis of the presence of gas. As we were only twenty-five miles behind the line many of the wounded reached us within a few hours of being wounded, having been taken off the train (half-way to Paris, at Creil) and brought to us twelve kilometres by ambulance. No matter at what hour of the day or night they arrived, the wounds were at once examined and the men sent to the *x*-ray room. Plates were taken and rapidly developed. When gas was found I sent an urgent note to our *médecin-chef,* Miss Frances Ivens. The patients with gas took precedence and were promptly operated on. *X*-ray plates showed distinct types of gas infiltration—(1) a mist, and full of "bubbles"; (2) streaks as of gas penetrating between the muscle fibres. This second type was the most dangerous and necessitated swift intervention. A few hours' delay made the prognosis much more serious. Dr. Weinberg was at that date working on the preparation of the serum which has since received wide recognition.

In the *Archives of Radiology and Electrotherapy* of December, 1916, I published several illustrations of these two types. The plates were also shown at the meeting of the Royal Society of Medicine Electrotherapeutic Section and published in the *Proceedings* of October, 1916. Other plates were published in Miss Ivens's address to the Surgical Section, December, 1916.—I am, etc.,

London, W.1, Nov. 11. AGNES SAVILL.

Treatment of Venereal Disease in the Field

SIR,—Lieutenant-Colonel E. T. Burke's letter in the *Journal* of November 4 (p. 928) is well timed and raises issues of the greatest importance. The wastage of man-power due to venereal disease in the 1914–18 war was emphasized in striking fashion by Sir Archdall Reid when he wrote (recommending methods of prevention), "At that time [spring, 1918] there were, but need not have been, in the venereal hospitals or in depots as convalescents British, French, and American soldiers, mature and trained men, otherwise fit for active service, sufficient not for an army corps only, but for a great army" (*Prevention of Venereal Disease,* 1920).

We are in complete agreement with the main idea underlying Lieutenant-Colonel Burke's valuable communication—namely, that the vast majority of cases of recently acquired syphilis and gonorrhoea can be adequately treated without removal from the divisional area and without complete loss of the man's services. In connexion with the treatment of early syphilis Lieutenant-Colonel Burke, "though not normally an advocate of the concurrent intermittent method of therapy," is "of the opinion that in the special circumstances—treatment in the field—that method should be adopted." As this concurrent intermittent treatment is the method which has been used successfully in the Edinburgh V.D. Clinic for the last twenty years, the following comments have the backing of an extensive experience. This has convinced us that the concurrent administration of arsenic and bismuth from the beginning of treatment affords the most intensive attack on *T. pallidum.* We aim at giving this dual therapy in such a way that the patient is rapidly rendered non-contagious and is not prevented from carrying on his ordinary civilian occupation, or even handicapped in doing so, or deprived of leisure time by frequent attendances.

Does not the weekly administration of 1 gramme of arsphenamine (? arsphenamine diglucoside) represent an ideal rather than a practicable proposition? We find that many patients will not tolerate more than 0.6 gramme "914" weekly, and, provided that bismuth is given concurrently, higher weekly dosage is not required. Three intravenous plus two intramuscular injections per week for eight successive weeks would occupy an unnecessarily large amount of the time of the soldiers and also the medical officers.

We recommend the following scheme as more practicable than that advocated by Lieutenant-Colonel Burke in that it encroaches less on the soldiers' time, and, if carried through, ensures a prospect of cure if not in 100 per cent. of cases at least in 99 per cent. The relapse rate in 675 male cases of early syphilis treated in the Edinburgh clinic was 0.9 per cent.

First or Unit Course

Week	Neoarsphenamine ("914") intravenously gramme	Bismuth intramuscularly gramme
1	0.3 0.45	0.2
2	0.3 0.3	0.3
3	0.6	0.3
4	0.6	0.3
5	0.6	0.3
6	0.6	0.3
7	0.6	0.3
8	0.6	0.3
9	0.6	0.3
10	0.6	0.3
Total	6.15	2.9

This unit course is followed by an interval of four weeks, and four unit courses are given provided the blood Wassermann (if positive at the start) be reversed by the first course. Completion of the active treatment is followed by three-monthly serological tests (blood Wassermann and Kahn) for two years. Provided bismuth is given from the start, it is, in our opinion, unnecessary after the first fortnight to give either the "914" or the bismuth more often than once weekly. Also, if the "914" is given twice weekly in the first week or fortnight it is sufficient to give the slowly absorbed bismuth metal once weekly. We prefer injectio bismuthi *B.P.* to the oil-soluble preparations; with the former, once-weekly administration means less stiffness and less pain in the hip muscles. Moreover, the gap in the administration of the arsenical drug is reduced (in our scheme) from seven weeks to the safe interval of four weeks. For those physicians who wish to use neoarsphenamine instead of stabilarsan, ampoules of sterile distilled water could be made just as readily available as those of sodium thiosulphate.

The plan of treatment outlined above, as contrasted with Lieutenant-Colonel Burke's, effects a saving in time and expense, with possibly greater efficiency through greater practicability. The adoption of this scheme would mean that after the first fortnight (during which "sores" are healed and non-infectivity secured) the soldier is available for full duty except for a once-weekly visit to the divisional treatment unit. Diagnosis and treatment would be facilitated and economy effected if the unit were a mobile one housed in a specially equipped ambulance car.

The routine to be followed in cases of gonorrhoea would be simplified without loss of efficiency by omitting irrigation during the first five days of chemotherapy. In cases in which the discharge persists, use irrigation of the anterior urethra for five days with a 1 in 10,000 solution of potassium permanganate, followed by five days of posterior irrigation with the same solution. Cases which resist this regime should be evacuated to a base hospital. A higher proportion of cures would be attained by using a higher initial dosage of sulphapyridine (M & B 693)—for example, six grammes in the first twenty-four hours and five grammes in the second. Administration of tablets of nicotinic acid in doses of 0.2 to 0.5 gramme per diem along with sulphapyridine reduces the toxic effects without diminishing the therapeutic efficiency.

It should also be stressed that the incidence of venereal disease among the troops can be minimized by sufficient provision of methods of prevention, such as facilities for prophylactic washing, irrigation, and inunction with mercurial cream, and the issue to all who desire them of condoms and prophylactic packets. New methods of prophylaxis and other means of minimizing infection may be evolved.

In conclusion, we wish to express our appreciation of the value and importance of the suggestions contained in Lieutenant-Colonel Burke's letter. Possibly the Army medical authorities have already forestalled them by introducing some similar organization, and information on this point would reassure the public that every effort has been made to prevent the tragic sequels of venereal disease.—We are, etc.,

R. C. L. BATCHELOR.
Edinburgh, Nov. 10. ROBERT LEES.

SIR,—Lieutenant-Colonel E. T. Burke's scheme of treatment for early syphilis as suggested in his letter is surely far too long and unnecessarily complicated.

I have since 1924 practised in the clinics I direct a course of treatment in primary and secondary syphilis which secures serological and clinical cure in 100 per cent. of cases and which gives a completely normal cerebrospinal fluid in the fifth year after infection. One course invariably reverses the Wassermann in sero-positive cases, but to ensure cure three courses are given—one three months after the first, and the third six months after the second. Two days in each week, not more than four days apart, are set as injection days. If Monday and Thursday are chosen, then 0.3 gramme N.A.B. is given on Monday and 0.45 gramme on Thursday until twelve injections have been administered; and every Monday 0.2 gramme of bismuth as bismuth oxychloride is given. In short, this course accomplishes in eighteen weeks what the suggested course takes forty weeks to do, and calls for thirty-six intravenous injections as against ninety-six, thus saving time and money.

I do, however, find myself in agreement with Lieutenant-Colonel Burke on the choice of sodium thiosulphate, since in 1925 I instituted its use as a vehicle for intravenous "914" in the treatment of syphilis.—I am, etc.,

A. O. F. ROSS,
Nov. 9. Venereal Diseases Officer, City and Port of Liverpool.

SIR,—During the 1914–18 war I had considerable experience of the treatment of venereal disease in the Army at the Brighton Grove Military Hospital of some 1,200 beds. At this period hospitalization until cure of every case was considered essential. I can therefore endorse Lieutenant-Colonel E. T. Burke's views as to the enforced idleness and wastage of man power so urgently needed elsewhere.

Since 1918 I have been continuously associated with the civilian clinics in this area, and have long since abandoned the view that hospitalization of other than complicated cases of venereal disease is necessary or desirable. The incidence of complications in gonorrhoea has been remarkably low, considering that over 50 per cent. of the patients are engaged in heavy manual labour. Cases of proved accidental contagion have been rare—chiefly vulvo-vaginitis in pre-pubertal girls and an infrequent case of *lues insontium*. The civilian clinics have adequately proved the possibilities of ambulatory treatment and the little risk of accidental contagion even in overcrowded areas.

In syphilitic infections the thrice-weekly dosage advocated by Lieutenant-Colonel Burke is impracticable in this area, but the results of a once-weekly dosage of 0.6 to 0.75 gramme of neoarsphenamine and insoluble bismuth (0.2 to 0.4 gramme) or mercury (1 to 1½ grammes) have given a high clinical and serological cure rate in early infective syphilis in the absence of default, gross intolerance, etc. Treatment is given in courses of ten to twelve weeks, totalling 4.65 to 6.75 grammes of "914" and 2.4 grammes of bismuth, and the patient receives three courses after his first negative Wassermann reaction. In my opinion Lieutenant-Colonel Burke's suggestions do not go far enough, as his "thrice-weekly" course necessitates considerable interference with duty, which would be obviated by the once-weekly system.

No uncomplicated case of gonorrhoea or syphilis should be off duty, whether in the front line or not. Investigations and the treatment could be carried out at battalion headquarters or other suitable rendezvous by mobile specialist units attached to brigade or divisional headquarters.

In gonorrhoea treatment with sulphapyridine (M & B 693) in initial doses of 4 grammes daily for three days, followed by two three-day courses of 3 to 4 grammes daily, has been well tolerated and given 80 to 85 per cent. cures on a three-months observation basis. Relapses and refractory cases are invariably associated with sealed-off foci in the prostate and vesicles or in the urethral glands. Late relapses have been noted up to seven months after infection. Despite apparent rapid cure, investigation for residual infections and tests of cure over a considerable period of time are necessary if considerations other than those of fighting fitness are to be taken into account.

In chancroid, where this is suspected in the absence of spirochaetes in a sore, treatment should be started forthwith with sulphanilamide or sulphapyridine. The use of these drugs will not prevent the demonstration of spirochaetes in any later examination, but will prevent any risk of phagedaena, etc.

With regard to records, every man undergoing treatment should carry a personal V.15, while records would also be kept by battalion headquarters or by mobile V.D. units, and transferred with the man.

Much of the above is also applicable to the "home front"; in view of the urgency of conserving hospital beds for A.R.P. eventualities.—I am, etc.,

Newcastle-upon-Tyne, Nov. 10. S. THOMPSON.

SIR,—I was very glad to read the letter of Dr. C. Hamilton-Wilkie in the *Journal* of November 11 (p. 974) regarding mine upon the above subject which appeared in the previous issue. Dr. Wilkie's unit course is certainly an excellent one; and, since his whole schedule of treatment by four such unit courses administered in a period of fifty-two weeks gives an efficiency index of 110, the cure rate must be one of 100 per cent. All treatment schedules for acute syphilis lasting for from twenty-six to forty-eight or more weeks whose efficiency indexes do not fall below 60 give such a cure rate. The schedule I advocated in my letter has an index figure of 116.

I had carefully considered the utilization of mobile V.D. units, but for a variety of reasons I came to the conclusion that stationary V.D. sections would be preferable. My view is that a soldier suffering from venereal disease should, while undergoing active treatment, be admitted to a V.D. section of the R.A.M.C. stationed in the corps or other area in which his unit is situated, and that he should be continually under observation. If, for example, the V.D. section was attached to a C.C.S. the man would, during his course of treatment, perform general duties, guards, etc. According to my suggested schedule of treatment for syphilis he would, as Dr. Wilkie points out, receive in every seven-day period three intravenous and two intramuscular injections. I regard that as being a most valuable method of keeping the man under closer and more continuous observation than he would be if Dr. Wilkie's suggestion were adopted. If complications due to treatment are to be avoided or diagnosed at the earliest moment the patient cannot be seen by the medical officer too often. I am convinced that it would be a bad principle to treat the man in his own unit by means of a mobile V.D. section, when he would be seen only twice weekly.

I feel sure that Dr. Wilkie and every experienced venereologist consider that it is to the advantage of the patient, the Army, and the civil population at home that all cases of venereal disease should be treated in the field.—I am, etc.,

E. T. BURKE,
Director of the L.C.C. (Whitechapel) Clinic.
London, E.1, Nov. 11.

Blood Transfusion

SIR,—I have read with interest Dr. J. L. Hamilton-Paterson's article on the use of stored blood for transfusion (*Journal*, November 4, p. 908). In five years of blood transfusion service in the University Medical Clinic of Turin, Italy, and in a field hospital in Spain, I have had a fairly good experience on this matter, both in peace and war; my conclusions (*Minerva Medica*, 1938, 23) are in complete agreement with those of Dr. Hamilton-Paterson. In the Spanish war no fewer than ten thousand transfusions were performed with blood conserved in a citrate–saline mixture (Russian method) and severe reactions were never observed. Very often, however, I had the impression that the same therapeutic result could have been obtained with a simple intravenous injection of the same dose of saline. The dramatic improvement which follows the pure-blood transfusion rarely appeared after stored-blood transfusion. The value of stored blood is definitely inferior, and, therefore, pure-blood transfusions should be used whenever possible.

Obviously enough, near the front line, in field hospitals, and in other mobile units the casualties requiring urgent transfusion are too numerous in comparison with the volunteer donors available in the zone, and stored blood is absolutely indispensable during a battle. Only when there is no rush of wounded is it possible to perform single fresh-blood transfusions, usually with blood given by the staff of the sanitary unit. In towns, where the casualties should amount to only a small percentage of the population, fresh-blood transfusions are possible and could be employed as a general routine, while only a small amount of blood might be kept stored for exceptional requirements. Blood donors classified according to their residence and the place of their employment could be available a few minutes after a telephone or personal call.

On the other hand it must be kept in mind that the stored blood also requires some preparation at the moment of its use, since it must be warmed to the body temperature, avoiding any exposure to a fairly superior heat. That cannot be made in advance, because the blood must be kept in a refrigerator as long as possible in order to avoid haemolysis. Thus the time of its preparation has no advantage over that of waiting for the arrival of a donor living in the neighbourhood. Furthermore, in all cases in which the stored blood will not be used before the expiration of its conservability there is an enormous waste of blood as well as of material for its collection and conservation.

In view of its therapeutic and economical advantages the fresh-blood transfusion service might be adopted in many towns, also in war time, and there is no reason why it should not operate smoothly. The stored blood should be reserved, so far as possible, to the very war zone, where it will be too difficult to find a sufficient number of donors at the moment when the most transfusions are required.—I am, etc.,

London, W.2, Nov. 7. PAOLO RAVENNA, M.D.

Gas Injuries to the Eye

SIR,—In the *A.R.P. Handbook No. 3,* page 59, line 12, the treatment for injury to the eyes from mustard gas includes the use of 1 per cent. atropine ointment every twelve hours. This no doubt was the proper treatment for the cases in the last war, when the majority of victims of mustard gas were soldiers under 40 years of age. Now that many old or middle-aged persons may be gassed the danger of precipitating or increasing glaucoma by such treatment is very great. I think it will be agreed that, even in the emergency of a gas raid, homatropine alone should be used instead of atropine for all but the young, and after the first application should not be repeated except under skilled medical advice. Otherwise terrible catastrophes may occur.—I am, etc.,

Colchester, Nov. 12. AGNES ESTCOURT-OSWALD.

SIR,—It would be desirable to know if Brevet Colonel L. T. Poole's opinion, as conveyed in his letter in your issue of November 11 (p. 972) addressed from the War Office, is the official Army medical view of the immediate treatment of mustard gas in its effects on the eyes—namely, that Nature with its lacrimal secretions supplies the best and apparently only first-aid measure required.

From Professor J. H. Burn's letter in the same issue of your *Journal* it appears that the German medical service uses other measures. In the French army a different treatment is in use.

For the almost suicidal pain at first experienced what does Colonel Poole suggest? Apparently only tears!—I am, etc.,

London, S.W.1, Nov. 11. REDMOND ROCHE.

SIR,—I have had no experience of first-aid treatment of mustard-gas burns of the eye, but during my sixteen years' service as ophthalmic surgeon at the Liverpool Pensions Hospital I saw many cases of its after-results.

For the recurrent attacks of subacute inflammation, keratitis, and severe pain I found that instillation of cod-liver oil was by far the best treatment. Relief of pain was immediate, followed by rapid disappearance of corneal roughness and lacrimation; and the treatment was easily carried out at the patient's home. First-aid treatment with cod-liver oil could do no harm and would relieve pain and promote surface healing. I would like to make a further suggestion about this remedy. It might be worth while to try the effect of the inhalation of atomized cod-liver oil in the treatment of pulmonary gas cases of the chronic type, perhaps even of the acute cases.—I am, etc.,

Hoylake, Cheshire, Nov. 13. EDGAR STEVENSON.

SIR,—I must ask your forgiveness for joining in this vital discussion, as, frankly speaking, I never yet saw or treated a similar case. But it is obvious that we are powerless against the chemical reaction of the direct contact of mustard gas with the eye, and we can only fight against the secondary infection complicating the initial injury. From that point of view I see a great similarity with the acute gonorrhoeal conjunctivitis of adults, and I usually had very striking results by giving the patient a protein shock (I prefer the T.A.B. vaccine) and continuous irrigation with a weak solution of potassium permanganate. I should be grateful to ophthalmologists of more experience than myself for their opinion of this kind of treatment in mustard-gas cases where the vascular system is not involved as yet.—I am, etc.,

London, E.1, Nov. 4. N. PINES.

Psychological Casualties in War

SIR,—I have read with great interest the letters of Dr. T. A. Ross and Dr. R. D. Gillespie in your issue of November 4 (pp. 925 and 926), and my many years' experience of psychiatry allows me to appreciate much in those letters.

My experience of the last war was that many potential mental cases were conscripted, in spite of strongly worded opinions of myself and others. Cases of adolescent insanity with short remissions, cases of mild epilepsy with post-epileptic automatism, and cases of hallucination of hearing and delusions of persecution were taken into the Army. Unfortunately I could not find out what had happened to them, but I knew they were quite unfit to be fighting soldiers. It would be of interest to know what became of these men, as also the number of men discharged on account of mental disease of some sort. In my medico-legal experience with cases under the Employers' Liability Act I have had difficulty in getting hold of the discharge papers of the plaintiffs, but in each case I ultimately found they had been discharged on account of delusional insanity, which had a great bearing on the ultimate result of the actions.

My experience while I ran a home for borderline cases was that as the war proceeded lady patients were falling off, and I soon found the reason: occupation of all sorts was keeping them well. Some took up Red Cross work, some helped in canteens, some drove cars and ambulances, while many took the place of conscripted men in banks and other places of business. In consequence their tendency to psychoneurotic ailments disappeared and many homes for such cases suffered very severely.—I am, etc.,

Bournemouth, Nov. 7. L. A. WEATHERLY, M.D.

SIR,—The letter from Dr. T. A. Ross in the *Journal* of November 4 (p. 925) calling attention to inadequate mental history taking and its unfortunate results of men called up or volunteering for service in H.M. Forces is one of first importance. Dr. Ross invites those of us who have met with cases similar to the two which he describes to write to him concerning them so that he may assess the gravity of the problem with a view to its solution. I hope that those who can assist him in this way will avail themselves of his invitation, for, if

I am not mistaken, the trouble is likely to increase and not diminish unless something can be done.

I too have already since this war began met with two instances of men being accepted for service who, had their histories been taken more carefully, would undoubtedly have been rejected. I would send details of these cases direct to Dr. Ross, as he asks, but it occurs to me that if I send them to you perhaps you might consider it useful to publish them in your columns if for no other reason than to call further attention to Dr. Ross's important letter.

Case 1.—A young man aged 21 was called up for service in the Militia during the summer. He was immediately examined, passed as fit, enrolled, and duly went to camp, from which he promptly ran away. He appeared at home, was seen by the family doctor, who correctly diagnosed acute anxiety neurosis, and a certificate to this effect was sent to the authorities. The father, whilst awaiting "instructions," brought the patient to me. At the first interview, which was short as I was hurried and the matter was urgent, it became obvious that the man was but poorly adapted to life. He hated school, never made friends with any boys or masters, took no interest in usual boyish occupations, but preferred to play the piano, jazz, etc., and to "make up," preparatory, he said, to going on the stage one day. His parents tried ineffectually to dissuade him from this course and offered him a choice from all the professions, but he refused. When attempts were made to discuss these matters with him he would become sullen, threatened suicide, and would disappear for hours on end. This behaviour, virtually blackmail, rendered his parents powerless. This, I think, is enough to show how unsuitable he is for military training, anyway at present. And I am of opinion the authorities should be thankful he deserted and thereby spared the country much expense and himself much suffering.

Case 2.—A man aged 28, a university graduate doing well in law, offered his services to the Army and was passed as medically fit. Shortly afterwards, while continuing his work and awaiting orders to go for training, he was suddenly seized with panic in a train. This attack was followed by others in quick succession, every day and with increasing severity. He came to me for advice, and his history as given that day revealed that for some years he had had a struggle with panics and fears—fear of his evangelical irritable father, fear of God, fear of men, and fear of going mad as a sister had died in an asylum. He had fought these fears and, as he said, had "conquered them," and was perfectly free from their effects when he offered himself for service. He did not mention his old trouble then, although probably given an opportunity to do so, because he did not realize its importance. Fortunately enlistment revealed, in time, the true state of affairs.

While on this subject may I say how helpful it would be for all concerned if some degree of uniformity could be decided upon as to the advisability of passing as suitable for service men who have had serious "nervous breakdowns" but who are now, after treatment, quite well. Two weeks ago an old patient who had had a schizoid illness with well-organized delusions was told by a doctor who knew he had once had a mental illness, but who did not know the history, that he was fit for service. Actually he was rejected because he was truthful enough to say he had been ill, but under the impression gained from the doctor he might, almost justifiably, have not mentioned the fact.—I am, etc.,

Byfleet, Surrey, Nov. 6. **H. Mark Palmer.**

Psychological Treatment Centres

Sir,—Dr. R. D. Gillespie (*Journal*, November 4, p. 926) suggests that during war "mental breakdowns of any sort may be fewer in the civil population than during peace." As evidence he quotes the somewhat lower incidence of admissions to mental hospitals during the years 1914-18. This appears to be his chief argument for adopting an optimistic view regarding the probable effects on mental health of the present war. But what of the years following 1918? Does Dr. Gillespie assume that the great war had no effect on psychoses certified then? Those with experience of mental cases know that a very large proportion of the psychic casualties of the last war, both civilian and service, did not become notifiable until some years after the war.

I think it is axiomatic that a period of great national stress, combined with a profound disturbance of normal routine, a period moreover of privation and danger, must produce more psychosis and neurosis. The disturbance of war involves a two-fold change—first peace to war, and then war to peace. The second change may be the more devastating for some individuals. I believe that potential subjects of psychoses given a fortunate environment may succeed in passing through life as useful citizens without quitting the ranks of those apparently normal mentality. On the other hand, any of us is capable of becoming psychotic. Wordsworth wrote of "man's unconquerable mind." He was wrong. We have only to think of solitary confinement in a dark and dirty mediaeval dungeon to realize this.

It is rather curious to find that Dr. Gillespie thinks that the British public will stand the stress of war well, but that "too wide advertising of emergency psychotherapy" causes a risk at the present time of "creating a national hypochondriasis." Centres such as Dr. A. C. D. Telfer suggests are required. Let us save such people as we can from the appalling fate of ending their days in a mental hospital or even of becoming chronic neurotics.—I am, etc.,

London, S.E.14, Nov. 4. **Allan A. Macdougall.**

X-ray Examination of Militiamen

Sir,—I have been following with great interest the correspondence in your columns on the subject of *x*-ray examination of the chest in militiamen. Having myself during the last three years screened over 10,000 industrial workers near London, I am very much aware of the necessity for *x*-ray examination of militiamen as part of the examination to be carried out on admission for military service. As I pointed out at the twenty-fifth Annual Conference of the National Association for the Prevention of Tuberculosis in June, 1939, my *x*-ray examinations showed that nearly 1 per cent. of the industrial population (exactly 8.3 per thousand, of which 0.2 per cent. are men and 1.2 per cent. are women) were found to be suffering from active pulmonary tuberculosis and had to be admitted into hospitals or sanatoriums for treatment. The workers were men and women between the ages of 14 and 55, and no definite preference of the disease for any age could be found.

I cannot agree with Dr. Gregory Kayne (*Journal*, October 7, p. 745) that *x*-ray examinations carried out by non-expert radiologists or physicians not specialized in tuberculosis are more likely to be a disadvantage than an advantage to the authorities on account of the mistakes made in interpretation of the findings. The interpretation of lung shadows by screening can easily be learned by any general practitioner with average intelligence in a few weeks, and with the help of *x*-ray photographs and sedimentation test of the suspected cases a fairly good judgment can be exercised about the activity of the lung process. Where there is any doubt the cases found active on routine examination can still be submitted to expert radiologists and tuberculosis physicians for opinion—as is always done in tuberculous cases found among the workers—for a final decision. According to my findings that 0.2 per cent. of working men are suffering from active pulmonary tuberculosis, about 1,000 men of the 500,000 standing Army are now doing heavy physical training and are exposed to all weather conditions, whereas they ought to be in sanatoriums having treatment for their lung disease. As the screening is bound to miss about 10 per cent. of the early infiltrations the estimated figure has to be put accordingly higher.

And now a word about screen photography. This method, in an improved form, has been compared with fluoroscopy and radiography by Burger of Eindhoven on 200 patients, and he found that radiography and screen photography gave about the same result, but the latter is in some respects superior to fluoroscopy. It is quite possible that some authorities—according to Dr. Kayne in the *Journal* of October 7 (p. 745)—consider this method unreliable, but I do not happen to know many methods in medicine about which all authorities agree. Whichever method is carried out, the fact still remains that we are in a position to prevent unnecessary suffering to a great many people and save a great deal of expense to the country, but we just do nothing about it.—I am, etc.,

London, W.1, Nov. 6 **L. Banszky.**

A Drop-wrist Splint

SIR,—By "dropped wrist" one usually infers dropped fingers and thumb—that is, an involvement of the posterior interosseous branch of the musculo-spiral nerve. If Mr. J. S. Kellett Smith means that his splint, illustrated in your issue of November 4 (p. 914), is literally one for a paralysis of extensor carpi radialis longior, brevior, and ulnaris only, well and good; but if not, I have seldom seen a worse one.

The illustration shows that the metacarpo-phalangeal joints of the fingers are flexed at an angle of 45 degrees and that the flexor longus pollicis is strongly in action, and in addition that there is no thumb abduction. In other words, the fingers and thumb are gripping the splint, and I cannot believe that this produces a satisfactory relaxation of extensor communis digitorum, extensor longus pollicis, brevis pollicis, and extensor ossis metacarpi pollicis. I can understand the men "appreciating" his splint, because when wearing it they could use their fingers and thumbs. However, his answer may be that he means "wrist-drop" only.

To maintain full relaxation in a complete musculo-spiral paralysis below triceps, nothing, in my opinion, beats a light long aluminium splint with thumb piece.—I am, etc.,

JOHN SAINSBURY, M.B., B.Ch.,
Late Medical Officer i/c Special Surgical
London, W.1, Nov. 10. Military Hospital, Ducane Road.

Administration of A.R.P. Casualty Services

SIR,—I read with interest the views of your correspondent "Casualty Service" in the *Journal* of November 4 (p. 929).

On the unification of the A.R.P. casualty services and hospital services and their co-ordination with the existing State medical services will depend the saving of life and mitigation of suffering as a result of enemy bombardment of the civil population. As regards training and recruitment accepted standards throughout the country should be arrived at; there would be no objection to local authorities conducting their own courses and examinations provided a recognized standard was reached in both cases. The administration of the A.R.P. casualty services should be in the hands of a competent medical officer. Such officer should wherever possible be the medical officer of health. He should be held responsible for the efficiency of the services in his area and to this extent given commensurate authority; in matters of less degree he should be given full powers, but major issues should be subject to the approval of higher authority. All this would have to be worked out, as it already has been in the defence medical services. Collective training should be carried out under the direction of the medical officer of health with the assistance of the local A.R.P. organizer and his staff; combined training likewise, along with the heads of the other services.

The suggestion of a sessional fee for attendance at a first-aid post during a raid would not appeal to me; so much is being done voluntarily that this additional demand seems somewhat invidious. Nurses at first-aid posts are as essential as the posts themselves. One nurse per post is well-nigh useless unless she is supported by several trained auxiliaries. The important point is that these people should live within easy reach of the post in order that it may be manned at very short notice. Only in very few instances indeed will this be found to be the case, and because of this I am very doubtful as to the ultimate value of first-aid posts. If, on the other hand, first-aid posts are to be staffed by inferiorly trained personnel who may or may not be available at short notice, these units as at present planned will be a menace rather than an advantage in reducing the air raid mortality rate. It is certainly expecting too much of first-aid-party personnel to decide the disposal of casualties on the spot; it would not be easy for experienced medical men working, as they might be, in protective clothing and respirators under subdued light. The alternative is to have medical officers on call who would go along with the first-aid parties to the scene of action. If, as we are told, medical officers would not be available, then it would seem far safer to send all casualties direct to hospital, where they could be seen at once by medical officers, who would decide their disposal.

Mobile units sound very attractive, but the delay involved in setting up a first-aid post at a building, if any, at or near the scene of disaster involves a serious time factor, and I doubt very much whether it would not be better to send all casualties direct to hospital after the most elementary first-aid treatment. A first-aid post adjacent to a hospital is in my view essential. The hospital must inevitably receive a number of casualties which after all only require elementary first-aid treatment. This would certainly be the case if casualties for some reason or another were sent direct—the nearest first-aid post might be too far away, and the mobile unit out of action.

The most useful function of scattered first-aid posts is that of decontamination of unwounded or slightly wounded casualties. Occasionally one will meet the case—a pretty desperate one—where the medical officer might have to decide whether to tackle the decontamination or the injury first. With skilled assistance both could be dealt with at the same time. There can be no doubt that any means at all which will expedite decontamination should be carefully considered.

I rather thought that the equipment of first-aid posts was of a high grade, much higher than I anticipated, and it obviously caters for a standard of first aid much more advanced than is generally recognized. Whether this will turn out to be a good or a bad thing remains to be seen.—I am, etc.,

Genito-urinary Infection in Childhood

SIR,—It was gratifying to find in the excellent article by Dr. Wilfrid Sheldon (*Journal*, September 9, p. 551) that he emphasized the need for a complete urological examination if pus and organisms were still present in the urine after the acute symptoms had subsided. It is possible that the more frequent occurrence in male infants may be due to the greater possibilities for minor degrees of stasis owing to maldevelopment or under-development of the urinary tract below the bladder sphincter.

The need for constant supervision of the reaction of the urine in these cases is repeatedly stressed, as it must be to-day. In my opinion litmus paper is obsolete for this purpose, and should be replaced by definite estimations of the urinary *p*H. I have found that "nitrazine" paper manufactured by Squibb is sufficiently reliable for constant clinical use. As an example, if the urine has a constant *p*H value of 7 or 7.5 it is useless to give any mandelate until the *p*H has been brought nearer 5. If the administration of acidifying agents fails to influence the *p*H the infection is probably due to a urea-splitting organism, in which case urinary antiseptics acting in an acid medium are useless.—I am, etc.,

Durban, South Africa, Oct. 5. S. MCMAHON.

Lambliasis

SIR,—In your annotation on lambliasis in the *Journal* of November 11 (p. 961) the only reference to treatment is the statement that "it appears that arsenical preparations, especially stovarsol, are effective." Since Pierre Martin recorded in 1937[1] the disappearance of *Giardia* from the stools of one of his patients treated with atebrin by Professor Galli-Valério there has been a very considerable number of papers confirming the effect of this drug, or its French equivalent quinacrine, on this infection, and the remarkable results obtained would suggest that this preparation should be the first considered where treatment of lambliasis is indicated.—I am, etc.,

London, W.1, Nov. 10. F. MURGATROYD.

Crataegus Oxyacantha in Hypertension

SIR,—The significant feature in Dr. James D. P. Graham's investigation of tincture of crataegus (*Journal*, November 11, p. 951) is the reduction of the pulse pressure caused by the large doses of the tincture. In every case except Case 8 the systolic pressure fell more steeply than the diastolic. This reduction of the pulse pressure I consider the chief clinical indication for crataegus medication. I have used it for a number of years with success in such cases, employing, however, much smaller doses (1 to 5 minims)—first, in those hyperpietics with a hypertrophied left ventricle, a regular pulse, and early signs of failure, such as breathlessness and paroxysmal nocturnal dyspnoea; and, secondly, in those patients who are recovering from a coronary thrombosis. I can confirm its failure in auricular fibrillation.

Dr. Graham had selected from his hyperpietics a small group whose renal or cerebral arteries had broken down under high pressure. I hope that if he extends his investigations he will next select a group in which failure is manifested in the heart itself.—I am, etc.,

Bristol, Nov. 12. FRANK BODMAN, M.D.

Immunization against Diphtheria

SIR,—Sir John Ledingham deserves to be congratulated upon his lecture and masterly summary of the present position of immunization (*Journal*, October 28, p. 841) and also because he had the courage to label certain societies as "anti-social." He uttered a truth when he suggested that liberty can become anti-social and that when it does it should be curtailed. I would suggest that he give another lecture and pillory by name these anti-social societies and call for their suppression. The attitude of the State and the profession towards vaccination has helped their propaganda and should be reviewed. Small-pox is not the scourge it was when compulsory vaccination was imposed. The danger having passed, the vaccination should pass too. If not, the law is held in contempt. It is bad when the law is held in contempt or becomes unenforceable. A law is bad when it is not necessary and is vexatious.

On the other hand, diphtheria is recognized by all as a dangerous disease. The mass of the people are willing to submit to a measure which will guarantee them a reasonable chance to escape from it. This is borne out by the attitude of the mass of Irish people towards immunization. In private practice parents ask for the treatment. I submit that the public are aware of the existence of this potent preventive treatment and wish it to be administered in an effective manner. I believe they would accept compulsory immunization and welcome it.—I am, etc.,

Clones, Nov. 4. M. G. KIERANS.

Virtues of Brown Bread

SIR,—Work on nutrition, particularly here in India, of Sir Robert McCarrison, and on vitamins throughout the world, has established that white bread as commonly used in England lacks vitamin B and is inferior to brown bread milled from whole wheat. I suggest that the British Medical Association urges the Government to bring in measures to encourage, if not to enforce, the eating of brown bread by everyone, at least during the war. At no time can we afford to waste the health and vitality of the nation—least of all during the present war.—I am, etc.,

GEOFFREY TAYLOR, Major I.M.S.,
Nov. 1. Professor of Clinical Medicine, Lahore.

In reply to numerous inquiries the Clothes Room Committee of the Ladies' Guild of the Royal Medical Benevolent Fund announces that the work is being continued throughout the present national emergency. Existing conditions make every effort much more difficult, but it is hoped that the committee may have sufficient support to help all beneficiaries. Parcels of clothing can be sent as usual to B.M.A. House, Tavistock Square, W.C.1.

Obituary

A. P. BEDDARD, M.D., F.R.C.P.

Consulting Physician to Guy's Hospital; Chairman of the Pharmacopoeia Commission

We regret to announce the sudden death on November 8 at Sandiway, Cheshire, of Dr. Arthur Philip Beddard, who was for many years a member of the senior staff of Guy's Hospital and in recent times served as chairman of the British Pharmacopoeia Commission. Dr. Beddard was vice-president of the Section of Anatomy and Physiology at the Annual Meeting of the British Medical Association at Belfast in 1909, and vice-president of the Section of Medicine at the Brighton Meeting in 1913. With his passing at the age of 72 there is the loss of an outstanding physician of the older school who had a real flair for clinical medicine.

He was educated at Shrewsbury School, where at a very young age he became head of the school and then was sent to work under the late Professor Ray Lankester in the University of London. The following year he entered Trinity College, Cambridge, of which he was a science scholar, where he studied comparative anatomy, and in both parts of the tripos and passed with first-class honours. In 1891 he decided to take up medicine and entered Guy's Hospital, graduating M.B., B.Ch.Cantab. in 1897. He gained his doctorate in 1899 and was made a Fellow of the Royal College of Physicians in 1903. His career had always been basically scientific, for having had such a distinguished training in biology he became demonstrator of physiology with the late Professor M. S. Pembrey and Professor E. H. Starling, with whom he did much valuable research work on problems of respiration and on functions of the kidney. At the same time he lectured in pharmacology at Guy's, and always retained throughout life an interest in this subject which led him after retirement from hospital practice to be chairman of the British Pharmacopoeia Commission. During these years of demonstrating physiology Beddard was appointed assistant physician and later became physician and consultant physician to the West London Hospital. In 1902 he took the vacancy created by the retirement of his godfather, Dr. Pye-Smith, from the Guy's staff, and he continued his work as a physician at Guy's Hospital until his retirement in 1927.

As a teacher he was outstanding; with an orderly mind of his own he had the great advantage of being able to impart his knowledge to his students, with the consequence that his teaching rounds at Guy's were always well attended, and no one went away from any round without a feeling of an afternoon well spent. He hated long names which often cloaked ignorance of a subject, and was particularly caustic with anyone who made use of subterfuges of any kind. His outspoken methods and utterances against quackery and ignorance of the elementary principles of biology and medicine caused him to be feared by some and to clash with others. But his honesty of purpose and his outstanding ability were recognized and admired by all. As a clinical observer, no detail was too small to be overlooked, and he was never content with a diagnosis unless he could fit all the known facts of the case into the making of the diagnosis. His last clinical round at Guy's will never be forgotten by those present, who included a number of the honorary physicians and surgeons. At the dinner in his honour which followed, every past house-physician was asked to tell two true stories of Beddard, and the quality of his quiet humour was shown not only by the quality of the stories but by his reply, in which he congratulated those present on the stories told but said he had no knowledge of any of the incidents recalled! As a physician he made a specialty of chest work; no one could elicit physical signs from a chest in the way that Beddard did. Probably his love of music was a great factor in this, for he was a skilled musician and had a vast knowledge of music.

Beddard enjoyed exceptionally good health until five years ago, when, following influenza and bronchitis, he developed asthmatic signs, which continued to undermine his health. The sympathy of all his friends and past students will go in deep measure to his wife, son, and daughter, who survive him.

E. C. W.

Dr. C. H. Hampshire, secretary to the British Pharmacopoeia Commission, writes:

The name of Dr. A. P. Beddard will always be remembered in connexion with the *British Pharmacopoeia.* The first British Pharmacopoeia Commission was appointed by the General Medical Council in 1928, following upon an inquiry by a subcommittee of the Committee of Civil Research into the method of production of the *Pharmacopoeia.* The *British Pharmacopoeia, 1914,* was in need of revision, and it was desirable in the public interest that a new *Pharmacopoeia* should be produced in the shortest possible time consistent with thorough work. Dr. Beddard was appointed chairman of the Commission and entered enthusiastically upon his duties, bringing his great intellectual gifts to bear upon the many problems of policy and of detail which are involved in the production of a pharmacopoeia. He was largely responsible for the policy of developing the *Pharmacopoeia* as a book of standards, while still retaining in it those features which are necessary to the maintenance of its position as an authoritative guide to the medical profession in the choice and use of drugs. He was keenly interested in the collaboration which was effected with committees on pharmacopoeia revision in the Dominions, and in maintaining the influence and usefulness of the *Pharmacopoeia* throughout the British Empire. His great breadth of view was also shown by his interest in establishing and maintaining collaboration with the pharmacopoeia authorities of other countries, in particular of the United States of America.

For nearly four years the Pharmacopoeia Commission met weekly and, under the guidance of Dr. Beddard, dealt with the considerable volume of reports, comments, and criticisms furnished by various subcommittees and correspondents. Dr. Beddard's charm of manner and qualities of leadership made him the ideal chairman in these early years. In the chair he always displayed great patience, preferring to allow difficult problems to solve themselves in friendly discussion rather than to force an issue. In private he gave unsparingly of his time and thought to the details of the work. I shall always retain the memory of long afternoons spent with him pleasantly, and without tedium, in the examination of drafts or the revision of proofs. A flash of wit or a sarcastic phrase would often enliven the task. When the sixth *British Pharmacopoeia* was published in 1932 it could truly be said that he was prepared to take personal responsibility for every statement made in it.

Four years of similar devoted work went to the production of the *Addendum,* which appeared in 1936, and he retained to the end, notwithstanding failing health, the control of the preparation of the seventh *British Pharmacopoeia,* which is now approaching completion. Eleven years of unremitting voluntary toil on pharmacopoeia revision represents a considerable public service, which should not be forgotten. His death means a loss to pharmacopoeial work which will be deplored by all his colleagues and helpers. To me it means the loss of a friendly, considerate, and inspiring chief.

[The photograph reproduced is by Elliott and Fry, Ltd.]

MABEL CAMPBELL, M.A., M.B.

The death of Dr. Mabel Campbell, which took place on November 3 at Allendale, leaves Newcastle-upon-Tyne and district the poorer by the loss of one of its best-known medical women and one of the most respected and trusted of practitioners.

Lizzie Mabel Renwick Campbell was a daughter of the manse, born at Newton, her father being the late John Campbell, D.D., of Kirkcaldy, Fife. There were eight daughters, four of whom entered the medical profession. Mabel was educated at St. Andrews, where she graduated M.A. in 1906 and M.B., Ch.B. in 1909. Shortly afterwards she went to Newcastle as house-surgeon to the Eye Infirmary, thereafter joining Dr. Ethel Williams in her large practice. Not long after the last war she went into practice on her own account, and at the time of her death no doctor was better known or more beloved in a district far beyond the confines of Newcastle and its immediate vicinity. Dr. Mabel Campbell held numerous appointments, but was principally identified with the Royal Victoria Infirmary, where she was for years on the staff as one of the anaesthetists, and the Princess Mary Maternity Hospital as one of the honorary obstetric physicians. She had been a member of the British Medical Association since 1910. She acted as secretary of the Section of Obstetrics and Gynaecology at the Annual Meeting at Newcastle in 1921, and at the Glasgow Meeting in the following year was vice-president of the Section of Anaesthetics.

Professor Grey Turner writes: What we most admired in Dr. Mabel was her wonderful unselfishness and her desire to be helpful. She had the greatest regard for all that concerned the circumstances and environment of her patients and took an active interest in everything that concerned their welfare, and no one better appreciated the problems covered by those tragic words "domestic difficulties." It will never be known to what extent she acted as general adviser and friend to hosts of families in all walks of life, though it was always done unobtrusively and without the slightest idea of favours conferred. Her work for all that concerned the welfare of women and girls was most valuable. But she was also a good doctor, a healer of the sick, and had an almost uncanny appreciation of what could be done to relieve people, and it was easy to be caught out by some suggestion concerning treatment of which she had somehow become apprised while many of us were still ignorant. Her professional standing was recognized by the British Medical Association and the Women's Medical Federation, in both of which bodies she held office at one time and another. As an anaesthetist she stuck to the older methods, but in their use was an expert, and the cheery way that she approached her patients and the feeling of easy confidence which she inspired were a great help in many a difficult case. Punctuality was not her special forte, and who will ever forget her late arrival, out of breath and palpitating but absolutely unflurried, and straightway proceeding with her work as if she had been first on the scene! She loved the country and the open air, and would make extraordinary journeys at any time of day or far into the night, returning in the early morning just in time to start a day's work, telling everybody what a wonderful outing she'd made and how she wished they had been able to share her pleasure. She was unselfish and generous to a fault, and would put herself to inconvenience if she could oblige a colleague or a friend, or, better still, one of her poorer patients. Her bravery in face of her last illness was something that can never be forgotten. Dr. Mabel had the art of conciliation developed to a high degree, and her younger friends and colleagues (and not only of her own sex) naturally turned to her in their difficulties, which were always most carefully considered. Her solution was always practical and to the point, for she was a realist, but a realist with a heart of gold. She was a fine judge of character and was very shrewd in summing up any situation where the human element played a part, and never forgot that "while the world changes man is always the same."

A colleague writes: Dr. Mabel Campbell's name will always recall to those who knew her a dynamic personality and a courage which not only upheld and inspired her patients but carried her herself through a long and painful illness, which she knew from the beginning could only have one end, with a steady cheerfulness and without one single word or sign of repining or regret. She inspired everyone whose personality touched hers with some measure of her vivid courage. She was a most competent doctor, never in a hurry with patients however long-winded, however difficult it might be to get the day's work in, and always ready to listen to complaints and attend to the most trivial details. Newcastle will long remember that vivid and handsome personality with flashing eyes and a ready smile in a very ramshackle old car. Her cars were always ramshackle, probably because she was always ready to lend them to all and sundry. She was an accomplished anaesthetist and an expert obstetrician. She will be remembered at the Princess Mary Hospital and the Gables Maternity Home for her cheerful service, unsparing of herself at any hour of the day or night. The women at the welfare centres will long remember the skill and knowledge of human nature which she so freely gave them.

Medical Notes in Parliament

Parliament will probably be prorogued on November 23 and a new Session opened on November 28. During the new Session legislation will be proposed for prolonging the life of the present Parliament till after the war.

Tyneside Blood Transfusion Service

On November 7 Miss **Horsbrugh** told Mr. D. Adams that the secretary of the Tyneside Blood Transfusion Service had been informed that any necessary expenditure incurred in grouping blood donors which could not be met from voluntary sources would be reimbursed on receipt, through the hospital officer, of vouchers showing the expenditure actually incurred. Up to date vouchers had been received for only £23 19s. 2d., and this had been paid. It was estimated that an additional £225 might be required for future expenditure, and if it proved necessary to incur this, and vouchers were forwarded, the cost would be met.

Medical Attention of Unaccompanied Children

On November 7 Mr. **Groves** asked the Minister of Health what precise arrangement had been made by his Department and the British Medical Association with regard to the treatment of unaccompanied children in reception areas, in view of the fact that a letter was sent from his Department to the Medical Practitioners' Union, dated October 15, 1939, referring to the agreed terms with the Association, and another letter, also from his Department, on October 27, stating that there was no formal agreement. Miss **Horsbrugh** replied that the arrangements provided that, as from the date on which the Government evacuation scheme took effect, sums calculated at the rate of 10s. a year for each unaccompanied child would be paid to the Local Emergency Committee, and from the funds so constituted payments would be made to medical practitioners on such basis, whether capitation or attendance, as might be found convenient. The amount paid covered the cost of attendance and the provision of medicines. The Medical Practitioners' Union was informed to this effect on October 5. As the arrangements were embodied in a letter from her Department which was accepted by the Association they were rightly referred to as "agreed terms," although the agreement was not formal.

Central Medical War Committee

On November 7 Mr. **Groves** asked if the Minister of Health would consider dissolving the Central Medical War Committee, which did not enjoy the complete confidence of the medical profession, and appointing in its stead the smaller and efficient Joint Committee on Medical Questions of the Trades Union Congress, which included among its members representatives of both the Medical Practitioners' Union and the British Medical Association. Miss **Horsbrugh** replied in the negative. She said that Dr. Elliot did not think that the change proposed would be justifiable.

Dr. **Elliot** informed Mr. Groves on the same day that since the constitution of the Central Medical War Committee on the outbreak of war the full committee had met twice. Fourteen members were absent on the first occasion, and nine on the second. In addition, there had been three meetings of the executive committee and one meeting of a special subcommittee.

In reply to a further question by Mr. Groves, Dr. **Elliot** said that a number of members of the Central Medical War Committee had been appointed without reference to any connexion they might have with the British Medical Association, and some of them were, in fact, not members of the Association.

In another reply to Mr. Groves, Dr. **Elliot** said that of the 44,608 qualified medical practitioners on the *Medical Register* and resident in Great Britain or Northern Ireland, 43,650 were included in the register kept by the Central Medical War Committee. The offers of service recorded in the register were, in the case of a number of practitioners, subject to their commitments to H.M. Forces or to local authorities or other bodies by which they were employed. He could not say how many medical practitioners had permitted their names to be included in the central register without any conditions or qualifications.

The 98 per cent. of the medical profession in the register of the Central Medical War Committee was not limited to medical practitioners who had signed the British Medical Association's scheme for the protection of the practices of doctors absent on war service.

Food Rationing

The Government has decided to take steps to enable the rationing of individual consumers to be put into operation. Instructions will be given to all Food Control Committees in the United Kingdom to issue the appropriate ration book for every individual consumer. There are only two commodities—bacon and butter—which the Government considers it necessary to ration, and even in the case of these two commodities it is not proposed to begin rationing yet. The actual date will be announced later. The Government does not desire to impose the rationing of sugar, and if each consumer restricts purchases to 1 lb. per head per week there will be sufficient supplies for some months. The manufacture of margarine has been greatly increased since the outbreak of war; the quantity of cooking fats available is equal to normal. In the case of meat adequate supplies should continue to be available. Mr. W. S. Morrison, in rationing butter, will do what he can to make special provision for invalids and diabetics.

Transfer of Medical Staff to Reception Areas

Mr. **David Adams** inquired on November 9 whether instructions had been given by the Ministry on the number or proportion of medical officers who should be transferred from evacuation to reception areas. Dr. **Elliot** said evacuation authorities had been urged to assist the authorities in reception areas by the transfer of staff where the conditions in the reception areas called for additional staff. In view of the varying circumstances in such areas it would not be practicable for him to lay down definite figures.

Hospital Accommodation for Civilians

Dr. ELLIOT, who was asked by Mr. Crowder on November 9 to consider authorizing the immediate reopening of London hospitals for the treatment of civil sick on a much larger scale than at present, replied that an inquiry made by him on November 6 showed that the nine big London hospitals—the London, St. Bartholomew's, University College, Middlesex, St. Mary's, Westminster, St. Thomas's, King's College, and Guy's Hospitals—all had vacant beds available for the ordinary needs of the population. He was, however, carefully examining, in consultation with the governing bodies and their staffs, what steps were possible to increase the facilities and beds available at the central hospitals.

In a further reply on November 9 to Mrs. Adamson, Dr. ELLIOT said that in maternity hospitals, sanatoria, general hospitals, and mental hospitals in evacuation and in other areas no beds were taken over or requisitioned for casualty cases. Before the war an estimate was made of the beds which could be made available at each institution in the scheme by relying on those normally empty, by sending home convalescent patients, and by transferring others to simpler accommodation, and in many cases additional beds were supplied by the Government for use in an emergency. The returns made to him daily since the outbreak of war did not enable him to say which of the beds vacant at any institution represented existing beds freed for the reception of casualties and which additional beds supplied by the Government. In the aggregate 110,000 out of the 170,000 vacant beds in hospitals rendering returns were additional beds supplied by the Government, and 60,000 were the original beds, including those which would have been empty in any case. The additional beds were being steadily increased as hutted accommodation was completed. In the same hospitals the number of beds occupied by the sick was shown in their returns as 156,000. The vacant beds were available if necessary for the sick requiring in-patient treatment as well as for casualties. In maternity hospitals no beds had been regarded as reserved for casualties. Casualty accommodation in mental hospitals had been provided entirely by beds supplied by the Government.

In-patient Treatment at London Hospitals

On November 9 Dr. ELLIOT informed Dr. Howitt that at the beginning of the war about 8,000 hospital beds in the county of London were evacuated by sending patients either to their homes or to other institutions. In addition there were about 7,500 beds already vacant, making 15,500 in all. At the present time there were in these hospitals about 13,000 vacant beds available not only for casualties but also for the civilian sick, who were admitted to the hospitals if in need of in-patient treatment. A letter was recently sent to London hospitals on this subject.

Dr. HOWITT asked whether sufficient physicians, surgeons, and specialists had returned to London to enable hospitals to deal with the civilian population. Dr. ELLIOT replied that adequate medical and nursing personnel was available for the cases at present coming forward. He had under consideration further proposals made to him by a committee representing all sides of the profession.

Infant Welfare Centres in London

Dr. ELLIOT informed Dr. Howitt on November 9 that infant welfare centres were open in the majority of the metropolitan boroughs. The reopening of further centres was a matter in the first instance for the responsible welfare authorities, acting in the light of their knowledge of local needs and of the facilities available in their areas. Dr. Elliot added that he was aware of the importance which mothers attached to being attended by medical practitioners in whom they had confidence.

Criminal Justice Bill

Sir SAMUEL HOARE announced on November 9 that the Government had regretfully decided time could not be found for the further stages of the Criminal Justice Bill. The Bill could not be carried over to another session, but he hoped that in some early session a Bill of the same kind would be introduced and passed without delay.

Service Allowances for Children

In the House of Commons on November 14 Mr. HORE-BELISHA announced an increase in the Service allowances. He said that the rates of allowances for children, after the first child, would be: 4s. for the second child against 3s. in the past, and 3s. each for all other children instead of 2s. for the third and 1s. each for subsequent children. Payment of the increased allowances would begin in three or four weeks' time, and would be retrospective to November 13 or the nearest related pay day.

Midwives and the Emergency Hospital Service.—Dr. ELLIOT told Mrs. Adamson on November 9 that no midwives or district nurses practising as midwives had been called up for service in emergency hospitals, since they were not enrolled as such in the Civil Nursing Reserve, from which nursing staff for hospitals under the Emergency Hospital Scheme was provided. Some nurses who possessed the certificate of the Central Midwives Board had been enrolled and called up. A number of midwives had been transferred from evacuation to reception areas for service in emergency maternity homes, which, according to the returns received, were adequately staffed.

The Position of Dentists.—Mr. GROVES asked the Secretary of State for War if he was aware of the serious hardships experienced by dentists at present, and if he would consider devising a scheme by which the services of civilian dental practitioners could be utilized by the Army Dental Corps. Mr. HORE-BELISHA said that the Army Dental Corps had already absorbed a number of civilian dental surgeons, who had been appointed to commissions since the outbreak of war, and many more would be required as expansion proceeded. The arrangements for the supply of dentists both for the Services and for civilian requirements were in the hands of the Central Dental War Committee, which included representatives of the profession.

Notes in Brief

The establishment of a first-aid post includes one trained nurse. Dr. Elliot does not feel in a position to recommend the enlargement of this establishment.

Asked about treatment facilities at present available at Droitwich, Dr. Elliot stated that vigorous efforts were being made by all concerned to ensure that these facilities would continue to be available to all those in need of such treatment.

Universities and Colleges

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council, held on November 10, the following appointments were made: Dr. J. B. H. Holroyd to be temporary lecturer in anaesthetics and Mr. J. Hardman to be temporary honorary lecturer in surgical anatomy, to carry on the duties respectively of Dr. R. E. Pleasance and Mr. J. C. Anderson, who are on military service; Dr. W. F. Mindham to be part-time demonstrator in anatomy for the session 1939–40; Professor H. N. Green and Professor E. J. Wayne were appointed two of the five representatives of the University on the Committee of Management of the Sheffield Hospitals Council.

The Council received and accepted with regret the resignation of Dr. Lucy Naish of the post of lecturer in osteology, and accorded its thanks to Dr. Naish for her services.

UNIVERSITY OF GLASGOW

At a ceremony of graduation on November 11 the degree of M.D. (with commendation) was conferred on P. K. Fraser (*in absentia*).

ROYAL COLLEGE OF SURGEONS OF ENGLAND

An ordinary meeting of the Council was held on November 9 with Mr. Hugh Lett, the President, in the chair. Mr. R. St. Leger Brockman of Sheffield was readmitted to the Court of

Examiners for a period of five years. The scientific report of the College for the year 1938-9 was approved and adopted.

Final Fellowship Examination

The Council decided to hold an additional Final Fellowship Examination in February, 1940. The Council recognizes that it may be difficult for some candidates to comply with the regulations for admission to the Final Fellowship Examination. It has been resolved therefore that those candidates who because of war work have been unable to comply with the regulation that requires six months' residence as house-surgeon in a recognized hospital may apply to the President, through the Director of Examinations, for special permission to enter for the examination. With his application a candidate must submit a certificate from his commanding officer giving (*a*) particulars of his appointment in the Navy, Army, or Air Force, (*b*) the dates of his service with the unit, and (*c*) an indication of the nature of the duties performed by him during such service. A candidate in the Emergency Medical Service or in a civil hospital should furnish similar particulars signed by the senior surgeon of the hospital in which he may have held the appointment.

Licence in Dental Surgery

Sundry alterations in the regulations for the Licence in Dental Surgery were agreed to. Details of the alterations have been sent to the medical and dental schools. Provisional recognition was granted to the Dental Faculty of the Punjab University so that graduates of the Faculty may be admitted to the Final Examination for the Licence in Dental Surgery on completing six months' general medical and surgical hospital practice in this country.

Grant of Diplomas

Diplomas of Membership were granted to the 297 candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London published in the *Journal* of November 4 (p. 930), and to P. J. Crowley, A. M. Goldthorpe, Joyce S. Miller, and Aileen E. M. Whetnall.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the Royal College of Physicians of Edinburgh, held on November 7, with Dr. Alexander Goodall, President, in the chair, Drs. David Dowie Dunn (Capetown), Jiwan Ram Maleri (Punjab), Beatrice Annie Sybil Russell (Gold Coast), George Robertson McNab (Birmingham), Philip Wolfe McKeag (Bath), Robert Patrick Anderson Macaulay (Trentham), and Harry Winton Dryerre (Edinburgh) were elected Fellows of the College.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the annual meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, held on November 6, the following officers were elected for the ensuing year: *President*, Dr. J. Souttar McKendrick; *Visitor*, Mr. Roy F. Young; *Honorary Treasurer*, Mr. William J. Richard; *Honorary Librarian*, Dr. W. R. Snodgrass; *Representative on General Medical Council*, Mr. G. H. Edington.

Medical News

The B.B.C. announces that on November 23 at 4.15 p.m., in the series "Talking it Over," a medical psychologist will discuss "States of Mind"; and that "physical exercise" broadcasts will be inaugurated on December 4, starting at 7.35 a.m.

It has been decided that the annual course of lectures and practical instruction for a Diploma in Psychological Medicine held at the Maudsley Hospital, Denmark Hill, S.E.5 (London County Council and University of London), will begin as usual on January 1, 1940. War conditions call for some changes in arrangements, but the clinical instruction necessary to satisfy the requirements of the various examining bodies will be provided. A notice of the course will appear later in the advertisement columns of this *Journal*. Inquiries should be addressed to the Honorary Director of the Medical School, The Central Pathological Laboratory, West Park Hospital, Epsom, Surrey.

The Copley Medal of the Royal Society has been awarded to Professor T. H. Morgan of the California Institute of Technology for his establishment of the modern science of genetics; and the Davy Medal to Professor J. W. McBain of Stanford University, California, for distinguished work in the study of colloidal electrolytes. A Royal Medal has been awarded to Professor D. Keilin, F.R.S., for his contributions to biochemistry and entomology; in particular for his demonstration of the part played by cytochrome in the oxidation-reduction mechanisms of the living cell; and for his studies of the higher Diptera.

Among four recipients of gold keys from the American Congress of Physical Therapy for distinguished research in physical therapy during the last year is Dr. J. B. Mennell of London. The award was made during the same month that Dr. Mennell took up his duties as president of the Section of Physical Medicine of the Royal Society of Medicine. This is the fourth occasion on which one of these keys has been awarded to a medical practitioner in this country; the last was to Sir Henry Gauvain in 1936.

The Institute for the Scientific Treatment of Delinquency announces that it has now been found practicable to reopen the clinic at 8, Portman Street, W.1, and applications may be made either by letter or telephone to the secretary. For the present the work of the clinic will be restricted to diagnosis and advice (including social work and disposal), but the directors are endeavouring to arrange for psychological treatment to be given in Central London. Arrangements are also being made for diagnosis and treatment in certain districts outside London.

The issue of *Nederlandsch Tijdschrift voor Geneeskunde*, the organ of the Dutch Medical Association, for October 21 contains a sympathetic obituary notice of Dr. Harvey Cushing by Dr. P. Brouwer, professor of neurology at Amsterdam, and two portraits, one in his study and the other in a group of Dutch peasants at Amsterdam.

The October issue of the *Psychiatric Quarterly* is dedicated to Dr. Robert Hutchings, who has retired after forty-seven years' service to New York State, and for the last four years has been editor of the journal.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

There has been a tendency in recent weeks for the incidence of diphtheria to increase, but in none of the localities affected have outbreaks attained epidemic proportions. In England and Wales notifications in the last four weeks were: 952, 941, 975, and 1,002 (week under review), and there has been a corresponding rise in the number of deaths from diphtheria; but the numbers notified each week have been below those recorded in the corresponding week of 1938. On the other hand, the number of deaths certified has in the last few weeks approached that for last year, suggesting that the disease is present in a more severe form. In Scotland and Ireland considerable fluctuations in diphtheria prevalence have been observed during the same period and no definite trend is discernible. Similarly, notifications of scarlet fever have varied from week to week—in England and Wales as well as in Scotland and Ireland. The usual seasonal trend has probably been disturbed by the abnormal distribution of many of the susceptibles and the varying conditions in different localities as regards reopening of schools.

The figures for pneumonia (primary and influenzal) in England and Wales have in the last four weeks increased irregularly, and there has been a steady rise in the deaths from influenza, although the numbers are still low.

The abnormal prevalence of dysentery in Scotland, principally affecting Edinburgh, continues. Notifications for the whole country were 52, compared with 39 in the previous week and 23 in the corresponding week last year. Of the 52 cases notified, 22 were in Edinburgh, 5 in Dundee, 4 in Glasgow, and 3 in Aberdeen.

No. 43

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 28, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for : (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for : (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases ; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The TELEGRAPHIC ADDRESSES are
EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*
SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Dochtúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Parotid Swelling in an Infant

Dr. COLIN H. HARPER (Kenilworth) asks if any reader has met a case similar to that recorded below and can offer a prognosis: The patient is a female infant, born September 1, 1939, who has had for the past five weeks a painless parotid swelling on the left side which refuses to resolve or alter in any way. The tumour is soft but does not fluctuate, and the overlying skin is normal. The child was full-term and a breech birth, and was quite healthy for the first fourteen days, at which time she developed an extensive white mouth. The mouth condition cleared up with coll. argentum after a week and was followed by the parotid swelling. The baby is making good progress on artificial feeding and is otherwise quite normal.

Foot Powder for Soldiers in Rubber Boots

"REGISTERED MEDICAL AUXILIARY" writes: In many cases those serving in the Army are required to wear rubber Wellingtons for several hours daily, and in some instances with deleterious effect, such as skin surface sensitiveness, congestion, liability to blister, etc. Sponging with methylated spirit is often advised with advantage after a footbath in which potassium permanganate is used. An authoritative pronouncement in regard to a suitable astringent powder, which could be dusted into the socks for use while wearing these rubbers, would be of great service to those who are anxious to help the feet of our soldiers.

Fractured Femur in the Field

"D. W." writes in reply to Dr. W. R. Wilson's inquiry (October 28, p. 896) regarding a method of treating fractured femurs in the field. This method was fully described (and illustrated) in a paper on field ambulance training which appeared in the *Journal of the Royal Army Medical Corps* of March, 1939. The writer (Major J. B. Fotheringham) stated that his attention was first drawn to this method in the last war by a brother officer who produced a cutting from a medical journal. This must have been Captain Chavasse's description in the *British Medical Journal* referred to by your correspondent. After this it was used in the field ambulance with which the writer was serving. He has taught the method in peace time. I myself while a Territorial D.A.D.M.S. introduced the method into the field ambulances of my division. Dr. Wilson states that extension is maintained by means of a strap passed between the legs and fastened to the head end of the stretcher. It is better (and more comfortable for the patient) to maintain extension from the shoulders. A triangular bandage is tied in a half-knot round each shoulder-joint over a pad in the axilla and the ends are fastened to the handle of the stretcher on the opposite side.

Income Tax

Deduction of Tax from Interest

"H. P." explains that he has a mortgage on some property, the interest being payable on April 1 and October 1. He has recently received the interest less tax at 8s. 6d. in the £. Is this correct?

⁂ No. The interest being secured on property is presumably "payable out of profits and gains brought into charge," and tax is deductible at the rate in force for the year in which it falls due. If the interest had been payable on April 6, etc., the rate for the year would be 7s. in the £, and as 5s. 6d. only was deducted in April 8s. 6d. would now be deductible to produce an average of 7s. But the April interest was taxable at last year's rate—that is, 5s. 6d.—and not at 7s., and therefore no special adjustment can properly be made from the October payment, which is taxable at 7s. only.

LETTERS, NOTES, ETC.

Safely Swallowed Safety-pin

Dr. D. S. BRYAN-BROWN (London, N.16) writes: On October 18 I was called to see a boy 23 months of age who for three days had refused to eat. His temperature was subnormal. There were signs of erupting molars and his submaxillary lymphatic glands were palpable. The tonsils were within normal limits. The parents were reassured. On October 26 I was sent for in a hurry as the child had passed a 1½-inch open safety-pin. The child is perfectly well and has remained so up till now. It seems remarkable that a sharp-pointed foreign body of this size should pass through the alimentary canal of such a small child with impunity.

Accommodation for Medical Boards

"MEDICO" writes: May I, as a member of one of the Military Service Act medical boards in London, draw attention to the unhealthy conditions under which the members of some of these boards are expected to work. Surely there should be plenty of suitable premises such as hotels and other buildings available for the purpose. As it is, a converted shop with practically no ventilation, no running water for washing or testing urine, and a stifling temperature often over 70° is the accommodation set aside for some boards. To ask medical men and other staff to work under such conditions is surely not fair and is uneconomical, because in an influenza epidemic most of the staff would be down sick. I hope that all premises will be surveyed with a view to their alteration or transference of the work to more suitable buildings.

Information for the Deaf

The National Institute for the Deaf (105, Gower Street, W.C.1) has issued a handbook entitled *All about the Deaf* (price 3s.; 3s. 3d. post free), which describes how the deaf are helped and how they may help themselves. It was first published in 1929 as *The Problem of the Deaf.* This volume of 125 pages gives trustworthy information on every aspect of deafness, and should be of great service to all those concerned with this subject. The two classes of patients whose interests are considered in the book are the "deaf and dumb" and the "deafened"—that is, those who were not born deaf but have acquired their hearing defect at some time since birth. The book includes articles on the legal aspects of deafness, the certification of mental defect in the deaf, the prevention of deafness, the education of the deaf and dumb, the use of hearing aids, and schools for the deaf; it also reminds the reader that the National Institute for the Deaf maintains a list of firms which have agreed to certain conditions in the sale of hearing aids to the public. Among much other valuable information there is also a list of hospitals in Great Britain where diseases of the ear, nose, and throat may be treated. The National Institute for the Deaf, in conjunction with the Department of Industrial Physiology of the London School of Hygiene and Tropical Medicine, has also issued a valuable report on *Employment of the Deaf in the United Kingdom,* by Miss M. L. Clark and Dr. G. P. Crowden.

"Foreign Pharmaceutical Products"

Messrs. COATES AND COOPER, Ltd., Clerkenwell Road, E.C.1, write: We note that in your issue dated October 28 you have incorporated under the heading "Foreign Pharmaceutical Products" the preparation idozan. We would like to draw attention to the fact that idozan has been manufactured in this country for some considerable time, and in October, 1938, a half-page advertisement to this effect appeared in your *Journal.*

LONDON SATURDAY NOVEMBER 25 1939

CLASSIFICATION OF NON-INFECTIVE ENLARGEMENT OF LYMPH NODES*

BY

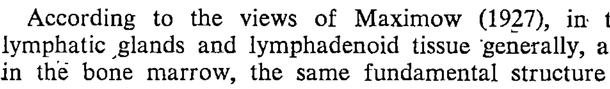
JOAN M. ROSS, M.D.
Reader in Pathology, University of London

In dealing with the "non-infective" enlargement of the lymph nodes it is necessary that uniformity of description and terminology should be arrived at by all pathologists on whom the onus of biopsy diagnosis rests. The reaction of various conditions to therapeutic measures cannot be pronounced with certainty until we are sure that similar conditions are being compared, nor can any prognosis be made until a considerable number of adequately diagnosed and classified conditions have been treated and the results assessed. In this paper a classification is put forward based on the cytology of the lymph gland, and the clinical conditions represented by the various groups are summarized so far as they are at present established.

Structure of Lymph Glands

According to the views of Maximow (1927), in the lymphatic glands and lymphadenoid tissue generally, and in the bone marrow, the same fundamental structure is present. This consists of a framework of argyrophil recticulin fibrils, closely associated with which is an undifferentiated syncytium. In the meshes are located the immature and maturing free cells of the blood. The undifferentiated syncytium is mesenchymal in its nature and is capable of differentiating along various lines (Table I).

TABLE I



The reticular syncytium does not perform any metabolic function, is not phagocytic in character, and does not store vital dyes. Under stimulation, reticulum cells are formed from the reticular syncytium. These are large oval or stellate cells, with an oval vesicular nucleus; a well-defined nucleolus is present. They still possess unrestricted potentialities for differentiation, and may be phagocytic and store vital dyes. Similar cells are found in connective tissues near the blood vessels.

The venous sinuses of the splenic pulp and bone marrow, and the lymphatic sinuses in the lymph glands, are lined by specially differentiated reticulum cells (sinus reticulum, or littoral cells). The stellate cells of von Kupffer in the liver are of this nature. Littoral cells are phagocytic in character and, under stimulation, differentiate to the actively phagocytic free histiocytes.

In the bone marrow the undifferentiated tissue gives rise at first to a primitive free cell, which was called the haemocytoblast by Ferrata. This cell may differentiate along various lines—to the monocyte, the myelocyte, the erythroblast, or the megakaryocyte. Maximow regards the haemocytoblast as similar in every way to the large lymphocyte of the lymphatic tissue—that is, the lymphoblast. This large lymphocyte (lymphoblast) arises normally from the reticulum cells in the lymphatic tissue. It does not enter the blood. It gives rise to the medium-sized lymphocyte, and that in turn, by mitosis, gives rise to the small lymphocyte. The medium-sized lymphocyte of the lymphatic tissue is the large lymphocyte of the peripheral blood stream. The plasma cell arises by alteration of the lymphocyte.

Another line of differentiation which has its origin through the reticulum cell results in the formation of the fibrocyte, and collagen fibres are thus produced. Normally reticulin fibres are produced by the reticular syncytium and its derivatives. Under pathological conditions a somewhat specialized reticulin-forming cell, the dictyocyte, becomes recognizable. It is a polygonal cell with cytoplasmic projections, which may be in contact with projections from adjacent cells. It is specially important in the discussion of the neoplasms of the lymph nodes.

The point which I wish to emphasize is this: There is, in the haemopoietic tissue and elsewhere, a common ancestral or stem-cell type which, given appropriate stimulus, may differentiate along any of the lines of development shown in the table. The appropriate stimulus, in a normal human adult, for the development of the myelocyte is present in the bone marrow; the appropriate stimulus for the development of the small lymphocyte is present in the lymphadenoid tissue. Under abnormal conditions there may be action of such stimulus in abnormal situations; or an abnormal stimulus may cause overproduction of any of the cell types, or abnormal combinations of cell types. This means that the tissue changes, in myeloid and lymphatic leukaemia, for instance, are not due to a fundamental difference in two tissue elements, but to the action of a different stimulus on a common

---

* Read in opening a discussion in the Section of Pathology and Bacteriology at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

4116

stem-cell. In the normal adult tissue of a human the development of this stem-cell into free blood cells rarely happens, except, possibly, in lymphatic tissue. This development does, however, become apparent in certain diseases.

Before going on to the classification of the diseases of the lymph glands, it remains to summarize the occurrence of these tissue elements in the lymph nodes. The reticulin fibrils in the medulla of the lymph node form a meshwork which supports the undifferentiated syncytium. The derivatives of the syncytium—reticulum cells, lymphocytes of all sizes, and histiocytes—lie in the meshes. At the margin of sinuses there is some condensation of these reticulin fibrils, and some cross the lumen of the sinus and are continuous with the capsule. These fibres serve as a support for the littoral cells. The follicles contain few reticulin fibrils, if any, the reticular syncytium acting as a supporting stroma for the large, medium, and small lymphocytes.

Classification

The non-infective enlargements of the lymph nodes are essentially hyperplasias, or neoplasms, of the reticulum or its derivative cells. The term "reticulosis" should be used for those diseases in which there is systematized hyperplasia of differentiated or undifferentiated mesenchymal cells, leading to generalized enlargement of the lymph nodes, the spleen, and the liver, with alteration of the bone marrow. This idea of cytological classification is an old one. MacCallum in his textbook gives it as his opinion that "if we knew accurately all the cellular types existent in the bone marrow and in the lymphoid tissue, and assumed that each is capable of undergoing independent hyperplasia, we should be able to tabulate all the possible diseases arising in this way." The recently acquired knowledge of the existence of the undifferentiated mesenchymal cell and its capacity for differentiation enables us to go a long way further in classification.

We may now assume that the unknown factor stimulating hyperplasia of any cell elements does not necessarily inhibit differentiation of that cell, although it may be regarded as determining the line or lines of differentiation which the hyperplastic cell may follow. The classification now proposed assumes that any one of the unknown aetiological factors will act on medulla or follicle or sinus, since such special site of action has been established for the known aetiological agents producing changes in the lymphatic glands (syphilis, etc.).

TABLE II.—*Non-infective Enlargements of Lymph Nodes*

(1) Reticulosis—hyperplasia of differentiated or undifferentiated mesenchyma
  A: Medullary reticulosis:
    (i) Primary:
      (*a*) Undifferentiated. (*b*) Haemic (leukaemias). (*c*) Fibromyeloid (lymphadenoma). (*d*) Histiocytic.
    (ii) Metabolic; generalized lipoidosis:
      (*a*) Gaucher's disease. (*b*) Niemann-Pick disease. (*c*) Primary xanthomatosis.
  B: Follicular reticulosis:
      (*a*) Lymphoid. (*b*) Fibrillary.
  C: Sinus reticulosis:
      (*a*) Acute. (*b*) Chronic.
(2) Primary neoplasms—reticulosarcoma

In medullary reticulosis the proliferating cells arise in the medulla of the lymph gland, spleen, and bone marrow. In follicular reticulosis the follicles of the lymph gland are affected and the proliferating cells have a follicular arrangement. In sinus reticulosis hyperplasia affects the littoral cells lining the lymphatic sinuses of the lymph glands and the venous sinuses of the liver, spleen, and bone marrow. Subdivisions can then be made in these groups according to the types of cells produced. Some of the groups given in Table II can be further subdivided. For instance, the haemic medullary reticuloses are the leukaemias (or leucoses), myeloid or lymphatic or monocytic. Possibly, according to some opinions, the more accurate position for monocytic leukaemia would be in the sinus reticulosis group; this is a matter on which more knowledge is badly needed.

Having outlined the classification of the diseases affecting the haemopoietic organs, it remains to provide a clinical picture of each type and briefly to indicate the changes found in the lymph nodes.

Undifferentiated Medullary Reticulosis

It may be taken as a rule that where there is little differentiation of the primitive cells the clinical picture is an acute one. This type of reticulosis is an acute disease affecting children. The course averages about six weeks. The symptoms are typhoid-like. There is generalized enlargement of the lymph glands, splenomegaly, and hepatomegaly. The intestinal lymphoid tissue may be affected. The predominating cell in the enlarged gland is the reticulum cell. Sometimes fibrils are formed, but phagocytosis is not present. Roussy and Oberling (1934) described about sixteen cases. A similar disease occurs in adults, but is very rare. In adults the course tends to be subacute.

Haemic Medullary Reticulosis

This group includes the myeloid, lymphocytic, and monocytic leukaemias, or leucoses. Chronic and acute myeloid leukaemia need not detain us. In myeloid leucoses the hyperplasia seems to affect cells which have already become differentiated and can only differentiate to more adult members of the granulocyte series. As a rule, in this condition there is no evidence of any reticular hyperplasia in the lymphatic gland. In lymphatic leukaemia there is, however, evidence in nearly all cases of hyperplasia of cells without a fixed line of differentiation—that is, hyperplasia of the reticulum cells. The following case illustrates this in a most striking degree. In other cases lesser degrees have always been found on careful examination of the lymph glands.

CASE I

This patient, a man aged 57, was admitted to hospital with a history of enlarged glands of the neck, axillae, and groins for three years, necessitating periodic rests from work. Two and a half years before admission a white blood count showed 60,400 cells, with 92 per cent. of lymphocytes; a gland removed at biopsy was said to be typical of lymphatic leukaemia. On admission the white cells of the peripheral blood stream were all of a primitive type—oxidase-negative non-granular cells (see Table III). There was pleural effusion, and the liver and spleen were enlarged. Later, after prolonged *x*-ray treatment, the cells were for the most part small lymphocytes. At necropsy the mediastinal, cervical, abdominal, and inguinal glands were all enlarged. The liver was large, weighing 2,041 grammes. The spleen weighed 1,415 grammes, and showed very large grey Malpighian bodies in a reddish pulp. Microscopically, adult lymphocytes were present in the pulp. The Malpighian bodies were normal but large. Microscopically, some glands were packed with small lymphocytes, with obliteration of the normal architecture; others showed reticulum hyperplasia with development of fibre-bearing cells, and giant cells with twin mirror-image nuclei were present. One of the points of interest in this case is that before the post-mortem histological examination there was no reason to suspect that the blood count, so typical of lymphatic leukaemia, did not give an accurate indication of the underlying tissue changes.

TABLE III

1936	R.B.C. (1,000's)	Hb %	W.B.C.	P.	Degen. Cells	Primitive Oxid. neg.	Lymph.

Treatment: Deep *x*-ray to spleen and chest. Frequent paracentesis.

There is some confusion in the literature of monocytic leukaemia as to the histological changes in the lymph gland and other organs, and at the present time it is not possible to formulate any opinion as to the true position of this disease. I have no personal experience of a true monocytic leukaemia. In a case of acute leukaemia with 10,500 white blood corpuscles per c.mm. 32 per cent. by vital staining were true monocytes and 41 per cent. small lymphocytes. The sternal puncture showed adult small lymphocytes. The case was diagnosed as acute mixed leukaemia, and the lymph glands showed hyperplasia of the sinus reticulum as well as medullary hyperplasia.

Fibromyeloid Medullary Reticulosis

This is the correct term in the suggested classification for that disease so long known as lymphadenoma or Hodgkin's disease. It is the best known of the primary reticuloses except those of the haemic group, and the clinical picture is well defined. The course is chronic. It is longer in duration than other reticuloses, with the possible exception of follicular reticulosis and Gaucher's disease. The lymph nodes in the cervical region are affected first as a rule, and the enlargement then spreads to the other groups. Splenomegaly occurs in about 70 per cent. of the cases; it is moderate and not constant. Massive involvement of the lung may occur in some cases.

The characteristic changes in the glands in fibromyeloid reticulosis are the proliferation and differentiation of the reticular syncytium. These changes have been described in great detail by Pullinger. The changes in the reticular syncytium and the cells derived from it may be summarized as follows:

> The nucleus becomes enlarged and the cytoplasm becomes partially separated. The swollen cells then separate out as individuals. The cells may show vacuolation and retraction of the cytoplasmic processes, and groups of cells may be seen showing ill-defined cell boundaries with large nuclei, perhaps twin. Cells appear with well-defined twin nuclei, which in characteristic Sternberg-Read giant cells are mirror images of one another. These giant cells are often seen in Hodgkin's disease.

The characteristic of lymphadenoma is, however, differentiation of the cells; a filigree of reticulin fibrils is present, and granular cells, many of them eosinophils, are developed from the reticulum cells, a considerable diversity of cell structure resulting. In late stages the production of collagen may give rise to a very dense fibrous tissue with only a few reticulum cells remaining.

Histiocytic Medullary Reticulosis

Histiocytic medullary reticulosis is a condition which has probably been classified as "atypical Hodgkin's disease." Pullinger described a case in 1932. The glandular lesion was characterized by areas of haemorrhage and necrosis. Macrophages were present, with chromatin particles and, frequently, red blood corpuscles in their cytoplasm. Giant cells having small nuclei arranged at the periphery were also present. Occasionally reticulum cells with twin nuclei were seen. Cells with eosinophilic cytoplasm and darkly staining nuclei were abundant. Some of these showed mitotic figures. (These cells have been termed prohistiocytes by Robb-Smith, 1938.) Bodley Scott and Robb-Smith (1936) have included this case with three others in a paper on histiocytic medullary reticulosis. These authors have been able to find six other cases in the literature and to assign a clinical picture to the condition. Briefly, the clinical course is characterized by fever, wasting, generalized glandular enlargement, splenomegaly, and hepatic enlargement. Jaundice, purpura, and anaemia with leucopenia are common in the final stages. The average duration of the disease is fifteen weeks, all cases ending fatally.

Generalized Lipoid Histiocytosis

Gaucher's disease is familial, the average duration being about forty-five years. The condition is characterized by great splenic enlargement, and although there may be generalized enlargement of the glands it would be unusual for diagnosis to rest on the biopsy of a gland. It is not always realized that patients suffering from Gaucher's disease may live for "three-score years and ten" and die of the cerebral complication of athero-sclerosis so common to the old without the metabolic disturbance being of clinical significance.

Follicular Reticulosis

Follicular reticulosis of the lymphoid type has been described by Brill, Baehr, and Rosenthal (1925) in America as follicular lymphoblastoma. It is a disease affecting adults, the average age being from 43 onwards. The course is typically remittent, lasting for four or five years. There is splenomegaly and enlargement of the lymph glands. The disease is characterized by serous effusion, and hypochromic anaemia is fairly constant. The clinical picture in some cases is that of hepatic cirrhosis with splenomegaly. Other cases, however, give the clinical picture of "splenic anaemia" with leucopenia and relative lymphocytosis. The lymph glands show on the cut surface numerous small white nodules. These are enlarged follicles, consisting of large lymphocytes. There is no reticulin increase, and occasional reticulum cells are present. In all about forty-five cases of the disease have been described. The American writers state that the condition responds well to irradiation.

CASE II

This case was diagnosed in life as reticulosis. The patient, a woman aged 58, was admitted for swelling in the abdomen. There was a ten-weeks' history of listlessness, dyspnoea on exertion, and swelling of the ankles. For six weeks there was enlargement of the abdomen with ascites, which was tapped, and at the onset constipation was present. She was admitted on May 24, 1938, and died on June 22, being under observation for four weeks. On admission the spleen was down to the umbilicus and the liver palpable. Glands were palpable in the axillae and groins. Paracentesis was performed on two occasions, 16 pints and 18½ pints of milky fluid being withdrawn. This was sterile and contained no fat. A blood

count showed: red cells, 5,160,000 per c.mm.; haemoglobin, 92 per cent.; white cells, 6,600 per c.mm.—75 per cent. polymorphs, 0.5 per cent. basophils, 0.5 per cent. eosinophils, 22 per cent. lymphocytes, 4 per cent. monocytes.

Post-mortem Examination.—There was oedema of the larynx, and ten pints or more of turbid fluid were present in the left pleural cavity. The lungs were collapsed at the base; the abdomen contained twenty pints or upwards of turbid fluid; the liver weighed 2,280 grammes and was firm and pale. The spleen weighed 1,120 grammes, was 22 cm. long, was dull pink with a thick capsule, and its cut surface was studded with white nodules. The lymph glands were all enlarged, were white, soft, and discrete, and numerous punctate white areas were present on the cut surface. The bone marrow showed similar small white nodules. Microscopical changes in the lymph nodes were recorded thus: "The white areas are the lymphoid follicles much enlarged. They consist of large lymphocytes, with occasional reticulum cells. There is no increase of reticulin fibrils in the follicles." This case was similar in many ways to one described by me in 1933.

CASE III

This patient, a Post Office worker, was under observation for five years. The onset of disease, with swelling of the glands in the groin, occurred when he was 43; later the glands in the axilla became enlarged. At the age of 47 he was admitted to hospital. He then had dental sepsis with ulceration of palate. The Wassermann reaction was negative. There was proptosis of the left eye, and enlarged glands were present about the left orbit and in the left cervical region. A biopsy on one of the cervical glands at this time showed follicular lymphoid reticulosis, with follicles consisting almost entirely of adult small lymphocytes. These glands disappeared under *x*-ray treatment. A blood count showed: 3,930,000 red cells per c.mm.; 68 per cent. haemoglobin; and 4,200 leucocytes, 74 per cent. being polymorphs, 2 per cent. basophils, 1 per cent. eosinophils, 4 per cent. monocytes, and 19 per cent. small lymphocytes. There was a recurrent enlargement of glands for a period of three years. As new groups of glands became enlarged and interfered with his work, *x*-ray treatment was given, the enlargement then subsiding. Three months before death he was admitted with generalized glandular enlargement and a cough. Death resulted from confluent bronchopneumonia with empyema.

Necropsy.—There was generalized enlargement of the lymph glands, and also a mass in the abdomen pressing on the right renal pelvis, causing hydronephrosis. The spleen was large, with a normal pattern. The glands showed small white nodules studded over the cut surface. Microscopically the glands revealed lymphoid follicular reticulosis, and in some of them there were adult and small lymphocytes in the follicles, as had been found in the biopsy material two years previously. In the mass in the abdomen the follicles consisted of large lymphocytes, and reticulum cells were also present. The feature of this case was the extraordinary sensitivity to *x* rays, whereby the disease was checked but not arrested. This was like a case of lymphadenoma, in that the one group of glands enlarged first, and the enlargement then took place in another group. The glandular enlargement was not generalized from the onset.

I believe that similar cases have in the past been regarded as radiosensitive Hodgkin's disease, and that this type of lymphoid follicular reticulosis in a clear-cut clinical entity.

Fibrillary Follicular Reticulosis

This disease is similar to lymphoid follicular reticulosis, but is evidently more rare. It occurs in adults. I described a case in a woman of 61 who was admitted to hospital with a diagnosis of hepatic cirrhosis with splenomegaly and generalized glandular enlargement. There had been recurrent ascites for eighteen months. The blood count was: red cells, 3,770,000; haemoglobin, 50 per cent.; leucocytes, 6,000, 47 per cent. being polymorphs, 5 per cent. monocytes, and 48 per cent. lymphocytes. The lymphatic glands, on naked-eye examination, showed numerous small white nodules. Microscopically these white nodules consisted of irregularly shaped reticulum cells with occasional binucleate forms. A great increase in reticulin fibrils was present in these follicles.

Primary Sinus Reticulosis

This group includes hyperplasia of sinus-lining or littoral cells. An acute type, running a clinical course of great rapidity, with jaundice and increasing anaemia, has been described by Debenedetti and Florentin (1931). It affects adults. The spleen and liver are enlarged, and in the lymphatic glands and elsewhere there is phagocytosis of the red blood corpuscles by the proliferating sinus-lining reticulum cells. Pryce and Reburn have described a similar case in this country.

There was also a chronic type which was originally described as occurring in the spleen (Stengel; Wolbach, 1911). When the lymph glands are affected the normal architecture of the gland is entirely destroyed: circular foci of cellular proliferation surrounded by a zone of peripheral fibrous tissue are scattered throughout the whole gland. The centre of each focus consists of proliferating cells of the histiocyte type, usually with one or more giant cells of the Langhans type. Occasionally the giant cells contain cytoplasmic inclusions. Necrosis has never been observed. Reticulin fibrils and collagen fibrils run in between the cells, as well as encircling the nodules, and fibrosis of the entire nodule results. The aetiology is quite unknown.

Conclusion

This concludes my survey of some of the conditions in which reticular hyperplasia is the underlying tissue change. I hope I have made it clear that well-defined clinical entities are represented by some of the groups into which the conditions have been classified. Cases of lymphadenoma, or Hodgkin's disease, lymphoid follicular reticulosis, myeloid leukaemia, histiocytic medullary reticulosis, Gaucher's disease, and some others fall into their correct position when the tissue changes in a lymph gland are subjected to careful analysis, and the clinical characteristics of other groups should be recognized as our knowledge of the reticular hyperplasias increases. The future should enable us to assign most conditions to their correct classes, but meanwhile the careful examination of lymph gland and bone marrow (preferably before treatment is begun) must take a prominent position in the diagnostic investigation of all cases.

It must be remembered that the ultimate object of classification is (1) to assist in the search for an aetiological factor, and (2) to provide a basis for information as to prognosis and the result of treatment. No real advance can be made until a definite cytological examination is carried out before treatment is begun.

THE VALUE OF THERAPEUTIC MEASURES IN DUODENAL ULCERATION

BY

JAMES RONALD, M.D., M.R.C.P.Ed.
Junior Assistant Physician, Victoria Infirmary, Glasgow

The number of methods recommended for the treatment of peptic ulcer is in itself an indication that there is no specific therapeutic measure for this condition. Treatment, however, whether medical or surgical, is designed to diminish the hyperchlorhydria which is almost always present. To achieve this end elaborate dietetic systems have been evolved, among which may be instanced the Sippy and Lenhartz regimes and their many modifications. Considerable claims have been made for all these methods, and much success has accompanied their use, but none of them has given invariably successful results. It has indeed been questioned whether equally good results may not be achieved without these meticulous dietetic and medical measures, simply by putting the patient to bed and feeding him at regular intervals with a bland light diet. Diminished gastric acidity has often been regarded as an essential to symptomatic improvement and as an important factor in the healing of peptic ulcers, but it has nevertheless been noted (Moore, 1938) that hyperchlorhydria may remain or may even become more intense while healing is taking place, with symptoms in abeyance.

It has thus seemed worth while to attempt to determine: (*a*) whether it is possible to control a severe degree of hyperchlorhydria throughout the day by the methods commonly adopted, and (*b*) whether such control, if attainable, is an essential to symptomatic improvement and to the healing of the ulcer. With a view to determining these points, sixty persons were investigated, fifteen of whom were healthy control subjects, free from symptoms and having presumably normal gastric function. The remaining forty-five cases were suffering from duodenal ulceration and hyperchlorhydria, the presence of ulceration having been confirmed radiologically.

Method of Investigation

The patients were divided into groups (see table) and three different methods of treatment adopted—namely, light hospital diet (the meals being given at regular and rather frequent intervals and without any drugs), a Sippy regime with alkalis, and a Sippy regime with magnesium trisilicate (magsorbent). The cases were treated in bed. Following a full routine examination an ordinary fractional test meal was carried out and the presence of hyperchlorhydria confirmed. Treatment was then instituted, and on the following day a Ryle's tube was again passed and a specimen of gastric contents obtained every hour for a period of twelve hours, the specimens being withdrawn midway between the taking of food or drug. This "long test meal" was repeated at the beginning of the third week. The urinary pH of the patients having alkalis was determined morning and evening by means of B.D.H. universal indicator, and the blood urea and the carbon dioxide combining power of the blood (van Slyke method) were estimated every few days. The Ryle's tube was left *in situ* for the whole period unless the patient preferred to re-swallow it hourly. Analysis of the gastric contents was carried out in the usual manner.

Table showing the Number of Cases in Each Group

Group	Treatment	Ulcer Cases	Healthy Controls
A	Light diet (no drugs)	15	5
B	Sippy diet (with alkalis)	15	5
C	Sippy diet (with magsorbent) ..	15	5

In employing this type of test in the present series certain admittedly artificial criteria have been adopted. It has been assumed that a free acidity of 40 clinical units represent the upper limit of normal (Vanzant *et al.*, 1932) and that acidity above this level represents hyperchlorhydria. Cases were therefore considered to be "controlled" if the free acidity did not exceed 40 oftener than twice in twelve hours, and then not in consecutive specimens. A case was regarded as "partially controlled" if the free acidity reached 40 on not more than three non-consecutive occasions, one of these being in the fasting juice. If these criteria were not satisfied the case was considered to be "not controlled."

Results

Group A.—In this group the healthy subjects showed a comparatively low level of free acid throughout the day, with slight fluctuations from hour to hour. The taking of food had little effect on the acid level. Very different results were noted in the ulcer cases. The hyperchlorhydria was pronounced throughout the day, and in only one case was "control" obtained. In several cases, on the other hand, the hyperchlorhydria became more severe. Clinically, however, these cases improved rapidly and became symptom-free. It was difficult to decide whether healing of the ulcer was taking place in the presence of the severe hyperchlorhydria, but in view of the disappearance of subjective and objective signs, and the fact that no relapse has occurred after a year, it seems likely that this was the case.

Group B.—In the healthy subjects in this group a low acid level obtained throughout the twelve hours, but in no case did complete neutralization occur. Sippy himself stated that "control (that is, absence of free hydrochloric acid) should be maintained from the beginning of treatment," but in the present investigation this was never obtained in either the normal or the hyperchlorhydric case. Of the fifteen hyperchlorhydric cases six were "controlled" and four "partially controlled." It was noted, however, that there was no method of distinguishing clinically between "controlled," "partially controlled," and "not controlled" cases. In the cases "not controlled" within the first two days no "control" was obtained after three weeks' therapy, nor did any significant variation occur in their acid curves. A similar observation was made in the "partially controlled" cases, in which no further alteration of acid level resulted from therapy. It would appear that if "control" is not obtained within the first few days no further modification of acid secretion can be expected by prolonged treatment. In none of these cases on massive alkali therapy did alkalosis develop. This complication was noted by Hardt and Rivers (1923) in some of Sippy's own cases, and has since received considerable attention (Cooke, 1932; Oakley, 1935). The alkali reserve and the blood urea tended to rise slightly during treatment, but they always remained well within normal limits, and no signs of alkalosis were noted clinically or by routine tests. Relief from symptoms was satisfactory in all cases, and there has not been a relapse during the past year.

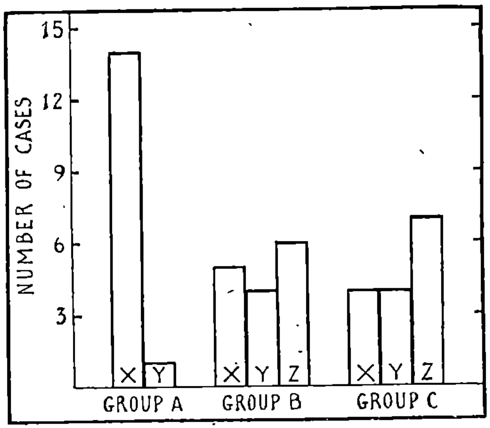
Group C.—The findings in this group were similar to those obtained in Group B. In the healthy subjects the degree of neutralization obtained was slightly less than in the analogous series in Group B. Of the hyperchlorhydric cases, seven were “controlled” and four “partially controlled.” Complete neutralization was not effected either in the normal or in the hyperchlorhydric cases, and it was again impossible on clinical grounds to discriminate between the different grades of “control.” No special advantage was noted in favour of magnesium trisilicate as compared with alkalis, although a slightly larger number of cases were “controlled” in this group. In cases in which the acid level was modified during the first few days no further modification took place after some weeks of treatment, and cases in which the acid curve was not affected during the first few days showed no significant alteration at a later date. All cases, however, showed rapid clinical improvement and became symptom-free: one case has since relapsed owing to a marked dietetic indiscretion, but the other cases have shown satisfactory progress over a period of one year.

Discussion

Many observers have indicated the disadvantages of the “short” test meal, and it seems probable that the “long” meal offers a better evaluation of gastric function, as the patient is proceeding with his ordinary occupations of the moment and becomes thoroughly accustomed to the procedure. The method has not as yet been widely employed, though among others who have made use of it may be mentioned Wosika and Emery (1936) and Mann (1937). Bengt Ihre (1938) has utilized it in an extensive investigation, using a Lagerlof-Agren tube and a special technique.

Hellbrandt and his colleagues (1936) showed that there was considerable variation in the composition of gastric juice examined at different periods of the day, and that the acidity often exceeded that demonstrable during an ordinary fractional test meal. These observations were confirmed in the present investigation, and it was further observed that the acid-level fluctuations occurring throughout the day in the healthy subject were surprisingly little affected by the taking of food or drugs, or by alterations in the type of food taken. Complete neutralization of free acid was never obtained, and there was considerable variation from hour to hour. The variations were slight in comparison to the fluctuations seen in the hyperchlorhydric cases, however, the latter showing very pronounced and unpredictable alteration from low to high acidity and vice versa. This alteration was unaccompanied by symptoms or clinical signs. The effect of diet and drugs in diminishing the height and duration of such spells of hypersecretion varied in individual patients, the acid level in some cases being considerably affected, and in others not at all. The graph indicates the relative degrees of “control” obtained by the different methods.

Although the cases were carefully studied, it was not found possible to correlate the variations in acid level with the symptoms and signs or with variations in these. The cases reacted similarly, irrespective of the treatment adopted, in that symptoms disappeared within a few days. Signs such as tenderness or rigidity took longer to disappear, but were absent in all cases by the end of ten to fourteen days. This improvement took place whether the acidity was diminished, unaltered, or increased, and clinically there was no indication as to whether or not the acidity had altered. Although twice as many cases on the diet–drug regime were “controlled” as those on light diet alone, the progress of both series has been similar, and there has been no relapse, during a period of one year, except in one case. To achieve “control” if possible seems physiologically sound, but these facts suggest that such “control” is not essential to the healing of the ulcer.



Graph showing results of treatment in hyperchlorhydric cases. X = “not controlled,” Y = “partially controlled,” Z = “controlled” cases.

Current research shows that there are factors other than hyperacidity concerned in the production of peptic ulceration, and the view that too much attention can be devoted to the local lesion is beginning to gain ground.

Summary and Conclusions

A series of cases of hyperchlorhydria associated with duodenal ulceration has been investigated, and it is noted that:

1. The hyperchlorhydria is but little modified by light diet without drugs, but symptoms are relieved.

2. The hyperchlorhydria is significantly modified by a Sippy regime.

3. No special advantage is noted in the use of magnesium trisilicate as compared with alkalis.

4. In the absence of vomiting, the risks of alkalosis developing during alkali therapy are slight.

5. No distinction can be drawn on clinical grounds between cases in which hyperchlorhydria during treatment is or is not altered.

6. Healing of a peptic ulcer and relief of symptoms can take place although the hyperchlorhydria is unaltered or even becomes more severe.

7. The “long test meal,” lasting at least twelve hours, is of considerable value in the investigation of gastric function and the assessment of the effect of different agents upon secretion.

It is a pleasure to express my thanks to Professor D. M. Dunlop and Dr. A. M. Scott for advice and criticism.

ESTIMATION OF BLOOD SUGAR BY THE PRACTITIONER

A MODIFICATION OF FOLIN AND WU'S METHOD

BY

H. R. MILLAR

(*From the Diabetic Clinic, King's College Hospital, London*)

The need for a quick, easy, and inexpensive method of blood-sugar estimation has long been felt by a large number of doctors in their own practices and at the smaller hospitals where no laboratory facilities are present. Usually the difficulty has been either the expense of a colorimeter or the tedious checking of solutions and the liability to error in the titration methods.

Folin and Wu's method is a colorimetric estimation which for greatest accuracy demands the use of a colorimeter, but I have found that a simple dilution of the final colours in specially calibrated tubes and comparison by the naked eye gives results within ±10 mg. of the more precise colorimeter reading; this is accurate enough for all clinical purposes. The results shown below are duplicated estimations, one being obtained by the original Folin-Wu method, using the colorimeter, and the other by the means here described.

Folin and Wu's Mg.	Dilution Method Mg.	Folin and Wu's Mg.	Dilution Method Mg.
172	180	126	130
98	100	178	180
208	220	200	190
169	180	325	320
250	240	189	200
88	90	187	180
86	95	194	190
149	160	111	120
73	80	400	400
303	280	260	250
152	160	72	80
104	120	95	97
170	160	317	320
136	145	212	205
261	260	303	300
175	170	303	300
196	200	130	130
106	107	104	100
95	95	160	167
143	147	114	115
87	85	246	238
237	230	253	260
172	158	176	167
200	198	168	175
144	147	206	205

It will be seen that of these fifty duplicated estimations twenty-three have a difference of less than 5 mg., sixteen of 5 to 10 mg., nine of 10 to 15 mg., one of 15 to 20 mg., and one exceeding 20 mg. Twenty of these estimations were also duplicated entirely by the modified method; of these eight have no difference, eight have a difference of 5 mg., and four a difference of 10 mg.

Description of Apparatus

The method has been designed to enable estimations to be done with the minimum of technical knowledge and laboratory experience. Thus the solutions, which are the same as those used in the original method, are placed in order of use from left to right in a specially arranged box which has a handle on top and is easily portable. Each bottle contains its own pipette of automatic design, and the necessary tubes are calibrated to requirements. The solutions remain stable for many months, and ccuracy with the standard glucose is ensured by putting he required amount in a small sealed ampoule. The omparison tubes in which the dilution of the final colour made are calibrated to show the actual blood-sugar ading in milligrammes per 100 c.cm. at the point where e two colours match after dilution. The complete apparatus, with solutions sufficient for thirty-six separate estimations, can be obtained from Messrs. Baird and Tatlock (London), Ltd., 14–17, St. Cross Street, Hatton Garden, E.C.1.

Directions for Use

Blood.—Into a tube marked A place water (see Note 8) up to the mark (3.5 c.cm.). Collect blood into the 0.1 c.cm. blood pipette up to the mark by pricking the ear or finger or from venous blood, and wash this into the water in tube A by sucking the water up and down until the pipette is quite clean. Add to this 0.2 c.cm. sulphuric acid solution, shake, and add 0.2 c.cm. sodium tungstate solution. Mix thoroughly by gentle shaking. Place a filter paper and funnel in tube B and filter into this the solution from tube A. When filtration is complete take 2 c.cm. of the filtrate by means of the pipette marked F and put into tube C (marked at 12.5 c.cm.). To this add 2 c.cm. Folin copper solution, shake gently to mix, and place a capillary stopper in the top of the tube.

Standard.—Into tube S1 put a standard ampoule. Break this on the bottom of the test-tube by means of the glass rod provided. Do not remove the rod, but hold it above the water-line and add water up to the mark on the test-tube, and to this add 0.4 c.cm. sulphuric acid and 0.4 c.cm. sodium tungstate (0.2 c.cm. twice). Shake thoroughly to mix, holding the glass rod on to the side of the test-tube.

When thoroughly mixed, wash the filtrate pipette by taking 2 c.cm. of the solution and discarding. Take another 2 c.cm. and put into tube S2 together with 2 c.cm. of Folin copper solution. Shake to mix, and place a capillary stopper in the top of the tube. Place both tubes (C and S2) in a water bath or small saucepan of *boiling* water and leave for six minutes. The water bath or saucepan must be small enough to allow the tubes to stand so that their tops are well out of the water. Cool the tubes for two minutes in cold water and then add to each 2 c.cm. of phosphomolybdic acid solution. Shake gently until there is no more frothing. Add water up to the mark and mix by inverting on the *clean* thumb. Into the comparison tube marked S pour the standard solution from tube S2 up to the 100 mg. mark, and into the comparison tube marked U pour the solution from tube C also up to the 100 mg. mark. Dilute the stronger coloured solution with water until the colours match. Mix by inverting on the thumb after each addition of water. The result of the estimation is marked on the tube at the point where the dilution is completed.

Notes

1. Background for Matching Colours.—A good method is to stand with the light coming from behind, the tubes held up in front of the face with one hand and a piece of white paper held at an angle behind the tubes with the other.

2. A space of about ten seconds should be allowed to elapse after each addition of water before comparing the colours.

3. When the unknown colour is very much stronger than the standard, a first dilution may be made large enough to take the comparison to within 60 mg. or so of the standard colour. Thereafter it is advisable to add water at the rate of 10 to 20 mg. at a time.

4. Where doubt is felt as to the final colour match, take a reading, add another 10 mg. of water, and compare again. If the first reading was correct the second will be obviously weaker.

5. Automatic Pipettes.—These are designed to "deliver" the required volume, and as each solution has its own pipette the excess which pours over into the bulb may be put back into the bottle. Those contained in the bottles need not be cleaned. The filtrate pipette, however, should be washed with water and allowed to drain. It

should never be used wet, except when enough solution is available to allow of a first wash.

6. The Folin copper solution has a tendency to deposit cuprous oxide. This can be seen on the bottom of the bottle when present, and is orange-red in colour. The solution is kept in a dark bottle to prevent this; but if it occurs the solution must be decanted and the bottle washed and dried before the solution is returned.

7. Cleaning.—A good wash under running cold water, and draining, is all the cleaning necessary. Wash tube A before it has time to dry.

8. Ordinary tap-water is perfectly safe to use in making the estimations.

In evolving this method I am greatly indebted to Dr. R. D. Lawrence for his invaluable criticism and suggestions and for his kind permission to carry out the work in the diabetic clinic at King's College Hospital. I owe thanks to the whole staff of the clinic for their encouragement.

THE SEROLOGICAL GROUPS AND TYPES OF STREPTOCOCCI ISOLATED FROM EXCISED TONSILS

BY

E. V. KEOGH, M.B., B.S.

IAN MACDONALD, M.B., B.S.

JOAN BATTLE, B.Sc.

R. T. SIMMONS, A.A.C.I.

AND

STANLEY WILLIAMS, M.D.

(*From the Commonwealth Serum Laboratories and the Children's Hospital, Melbourne*)

A survey of the serological types of haemolytic streptococci in Australia has been proceeding at these laboratories for the past year. The progress findings in respect of the streptococci isolated from scarlet fever patients in Melbourne and Adelaide, from puerperal and surgical infections, and from normal throats in Melbourne have already been reported (Keogh and Kelsey, 1939; Keogh, Macdonald, Battle, and Puckey, 1939). The strains found in scarlet fever patients were rarely isolated from normal throats or from patients with puerperal or surgical infections. This present study was undertaken primarily to discover whether the predominant serological types of streptococci encountered in the tonsils would be those commonly associated with scarlet fever or those commonly found in surgical infections and in the throats of healthy adults and children. The results, however, will be discussed not so much from that particular viewpoint as from their bearing on the much-debated question of the indications for tonsillectomy.

There have been numerous previous investigations of the bacterial flora of tonsils, most of them, however, undertaken before the introduction by Lancefield of the precipitin methods, which enable a distinction to be made between probable pathogens (Group A) and probable non-pathogens (not Group A) among strains of haemolytic streptococci. So far as we are aware, no study of the tonsillar flora using the finer analysis of identification of the type of strains by the slide agglutination method of Griffith has been carried out, though a similar line of inquiry is being pursued in Sydney at the present time.

Methods

The tonsils examined were removed at routine operations at the Children's Hospital, Melbourne, during last summer and autumn (November, 1938, to March, 1939). Immediately after excision they were put in sterile containers and placed in a refrigerator until the following morning. Both tonsils of each patient were minced up in a single tube of sterile broth, a drop of which was plated on neo-peptone blood agar. Subcultures into tryptic digest broth were made from the various colonial types of beta-haemolytic streptococci present on the plates. The broth tubes were incubated overnight at 30° C. and the deposit used for typing by Griffith's technique. Strains which failed to show specific agglutination with the type sera at our disposal were then allotted to their respective Lancefield groups, using the formamide method of Fuller (1938) for extraction of the group polysaccharide. Any strains which agglutinated with our Type 4 or Type 28 sera were also checked as to group, since we find that these sera may give apparently specific agglutination with strains belonging to Group B, C, or G. The sera used had already been employed in the classification of large numbers of strains, and included samples of the following Australian types not appearing in the Griffith series, provisionally named "Wade," "Stewart," "Hale," "Woodbury," "John," and "Alli," which had been isolated from surgical and puerperal infections.

Results

Haemolytic streptococci were isolated from 259 of 378 pairs of tonsils (68.5 per cent.). Sawers and Barrett (1933) found haemolytic streptococci in the crypts of 61 per cent. of tonsils examined by them in Sydney. The strains which we isolated belonged to the following groups (Lancefield): Group A, 189 (50 per cent.); Group B, 21 (5.5 per cent.); Group C, 33 (8.7 per cent.); Group G, 28 (7.4 per cent.). It will be noted that 271 strains were isolated from 259 tonsils; in twelve cases two different strains were present. In eleven instances one strain belonged to Group A, the other to either Group B, C, or G; in the remaining case two different serological types of Group A streptococci were isolated (Types 12 and "Alli"). This incidence of Group A strains in the tonsils is ten times higher than in the throats of healthy children and adults. The details are set out in Table I.

TABLE I

Source of Strains	Percentage from which Haemolytic Streptococci were Isolated	
	Group A	Groups B, C, G
378 tonsils removed at operation	50.0	21.7
466 throats of healthy adults and children	4.5	13.1

This comparative incidence of Group A and non-Grou A strains in the throats of healthy subjects agrees with th findings of workers in other countries. Hare (1935) esti mated that in England about 7 per cent. of the genera population carry Group A streptococci and 13 per cen other groups. Davis and Guzdar (1936) found a carri rate of 3 per cent. of Group A streptococci and 6.4 p cent. of non-Group A streptococci in healthy Chine Our figures in the healthy group for Groups B, C, G (1 per cent.) may be high, owing to the inclusion of a num of children from an institution many of whom w carriers of a Group C strain. The objection may be ra that this very high incidence of the potentially pathoge

Group A strains is due to a greater *a priori* probability of isolating haemolytic streptococci from the excised tonsil than from a throat swab. But since there is no statistically significant difference in the percentages of non-Group A strains recovered from both sources, this factor cannot entirely account for the discrepancy. Further evidence against this assumption is provided by the fact that if haemolytic streptococci were present in the tonsils they were usually the predominant organism and were frequently obtained in practically pure culture. The data are shown in Table II.

TABLE II.—*Percentage of Haemolytic Streptococci in Bacterial Flora of Excised Tonsils (excluding 12 Tonsils which contained Two Strains each)*

Percentage of Colonies of Haemolytic Streptococci to Total Colonies per Plate	Group A Strains	Non-A Strains	Total
Less than 10..	30 (17.1%)	14 (19.7%)	44 (17.8%)
10 to 50	37 (21.0%)	10 (14.1%)	47 (19.0%)
50 to 90	50 (18.4%)	18 (25.4%)	68 (27.5%)
90 to 100	59 (33.5%)	39 (40.8%)	88 (35.6%)

It will be seen that colonies of haemolytic streptococci predominated in the plates from 63 per cent. of these infected tonsils, and were practically the only colonies present in 36 per cent. of them. It is improbable that throat swabs taken by an experienced paediatrician or otorhinologist, as were all in our "normal" series, would have failed to disclose the presence of streptococci in tonsils harbouring them in such numbers. Tonsils from which either the predominant scarlatinal strains (2, 17, "Wade") or non-scarlatinal strains (6, 27, "Stewart") were isolated showed no significant differences in the intensity of infection when these two groups were compared with each other or with the group of tonsils infected by other types. Taken at their face value the results reveal that, as a group, children coming up for tonsillectomy at the Children's Hospital, Melbourne, show a significant and large increase in the incidence of pathogenic streptococci in their tonsils, but no significant increase in the incidence of the doubtfully pathogenic non-Group A strains.

Of the 189 Group A strains isolated from the tonsils, 143 (75.6 per cent.) were identifiable by the type sera at our disposal. The distribution of types was as follows:

Type	No.	Type	No.
6	38	"Coleman"	4
"Stewart"	23	22	4
27	16	"Wade"	3
2	11	"Hale"	3
4	10	"Murphy"	2
"Alli"	10	9	1
11	6	"John"	1
17	6	Untyped..	46
12	5		

Of these, Types 6, "Stewart," and 27 account for 40.7 per cent. of the total. They are the types encountered most often in surgical streptococcal infections and in the throats of healthy subjects. Strains of the types (2, 17, and "Wade") which were together responsible for 90.5 per cent. of cases of scarlet fever in Melbourne during the same period are only rarely found in the tonsils, being 10.6 per cent. of the total. The data are given in Table III.

TABLE III

Source of Strains	No. of Strains	Type 2, 17, or "Wade"	Type 6, 27, or "Stewart"
Scarlet fever	198	90.5%	1.5%
Surgical infections	31	6.5%	58.1%
Tonsils (removed at operation)	271	10.6%	40.7%

The close correlation between the distribution of types in the tonsils removed at operation and in surgical infections is apparent. We have not yet investigated the streptococci associated with acute follicular tonsillitis, but sixteen strains labelled "tonsillitis" which we have received during the past year from various sources in Melbourne were equally distributed between "scarlatinal" and "non-scarlatinal" types: seven being either Type 2, 17, or "Wade," seven being either Type 6, 27, or "Stewart," and two belonging to other types. Also, of five strains isolated from cases of bronchopneumonia, three of which were complicated by empyemata, two belonged to Type 17, two to Type "Stewart," and one to Type "Wade." These findings, although limited in number, suggest that there may be no great difference in pathogenicity between these "scarlatinal" and "non-scarlatinal" strains, although infection with the "scarlatinal" types is much more likely to be associated with the appearance of a rash.

In a small group of the children there is conclusive evidence that the streptococci isolated from the removed tonsils had been present in the throat months previously and were responsible originally for acute or mild symptoms. Of eleven children from whose excised tonsils Type 2 strains were isolated the histories of ten could be traced. Of these ten, two had had scarlet fever due to Type 2, and six had been direct contacts of scarlet fever patients (Type 2). One had a history of severe septic sore throat (diagnosed in the acute stage at the Children's Hospital, Melbourne) but no history of direct contact with scarlet fever. The remaining child had not, so far as could be ascertained, been in contact with scarlet fever, nor had he any very acute symptoms. In respect of the two children who had had scarlet fever, and of one contact, we know the original date of isolation of the Type 2 strain, and can state definitely, therefore, that in these children the same strain of streptococcus had been present in the tonsils for four, five, and five months, respectively. As yet no such evidence is available for those types not associated with a rash, since the onset of the original infection is not so easily determined. We hope, however, in the next year, to follow the state of tonsils in children bacteriologically examined during an attack of follicular tonsillitis.

Discussion

The findings presented in this paper leave little room for doubt that the tonsils removed at the Children's Hospital, Melbourne, contain haemolytic streptococci in a proportion greatly in excess of normal—a difference due almost entirely to a preponderance of pathogenic strains (Group A), with no corresponding increase in the number of doubtfully pathogenic strains of other groups. The clinical indications for tonsillectomy, therefore, seem to be supported by the bacterial findings in about 33 to 50 per cent. of the cases. It seemed not unlikely that more rigorous indications for the operation might be required in a teaching hospital than in general practice. We therefore examined all tonsils (twenty) removed during a three-week period at a large private hospital. We were unaware of the names of the surgeons, who were ignorant of the purpose of the inquiry. The bacteriological findings in this group coincided so precisely with those of the hospital group that we did not pursue this line of investigation.

It can be argued that, given enough time, the natural resistance of the children would have succeeded in eliminating the streptococci from the infected tonsils, and that, even if the infection persisted indefinitely, there is no direct evidence that a tonsillar carrier of pathogenic streptococci suffers any disturbance in health. In the three instances in which there is certain evidence of the date of the original infection it could be shown that this had persisted for from four to five months and that the cocci were still present in large numbers at operation. We have no definite information as to the duration of infection with types other than Type 2. But since from four to eight weeks usually elapsed between the recommendation for operation and its actual performance, and in most cases symptoms had been present for weeks or months before operation was advised, the presumption is that if these symptoms were due to streptococcal infection of the tonsils spontaneous cure had not occurred.

Chronic tonsillar carriers of diphtheria bacilli do not suffer any apparent ill effects from continued absorption of toxin if it occurs. Such evidence is also lacking in regard to chronic streptococcal infections of the tonsils, apart from their debatable relation to rheumatic conditions. Group A streptococci produce erythrogenic toxin *in vitro*, whether they are commonly associated with scarlet fever or not, though there is a certain amount of direct and indirect evidence that strains of types commonly causing scarlet fever are more powerful toxin producers (Allison, 1932). The chronic nasal diphtheria carrier often has a persistent sanguineous nasal discharge, usually without any noticeable constitutional upset. Perhaps the child with chronic streptococcal tonsillitis suffers a roughly comparable inconvenience. Were the chronic diphtheritic rhinitis curable by as simple an operation as tonsillectomy the indication for such treatment would be strong, from the point of view of both benefit to the child and elimination of a carrier. Chronic streptococcal carriers must menace the health of other children, and we know of instances where they have been the origin of cases of scarlet fever. It would be premature to recommend tonsillectomy on these grounds alone, except in special circumstances.

The preceding remarks refer only to the children—from a half to a third of the total—from whose tonsils streptococci were isolated. It has been urged by various writers that not only are a number of tonsillectomies carried out when the symptoms are in reality due to sinusitis, but, further, that the chronic infection of the tonsils is caused by reinfection from the sinus secretions. We wish only to discuss whether such a process could account for the high proportion of streptococcal tonsillar infections in this series. Simultaneously with this investigation of the tonsils, McInnes, at these laboratories, has been studying the bacterial flora of acute and chronic infections of the maxillary antrum. Out of 100 consecutive cases haemolytic streptococci were isolated on only five occasions, and only two of the five strains belonged to Group A. It is unlikely, therefore, that the tonsillar infection with streptococci is secondary to streptococcal antral infection.

The above should not be construed as a panegyric on routine tonsillectomy. In Melbourne about 17 per cent. of children of school age have lost their tonsils, as compared with 50 per cent. in the English "public" schools, and of these 17 per cent. probably not more than a third could ever have been classed as streptococcal carriers. The deductions from the data form a working hypothesis for further investigations on these lines, in which we shall attempt to correlate the clinical, bacteriological, and histopathological findings.

Summary

Group A haemolytic streptococci were isolated from 50 per cent. of a group of tonsils removed at operation in Melbourne, but from only 4.5 per cent. of throat swabs from healthy children and adults.

Haemolytic streptococci of others groups (B, C, G), which are rarely the cause of serious human infections, were recovered from 22 per cent. of the tonsils and from 13 per cent. of the throat swabs of the healthy group.

The significance of these findings is discussed in relation to the indications for tonsillectomy.

RETROPULSION OF THE NUCLEUS PULPOSUS

A CRITICAL REVIEW

BY

SIDNEY PAPPWORTH, M.Ch.Orth.

There should be a close season for the writing of articles. This would provide a breathing space in which the new ideas could be digested and the new operative procedures considered thoroughly from their theoretical aspects before embarking on the practice of them. Orthopaedic surgery is in great need of this close season. With the change from the use of hands and simple apparatus to the use of pneumatic hammers and mechanical marvels of rare alloys—a change, as it were, from the white coat to the boiler suit—there has resulted a flux of articles, mostly advocating some bolder, and therefore better, operative procedure. I, fortunately, have had enough leisure to examine in some detail the claims of a new procedure.

Before operating I decided to solve certain questions. These were: Can retropulsion of the nucleus pulposus cause symptoms? If it can, is laminectomy the only treatment? Are the results of laminectomy such as to justify operation? A study of the main articles on the subject revealed certain surprising facts which are the subject of this essay. The articles under review are:

I. Mixter and Barr (1934). *New Engl. J. Med.*, **211**, 210.
II. Mixter and Ayer (1935). Ibid., **213**, 385.
III. Barr (1937). *J. Bone Jt. Surg.*, **19**, 323.
IV. Barr, Hampton, and Mixter (1937). *J. Amer. med. Ass.*, **109**, 1265.
V. Mixter (1937). *Ann. Surg.*, **106**, 777.
VI. Barr (1938). *British Medical Journal*, **2**, 1247.
VII. Live and Camp (1937). *J. Bone Jt. Surg.*, **19**, 776.

The first six articles deal with a gradually increasing number of cases under the care of the same group of Boston authors, each article including the previously recorded cases in the series. I propose to refer to statements in these articles, and I shall then give the number of the article, the page, and the column for easy verification.

Can the Retropulsion cause Symptoms?

That retropulsion of the nucleus pulposus does occur is quite true. Andrae, working with Schmorl, found it in 15.2 per cent. of all spines. It must therefore be shown conclusively that the retropulsion actually causes the symptoms and is not merely an incidental finding.

AETIOLOGY

The condition is supposed to be traumatic in origin. In the first series there were nineteen cases, eight (41.2 per cent.) with a history, five of them of recent trauma (I, table opposite page 210). In the second series the percentage was 41.2—that is, fourteen out of thirty-four, seven having a recent trauma (II, page 386, column i). In the third series, which, of course, included the first two, the percentage had unaccountably risen to 77.5—that is, thirty-one out of forty, twenty-one having a recent trauma (III, 328). The percentage was given as about 80, with 50 per cent. of recent trauma, in the fourth article (IV, 1265, ii); became "about 60 per cent. of these cases will give a history of trauma at, or shortly before, the onset" in the fifth (V, 777); and returned to 80 per cent., with 50 per cent. of recent trauma, in the sixth article (VI, 1248). Love and Camp do not believe trauma to be an important aetiological factor, and give no details of its incidence in their cases.

AGE OF PATIENTS

Mixter and Barr's average was 39.3 years (I, table, 210). The second article does not give an average, but states that the youngest patient was 20, the oldest 64, and that two-thirds were between 30 and 50 (II, 386, i). Barr, in his series, while including the previous cases, seems to have forgotten the patient of 64, for he gives the ages as varying from 20 to 58, with an average of 37 (III, 327). The next article has the same average of 37 (IV, 1266, i). The ages are not stated in the next two articles. Love and Camp give the average age of their patients as 39.8. We may therefore take it that the average age of all the patients was about forty years. This is of great significance, because at this age, or even many years before, it is rare to find a "normal" disk among "normal" people if we take the adolescent spine as the "normal" (cp. Beadle (1931), Med. Res. Cncl. Spec. Rep. Ser. No. 161, p. 32). This must raise doubts again as to whether any disk lesion may not be incidental rather than causative of symptoms.

SYMPTOMS AND SIGNS

The main symptom is pain, but pain differing in no way from the ordinary case of "sciatica" or "low back ache." It has a certain remarkable peculiarity: the distribution bears no relation to the nerve root alleged to be pressed upon. All cases had pain in the postero-lateral area of the thigh—that is, the second sacral dermatome (III, 329). "The areas of referred pain were identical no matter whether the fifth lumbar or first sacral nerve was involved" (III, 330). Where there was loss of sensation this also did not occur in the expected dermatome. In view of Foerster's work one would not expect to find any loss of sensation in pressure on a nerve root. Once again, is the incidental finding being mistaken for the causative factor?

Muscular weakness and paralysis were found in the first series (I, table, 210). The authors of the second paper say that the "weakness is more apparent than real, due to the protective spasm. Yet flaccid weakness and rarely paralysis were definitely observed in six patients, a unilateral foot-drop being a rare but striking finding" (II, 387, i). Still more striking were the cases of Barr: "In one instance one foot was essentially flail. In one case the gastrocnemius was the only muscle involved" (III, 332). On anatomical grounds it would be difficult to explain how pressure on a nerve root could cause a flail foot; it would be even more difficult to explain how it could cause an isolated muscle paralysis.

If symptoms are due to pressure on a nerve root it is difficult to conceive of its causing intermittent symptoms. "Symptoms have remained unilateral and have been intermittent over a period of months or years, the patient enjoying relatively good health between attacks" (II, 387, ii). Barr (III, 329, and VI, 1248) says that 40 per cent. have remissions. "Almost half had a history of remissions and exacerbations" (IV, 1265, ii). "The pain comes in attacks and there may be long remissions" (V, 778).

The only significant change in the tendon reflexes is a loss of the ankle-jerk in 40 to 50 per cent. of cases—no matter which nerve root is affected. Mixter and Ayer say that "occasionally the knee-jerk was sluggish" (II, 387, i). Barr included these cases in his later series, yet says that the knee-jerks were normal in every instance (III, 331).

In the cervical cases of Mixter and Ayer there was a dynamic block in the cerebrospinal fluid in seven out of the eight cases, but it was "always partial and sometimes very slight indeed" (II, 389, ii). Yet this series contained Mixter and Barr's cases in which there was one complete block (I, table, 210). A co-ordination committee appears to be required in Boston.

The first significant pathological finding is a raised protein content of the cerebrospinal fluid. "Every fluid showed an elevation of its protein content. The amounts were between 56 and 91 mg. per 100 c.cm." (II, 387, ii). Perusal of the table in the first article raises doubts as to whether this is completely accurate, while the later articles reveal a normal protein content in from 12.5 (III, 334) to 15 per cent. (VI, 1248) of cases. The following point must be stressed: "The causes of a total protein content above normal limits need further investigation. We have records of twenty-one unoperated-upon cases that were subjected to lipiodol examination with negative findings. In four the total protein was below 40 mg. per 100 c.cm. and in seventeen the elevated protein content has not been explained satisfactorily" (V, 779). Is the raised protein in the operated-upon cases also a coincidence?

The direct radiograph is of no value. Intrathecal lipiodol examination reveals deformation of the dural sac shadow in the Boston series, but "a broadening of the nerve root shadows or displacement or deformity of the nerve root shadows" is looked for by the Mayo Clinic authors—Love and Camp. The true appearance of a disk lesion is therefore not clear. Whether the pictures reveal real pathology or merely incidental markings is even less clear.

DIFFERENTIAL DIAGNOSIS

Love and Camp sum up this question by saying that "there are no physical, neurological, or orthopaedic signs which are found alone in protrusions of the intervertebral disks. All of the known signs may also be found in other conditions." Other conditions were, however, considered. Thus we find Mixter and Ayer stating that "in several [cervical] cases a diagnosis of multiple sclerosis was considered until the demonstration of block [by lipiodol] made that diagnosis untenable" (II, 390, i). Lest it be thought strange that there should be any confusion between multiple sclerosis and pressure on a nerve root or on the spinal cord, I must add that Love and Camp also seem to have found difficulty even in their lumbar cases, for they write: "Usually there is a paucity of neurological findings in cases of protrusions of the disks, but in some there is definite and well-marked evidence of disease of the spinal cord. In some of these cases the clinical picture may be that of syringomyelia or multiple sclerosis. In one of our cases at the clinic, because of an associated severe diabetes mellitus, the diagnosis of diabetic neuritis was entertained until fluoroscopic study with lipiodol settled the question." We are not told how this confusion between pressure on a nerve root and the symptoms and signs of disseminated sclerosis or the dissociated anaesthesia, etc., of syringomyelia can arise.

Thoughts about the danger of confusing causative factors with incidental findings are bound to arise when we consider certain cases. Mixter and Ayer, for example, found matting of the roots of the cauda equina in one of their cases; Love and Camp found two cases of tumour in addition to the retropulsion. Again, Love and Camp had six cases of multiple lesions: one case had lesions of all disks between the eleventh dorsal and fifth lumbar vertebrae. We are not given the symptoms and signs in these cases, so we cannot discover which disk was responsible for symptoms and which were incidental findings. Case 5 of Mixter and Barr's series (I, table, 210) is that of a woman aged 53. There was no history of trauma. She complained of numbness and stiffness of the legs. She had incontinence and a complete motor and sensory paraplegia. There was a partial dynamic block of spinal fluid. The total protein in the cerebrospinal fluid was 37 mg. per 100 c.cm. A direct radiograph showed calcification in the disk between the fourth and fifth dorsal vertebrae. Lipiodol examination was not performed and operation was not allowed. She died later, and necropsy revealed calcification in a posteriorly prolapsed nucleus pulposus at the expected level. The patient, however, died of pernicious anaemia. Could this have really been a case of subacute combined degeneration of the cord, and the retropulsion merely an incidental finding—one of the 15.2 per cent.?

Treatment and End-results

Mixter and Ayer, in the second paper, report negative findings at laminectomy after negative lipiodol examination; yet Barr, while including these cases in his series, says that at operation the retropulsion was found in all cases. The next paper, however, states: "One exploration after a positive roentgenological diagnosis and six after a negative diagnosis gave negative results" (IV, 1268, ii). Mixter mentions these seven cases, but says: "In only two of these cases did the roentgenological findings suggest a ruptured disk" (V, 782).

There is one important point to consider about the actual operative technique—the question of spinal fusion. Barr states that spinal fusion and complete removal of the nucleus is desirable to prevent further extrusion (III, 337). "We believe that this lesion tends to weaken the spine and that exploration of the spinal canal will weaken it still further. Therefore we plan our approach to preserve the strength of the spine as much as possible and follow laminectomy by a bone graft if the patient does heavy work" (IV, 1268, ii). Fusion operations were done in 40 to 50 per cent. of the cases (IV, 1270, ii). Can the time in bed and the absence from work or the fusion itself have caused the relief of symptoms?

In the first series we find Case 19, a woman of 35, with no history of trauma. Her complaints were pain in the buttocks, anus, and vulva, and down the left thigh posteriorly. She had incontinence of urine and faeces, saddle anaesthesia of perineum and buttocks, and sphincter paralysis. Her legs were "essentially normal." The cerebrospinal fluid had no dynamic block, but 140 mg. of protein per 100 c.cm. *X*-ray examination showed "no changes of consequence," and lipiodol examination was negative. A lumbo-sacral laminectomy was performed, and a tumour, compressing the lowest fibres of the cauda equina and consisting of annulus fibrosus and nucleus pulposus, was removed. She developed a wound infection and died.

The next paper mentions this death and adds that three other patients in the earlier group had since died, two probably of urinary sepsis, while the cause of death in the third was unknown (II, 391, i). Though his series included all these cases, Barr reports that "two cases have died. One died of uraemia following a complete paraplegia with urinary incontinence due to the disk lesion which was present pre-operatively. The second patient died of pneumonia well over a year after operation" (III, 336). What happened to the other case of urinary sepsis and to the patient who died of wound infection? This latter death appears again in the next paper by Barr, Hampton, and Mixter—"There was one post-operative death. Three other patients have died of incidental causes but were relieved of their pain during their post-operative life" (IV, 1268, ii, et seq.)—and also in the paper by Mixter (V, 783). Yet in the sixth and latest paper Barr states: "There have been two deaths in our series: both of these patients had severe irreparable nerve damage from large ruptured disks" (VI, 1251). One is tempted to ask Professor Barr his method for the resurrection of the dead.

It is extremely difficult to evaluate results which are classified as cured, relieved, and unrelieved. Doubts as to the value of this method must inevitably arise when we consider certain cases in the first paper—the only one to give individual case histories (I, table, 210).

Case 6.—A woman of 63, with no history of trauma, complained of pain in the legs and around the abdomen, and of inability to walk. She was found to have hyperaesthesia of the legs and abdomen, spasticity of the legs, with increased reflexes; a cerebrospinal fluid protein content of 67 mg. per 100 c.cm., and a partial dynamic block. *X*-ray examination revealed hypertrophic changes, a narrow disk, and lipiodol block at the sixth to seventh dorsal vertebrae. A dorsal laminectomy was performed and an extradural mass compressing the cord was removed from the intervertebral disk involved. It consisted of nucleus pulposus. She developed a complete motor and sensory paraplegia. Under the column for results she is reported to be "unrelieved."

Case 7.—A man of 42 had no history of trauma. He complained of numbness of legs, of increasing difficulty in walking, and of pain in the back. He exhibited hypaesthesia below the umbilicus, and spasticity of legs with increased reflexes. The cerebrospinal fluid had partial (? complete) dynamic block and 114 mg. of protein per 100 c.cm. No films are reported, and lipiodol examination was not done. A dorsal laminectomy, with piecemeal removal of a mass from the intervertebral disk, consting of annulus fibrosus and nucleur pulposus and compressing the spinal cord, was performed. This man also developed a complete paraplegia, and he, too, is reported to be unrelieved.

The nucleus pulposus is degenerating notochordal remnants, degenerating because of lack of blood supply; even the rest of the disk has a poor, indirect blood supply. Retropulsed through a fissured disk the nucleus must degenerate more rapidly. Andrae quotes Ribbert as having produced herniations of the nucleus pulposus, and as having found that they are absorbed or become cicatrized and so shrink. Therefore, should not conservative treatment cure the condition without any deaths from wound infection, and without running the risk of reproach for having transgressed the principle of *Primum non nocere*?

Summary

I have made use of a number of articles to clear up doubts concerning a new procedure in an attempt to solve three questions: Can retropulsion of the nucleus pulposus cause symptoms? If it can, is laminectomy the only treatment? Are the results of laminectomy such as to justify operation? The condition of retropulsion of the nucleus pulposus is used as an example in a plea for a more careful consideration of new ideas before their adoption.

In March of this year the British Standards Institution circulated for comment a "Draft British Standard Specification for Haemoglobinometers." The draft was based on the carboxyhaemoglobin (Haldane) method. As a result of circulating this draft the institution has received a number of requests that an acid haematin (for example, Sahli) method, not involving the use of coal gas or carbon monoxide, should also be standardized. Before deciding to proceed with the additional standardization the institution desires further information and has accordingly circulated a memorandum on the subject to medical organizations and individual practitioners known to be interested in the subject. Any reader who would like a copy of this memorandum can obtain one on application to the Director, British Standards Institution, 28, Victoria Street, London, S.W.1.

Clinical Memoranda

Sulphapyridine and Soluseptasine in Meningitis due to Pfeiffer Bacillus: Recovery

Pfeiffer meningitis is usually fatal. Bloom (1931) reviews records of 302 cases with a mortality of 92 per cent. Neal *et al.* (1934) record 111 cases with a mortality of 96 per cent. If recovery occurs convalescence is usually prolonged over months, and residual palsies, blindness, and deafness are frequent. Wigers (1939) records a case with recovery treated with prontosil, polyvalent serum, and omnadin. He considers the prontosil had no evident effect. Teggart (1938) records a case with recovery treated by soluseptasine.

Case Report

On May 22, 1939, a boy aged 6, following a slight cold, complained of not feeling well and was found to have a temperature of 100°. He was sent to bed. He had been quite lively throughout the day and went to sleep as usual. At 11 p.m. he was fast asleep. About 3 a.m. on May 23 he woke screaming and complained of headache. When seen at 6 a.m. his temperature was 102°, pulse 140, and respiration 40. He was restless and semiconscious, with marked head retraction, photophobia, neck rigidity, double Kernig's sign, and papilloedema. At 10 a.m. 0.25 gramme of sulphapyridine (M & B 693) was given. The cerebrospinal fluid showed: turbid fluid under pressure; no clot; 4,000 white cells per c.mm. (normal, 2 per c.mm.), all polymorphs; and numerous Gram-negative bacilli. Cultures gave a growth of a pleomorphic bacillus having the cultural and microscopical character of haemophilic bacillus (Pfeiffer's, or "influenza" bacillus).

Treatment was continued with sulphapyridine 0.25 gramme four-hourly. The restlessness was controlled by 10 grains of potassium bromide as required. Orange juice, glucose, and water were taken well. On receipt of the report on the cerebrospinal fluid soluseptasine 2.5 c.cm. was given at 6 p.m., and on the 24th 2.5 c.cm. at 3 a.m., 4 c.cm. at 10 a.m., and 5 c.cm. at 6 p.m. By 10 p.m. on the 24th the temperature was 98.6°, pulse 90, respiration 32. The patient's general condition was much improved; he was quieter, and was taking fluids freely. On the 25th a second lumbar puncture gave a count of 720 cells per c.mm. The film showed these to be chiefly polymorph leucocytes. Numerous Pfeiffer bacilli were present, but not so many apparently as on the previous examination. Few colonies only of the bacillus were seen on culture. Chlorides amounted to 0.685 per cent. (normal 0.72 to 0.75 per cent.).

Soluseptasine 5 c.cm. twice daily and sulphapyridine four-hourly were continued till June 5, when a third lumbar puncture showed: 28 cells per c.mm.; reds 16,000. Cells appear in blood proportions, with no excess of polymorphs. No pus or organisms were found. Cultures gave no growth. The presence of blood vitiated further tests. Treatment was continued for a further week. Although the boy seemed perfectly well, papilloedema was still present. On July 25 he appeared to have fully recovered.

The rapid onset and quick response to treatment are worthy of note. At no time was the patient upset by the drugs.

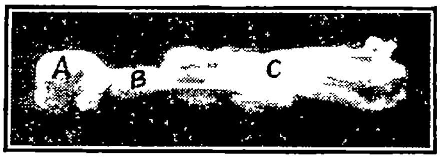
Sterilization by Section and Ligature of the Fallopian Tubes

Although a simple operation, sterilization by occluding the Fallopian tubes has in a certain number of cases resulted in failure in that pregnancy has supervened. Perusal of the literature almost gives the impression that the Fallopian tube when occluded had the property of recanalization. There is no evidence that this is so.

It is generally agreed that the safest operations are those which excise the interstitial portion of the tube or in which, when the tube is sectioned, the cut ends are buried in the broad ligament. If the tube is occluded by simply ligaturing with catgut it is not difficult to realize that the ligature may slip during tying. On the other hand, it is difficult to appreciate that a tube which has been well and truly cut and securely tied can recanalize. In many pelvic operations the anatomy is considerably distorted, and it is within the bounds of possibility that an inexperienced operator could pick up and operate on the round ligaments instead of the tubes.

A woman was brought to see me who on November 9, 1938, had had a "severe" operation for "something to do with the uterus." Owing to a bad obstetric history she had been sterilized. She had a period on November 25 and the last on December 20. The size of the uterus was that of a six-weeks pregnancy. Assuming that she conceived ten days after December 20, a tube must have canalized in less than seven weeks from the day of operation—a pathological event which was highly improbable. Her tubes had been occluded by ligatures, which I consider had either slipped or been applied to the round ligaments.



A = Uterine end of tube, patent. B = Fibrous cord.
C = Isthmal end of tube, patent.

My own practice is to pick up and tightly clamp the tubes about one-third of an inch from the uterine ends. The tube is cut between the clamps and tied with silk. No burying of the ends is attempted. The method is simple and there is no haemorrhage. I was fortunate to be able to examine the end-results of this method when operating on a patient whom I had previously sterilized and who wished to have another child. No adhesions were present and the tubes were lying free in the pelvis. The appearance of both tubes was the same, and is shown in the illustration. The cut ends were hard and fibrosed, and were joined by a cord of fibrous tissue. It was impossible to imagine that canalization could occur. The woman had been sterile for three years.

The specimen of one side was examined histologically. Four sections were examined from the site B and showed fibrous tissue only. Eight sections from A and C showed a patent lumen. The appearance of the specimen, the histological report, and the clinical history would indicate that the simple operation of section and ligature with silk is a satisfactory method of sterilization.

Reviews

CHROMOSOME MECHANICS

The Evolution of Genetic Systems. By C. D. Darlington. (Pp. 149; 26 figures. 10s. 6d. net.) Cambridge: The University Press; London: Cambridge University Press. 1939.

The purpose behind the writing of this book is so clearly and succinctly expounded in the brief preface that this is quoted in full.

> "In the present sketch I have attempted to show genetics as the study of systems of heredity and variation, systems which rest on the basis of the chromosomes and are related to one another by processes of natural selection. I believe that the combination of the material basis with the evolutionary framework provides the only means of making sense of biology as a whole. I hope, moreover, that this elementary exposition will enable its readers to realize that the chromosome theory is now something more than a profession of faith, or even an instrument of genetic discovery; it is the key with which we are opening the door between the physical and the biological sciences."

The book is of the nature of a *tour de force.* Dr. Darlington, one of the world's leading cytologists, expounds his views on chromosome mechanics, their meaning, and their evolutionary significance. In this constructive task it is of course inevitable that much should be included that is at present uncertain and unproved. The only real criticism, however, is that a reader unfamiliar with the subject would be unable to discover how much is generally accepted, how much has a high probability behind it, and how much is based upon the author's own theories; for it must be admitted that some of the views put forward would not, in all probability, be accepted by the majority of Dr. Darlington's fellow cytologists. The preface describes the exposition as "elementary," but it is to be feared that the author will be alone in cherishing this illusion; actually it is a very difficult book indeed. Apart, however, from the one regret —that more guidance is not given to the reader as to the weight of evidence behind the various propositions advanced—this book is to be welcomed as a brilliant and stimulating attempt to build up a great mass of scattered observation into an ordered whole.

HOSPITAL ADMINISTRATION AND PLANNING

Hospital Organization and Management (including Planning and Construction). By Captain J. E. Stone, *M.C.*, F.S.A.A., F.R.Econ.S. Third edition. (Pp. 920; illustrated. 31s. 6d. net.) London: Faber and Faber. 1939.

The publication of a third edition of Captain J. E. Stone's *Hospital Organization and Management* is an important event. This is evidenced not only by a number of "forewords" and "introductions" by public men eminent in the hospital world, but by the acknowledged and accepted position which the two previous editions (1927 and 1932) have achieved as the most comprehensive and authoritative compendium in the field indicated by the title. The new edition is at once less and more complete than its predecessors. They contained a chapter on hospital law. This has now been omitted and expanded into a separate book, *Law for Hospital Authorities.* In every other respect it is almost impossible to conceive of a volume more comprehensive, more up-to-date, more accurate, more complete in every sense than this. Its more than 900 closely packed pages make it, of course, primarily a book of reference, but there are many consecutive pages which can be read seriatim with great interest. The variety of subjects dealt with is naturally very large, but the index is good.

The contents may be divided into two parts, though they are not formally arranged in this fashion. There are what may be described as the general problems of hospital policy, and there are the more specifically technical problems of construction, supplies, kitchen, laundry, and nursing arrangements, finance and accounting, administration and management. In the former of these divisions of subject-matter—the more important to those members of the medical profession and others who are not concerned with the detailed and intricate affairs of management—there is no problem which does not receive adequate statement and fair consideration. The latest reports and announcements are epitomized. Those of the recent Voluntary Hospitals Commission, the Committee on Scottish Health Services, the Committees of King Edward's Hospital Fund on Out-patients and on Pay-beds, the Medical Research Council, are all adequately noted, as well as the P E P Report on British Health Services, the British Medical Association scheme for a General Medical Service for the Nation and its Hospital Policy, and the B.M.A. and B.H.A. Joint Report on Contributory Schemes. The B.M.A. attitude towards other matters, such as the training of nurses, the payment of medical staffs, provident associations, and the relation of private practitioners and hospital services, is dealt with, and the London County Council Hospital and Medical Services are somewhat fully described. These are examples of the thoroughness with which the author uses and arranges his vast material. This *Journal* has previously described the book as "invaluable to all hospital workers"; in its latest form it is invaluable also to large numbers of persons who cannot be strictly so described.

GONORRHOEA AND ITS TREATMENT BY CHEMOTHERAPY

Traitement de la Blennorragie par le Sulfamide, une Sulfone et leurs Dérivés. By M. Palazzoli and F. Nitti. Preface by Professors F. Legueu and E. Fourneau. (Pp. 195; 19 figures. 35 fr.) Paris: Masson et Cie. 1939.

This little book contains more than its title suggests, for though it is called "Treatment of Gonorrhoea by Sulphonamide, a Sulphone and their Derivatives," the first eighty-five pages are mainly devoted to a description of the gonococcus and its characteristics, the normal histology of the urethra and its adnexa, the various examinations necessary in a case of gonorrhoea, and its complications and treatment. The last-named is reviewed historically, starting with the "laisser couler" attitude and passing through the balsams, injections, and irrigations up to the time of the introduction of the sulphonamides. This part is on classical stereotyped lines and makes no attempt to deal with the more difficult complications.

The second part contains a most interesting account of the rapid development of chemotherapy following the comparative failure of such substances as methylene-blue, mercurochrome, and trypaflavine. Of the sulphonamides the ones chiefly considered are para-amino-benzene-sulphonamide (1162 F., sulphanilamide), di-acetyl-diamino-phenyl-sulfone (1399 F.), para-(amino-phenyl-sulphamido)-pyridine (sulphapyridine, M & B 693), para-amino-benzene-acetyl-sulphonamide, and uleron. Some of these are actively bactericidal in themselves, others merely bacteriostatic, and the latter require the assistance of the body defences in order to complete the destruction of all gonococci. In any case the two desiderata for successful chemotherapy are (1) absorption of enough of the drug to make the tissue fluids bactericidal, and (2) a sufficiently prolonged concentration of the drug in the tissues.

The authors are whole-hearted supporters of chemotherapy plus adjuvant treatment in the form of protargol 1 in 2,000 or potassium permanganate 1 in 5,000, and hold that by this means a lower dosage of drug is required, less reactions are caused, and the course of the disease is shortened. They also consider that most people use much too heavy a dosage, and claim that in the case of 1399 F. 2 grammes the first day, 1 gramme the second day, and thereafter half a gramme per day are sufficient; a total dosage of 7 to 8 grammes is effective in favourable cases, while this may be extended to 12 to 14 grammes in cases which do not react so well. For sulphapyridine they recommend 3 grammes the first day, 2 the second, and 1 gramme the third, plus irrigations, and claim that a total of 6 to 7 grammes is sufficient for cure in the great majority of cases. Not everyone will agree with the doses given; many leading venereologists in this country and in America believe in a heavy initial dosage, particularly in the case of sulphanilamide, while the question of concurrent irrigations must still be considered *sub judice;* in any case 1 in 5,000 potassium permanganate seems unnecessarily strong for use in the very early stages. However, the proof of the pudding is in the eating, and these French experts certainly get results. All venereologists will do well to study this little book, in which they will see "the other man's" point of view and in which they will find much of interest.

ANTE-NATAL CARE

Ante-natal and Post-natal Care. By Francis J. Browne, M.D., D.Sc., F.R.C.S., F.R.C.O.G. Third edition. (Pp. 622; 101 figures. 21s. net.) London: J. and A. Churchill Ltd. 1939.

Professor F. J. Browne's *Ante-natal Care* is by now an established favourite with student and practitioner alike. The third edition is a larger book than its predecessors, and in addition to two new chapters it contains further illustrations and many sections that have been revised. A chapter on heredity, with its necessary references to wrinkled peas, Andalusian fowls, and fruit flies, makes very interesting reading, but the study of human heredity is a difficult one, and the application of Mendel's laws to the inheritance of morbid characteristics is by no means clearly established. The other new chapter discusses unsuccessful pregnancy. Sections that have been extensively revised deal with pregnancy anaemia, radiology in obstetrics, and the remote prognosis of toxaemia of pregnancy based on a twelve-year follow-up of toxaemic patients conducted by Professor Browne and Dr. Gladys Dodds. The fact is established that there is a 50 per cent. incidence of hypertension occurring after pre-eclamptic toxaemia and a 70 per cent. incidence after eclampsia. The theory is propounded that the hypertension may have occurred even in the absence of pregnancy, but facts and theories are not sufficiently differentiated. It is to be hoped that the vital issues involved will be clarified in the future.

The practice of waiting for repeated haemorrhages before examining for placenta praevia does not commend itself, and few surgeons would agree that an indication for Caesarean section is a "patient *in extremis.*" The danger of shock proving fatal in accidental haemorrhage is emphasized, but the fact is overlooked that shock may be aggravated by the immediate transfer of the patient to hospital. The administration of morphine and the application of heat can be life-saving, especially where long distances have to be travelled, but they are too often forgotten in practice and are not mentioned in the discussion of treatment.

The book is filled with a surprising amount of useful information and valuable advice. Many minor criticisms can be made, but these do not detract from the general excellence of an edition which is assured of a well-deserved popularity.

THOUGHTS ON THE STUDY OF ANATOMY

The Study of Anatomy. By S. E. Whitnall, M.D., B.Ch., F.R.S.C. Fourth edition, revised and enlarged. (Pp. 113. 4s. 6d. net.) London: Edward Arnold. 1939.

Professor S. E. Whitnall has recently revised his charming little brochure *The Study of Anatomy,* written for the medical student. This book, which was first published in 1922, is well known to teachers of anatomy, and may be read with profit by all students of medicine. In it they will find the thoughts of an experienced anatomy teacher who conceives anatomy from the same high point of view that inspired the unknown author of that wonderful poem dedicated to a skeleton, the manuscript of which was found lying beside a museum specimen in the Royal College of Surgeons of England. The poem is quoted in full in the early part of the book. The additional brief notes which appear in the fourth edition of this work include the importance of a knowledge of anatomy in the practice of preventive medicine; a "mild tilt" at certain mechanized physical exercises; and some characteristic and amusing remarks on teaching and lectures. The author also gives a short list of books which may be read as recreation and diversion from the more technical studies of the prescribed medical textbooks, and which may help the reader to discern the big things in life, which physicians should both know and make known.

Commenting on "lecturers and listeners," Professor Whitnall upholds the value of systematic lectures on anatomy by speakers who can hold their audiences by their personality, originality, and mode of presentation; while, referring to the listeners, he draws the pertinent distinction between "*hearing*" (exercising one of the senses but being intellectually passive) and "listening" (hearing with a purpose and taking note—"not necessarily notes"!). We may safely predict that the present edition of this book will meet with the same general approval and appreciation that has been accorded to its predecessors.

Notes on Books

Portions of the infra-red spectrum have been photographed for more than fifty years, but technical advances have only recently brought infra-red photography into practical use. Its application is very varied, and Dr. WALTER CLARK'S book *Photography by Infra-red* (Chapman and Hall, 25s.) worthily fills a long-standing need. It is a serious and comprehensive textbook of the whole subject and contains many basic scientific data, such as the characteristics of photographic materials and the methods of sensitizing emulsions, the optical characteristics of materials in the infra-red, and lists of materials which are available commercially. The chapter on medical infra-red photography surveys the work of a surprisingly large number of authors and lists the best sources of information. The study of the superficial venous system is one of the most fruitful applications, and the author gives detailed instructions for the arrangement of lights and camera and exposure data. He also describes the infra-red photography of gross specimens and of the eye, the use of the method in dermatology; transillumination, simultaneous infra-red and *x*-ray photography, and the differentiation of blood. Other chapters deal with the uses of the infra-red camera in botany and palaeontology, photomicrography, and such special applications as landscape photography, aerial survey, and long-distance ground photography. Infra-red radiation can also be measured by photographic means, which the author describes, and he includes two chapters on the penetration of radiation through the atmosphere. Some beautiful reproductions of infra-red photographs are included.

In *Human Development and Learning: An Interpretative Introduction to Psychology* FRANK SEELY SALISBURY, Ph.D. (McGraw Hill, 18s.) presents a volume which purports to trace the development of the human mind and the way in which the human being learns to cope with his environment. In this particular narrative there is nothing very original or new, and to English readers at least it will be found that the presentation is neither clear nor easy to read.

To help medical students with the difficulties of securing a clear-cut line of action in the management of infant feeding, Dr. V. L. COLLINS of Melbourne has drawn upon his experience as medical superintendent of the children's hospital in that city to produce an excellent small book called *Infant Feeding.* In less than 100 pages the subject is clearly set out, with definite instructions on a reasoned basis, and the treatment of artificial feeding is free from the bias of the Truby King school. The book is published in Melbourne by W. Ramsay, price 3s. 9d.

Pleasant Food for Diabetics, by A. SANDERS, formerly Sister at St. George's Hospital, is published at 3s. 6d. by Faber and Faber. In this small book carbohydrate, protein, fat, and calorie values have been entirely omitted; and the list of carbohydrate equivalents for 1 oz. bread is full of errors. Some of these "pleasant" recipes will produce unpleasant effects if used indiscriminately.

We have received a copy of an agreeable little book, *Plain Verse and Random Rhymes*, by R. D. MOTHERSOLE, M.D., M.S., F.R.C.S., published by John Read of Bolton. This collection includes items composed at intervals during the past sixty-five years. The sonnets entitled "Aquae Solis," "Cambridge," and "Mancunium" were written by Dr. Mothersole on the occasion of the B.M.A. Representative Meetings at Bath, Cambridge, and Manchester. Three other pieces appeared in the *Guy's Hospital Gazette.* Among the lighter numbers is a quatrain of advice to motorists:

If you aim at decent driving
Let this maxim be your guide:
Take your left-hand corners narrow
And your right-hand turnings wide.

On the occasion of his retirement from the chair of clinical medicine of the University of Perugia on reaching the age limit, the *Annali della Facolta Medico-Chirurgica della R. Universita de Perugia* has dedicated its twenty-eighth volume of over 850 pages to Professor Raffaello Silvestrini, formerly rector of the university and president of the medical faculty and Academy of Medicine. The volume contains fifty-three articles by Professor Silvestrini's colleagues at Perugia and other Italian universities or important cities. In addition to the first article, on microbiological methods for the investigation and identification of some sugars and other carbohydrates, attention may be drawn to the following papers: the feeding of the newborn deprived of their mothers, haemolytic anaemia in chronic malaria, syphilis and cancer, nitroglycerin poisoning, venous septicaemia, torsion of the great omentum, the effects of thyroid extracts on the course of pulmonary tuberculosis, electrocardiographic changes in experimental beriberi, cirrhogenic yellow atrophy of the liver, haematoma of the ascending mesocolon, oesophageal myomata, pituitary dwarfism, tuberculosis in the Italian army, menstrual asthma, cystic intestinal pneumatosis, pellagra in Spain, prophylaxis of dental caries in the Italian youth, trauma and tumours, diagnosis and treatment of pneumococcal peritonitis, autovaccinotherapy of typhoid fever, congenital osseous fragility, volvulus of the caecum caused by acute appendicitis, vitamin C in treatment of haemoptysis, nephritis and autovaccine treatment, diphtheria of the oesophagus, and thirty-four cases of fracture of the vertebral column. A bibliography of Professor Silvestrini's 138 publications from 1891 to 1938 and his portrait are prefixed to the volume.

Preparations and Appliances

EMERGENCY LIGHTING EQUIPMENT

An emergency electric lighting equipment which claims to be both automatic and economical has been brought out by the Salisbury Transformer and Electrical Company, Ltd. (70A, Hamilton Road, Salisbury). It is described as suitable not only for first-aid posts but also for operating theatres, observation wards of mental hospitals, control rooms, or any place where the sudden cessation of light would be inconvenient or perhaps dangerous. The equipment, working off the alternating supply, consists of a steel cabinet housing a charging unit, a transformer, and an all-metal rectifier, together with the necessary controlling devices. With it goes a sealed 12-volt battery of 72 ampere-hours' capacity, and, in the model we saw, six lamps, but any multiple of six can be provided with larger models. The disposition and power of the lamps can be modified to suit requirements.

On plugging the apparatus to the main supply the battery is charged at a rate of 6 to 7 amperes. When the battery is fully charged the main is cut off, and only a "trickle" allowed in order to keep the battery steady. Immediately on any failure of the main lighting supply the emergency lamps light up and remain lighted until the supply is restored, when the controlling device instantly switches off the emergency lamps and the charging of the battery begins again to replace the current taken. The battery when fully charged will run the six lamps for ten hours, or, with an additional battery, for twenty, which should suffice for the most dire emergency. The equipment can also be used for underground shelters, with the lamps arranged at convenient points. The apparatus in that case is plugged in to the mains supply, and when light is required it is necessary only to bring a pointer on the dial to the position of "immediate lighting." If then the mains current should be interrupted the lamps will continue to feed from the battery, and on restoration the battery will automatically charge up again.

PHRENAZOL

"Phrenazol (Boots Pure Drug Co., Ltd.) is a preparation of pentamethylene tetrazol. The chief clinical use of this compound is as a circulatory stimulant, since it acts on the vasomotor and respiratory centres and thus improves the oxygen supply of the heart. Phrenazol when administered by quick intravenous injection produces convulsions. In 1934 von Meduna introduced convulsion therapy for relief of schizophrenia. The value of this method of treatment is still a controversial question, but it is widely employed. Messrs. Boots provide two leaflets describing the use of phrenazol as a cardiac stimulant and as a convulsive agent.

IMMUNIZATION AGAINST SCARLET FEVER

Lederle Laboratories announce the issue of an improved streptococcus toxin for use in immunization against scarlet fever. Unpleasant reactions following administration are claimed to be greatly reduced by substitution of peptone in a concentration not exceeding 1 per cent. for blood or serum in the preparation of this toxin, without loss of immunizing properties. The product is marketed in this country by C. F. Thackray, Ltd., Leeds.

PREPARATION OF HOG'S STOMACH

Neopepsac brand of concentrated stomach substance (Boots Pure Drug Co., Ltd.) is a tasteless preparation of hog's stomach. The vendors recommend it for the maintenance treatment of cases of pernicious anaemia.

LONDON

SATURDAY NOVEMBER 25 1939

A NEW EMERGENCY MEDICAL SERVICE

The medical services of this country have undergone profound disruption as the result of a war whose slow development is without parallel in history. The much-heralded *Blitzkrieg* is still in the textbook stage, and its place has been taken by a series of long-range diplomatic offensives, accompanied by the rumbling of distant thunder and very little lightning. One observer on the home medical front, disappointed, perhaps, at the sluggishness of events, has already sounded the death-knell of consulting practice. Men in consultant and specialist practice have indeed been hard hit, but their vigour, enterprise, and importance in medical life are such as to make us doubt whether they will consent readily to ante-mortem burial. The distribution and dispersal of medical personnel at the outbreak of war were based on what turned out to be an inaccurate forecast of "the shape of things to come" in the first few days. They did not come. Medical services have continued to be a rationed commodity, but there could be no corresponding rationing of civilian sickness. It is easy to allocate praise and blame after events have falsified prophecies, so we will here set down the facts in relation to the Emergency Medical Service and the position of consultants and specialists therein.

In July of this year the Central Emergency Committee of the B.M.A., in response to a request from the Ministry of Health, made suggestions for the terms and conditions of service of an Emergency Hospital Medical Service. It recommended that there should be two types of medical appointment within the service—a Class A or whole-time appointment, and a Class B or part-time appointment, which in the case of consultants permitted a maximum annual pay-out of £500; it recommended that an establishment of Class A officers should be set up by the Ministry. In general the Ministry accepted the Committee's recommendations, although it modified those relating to salaries and did not accept a proposal that a Class A establishment should be set up or a recommendation that special rates of compensation for death or injury should be paid. From this point the Ministry of Health, aided by its consultant advisers, its Hospital Officers, and its Group Officers, began the work of recruitment, handicapped, as it appeared later, by the lack of a defined Class A establishment. Outside London the great majority of appointments were made on a part-time basis. In the London area, however, the Ministry, advised by its Group Officers, permitted extensive recruitment to Class A. This action was supported at the time by many powerful considerations and expectations. It was believed that there would be a considerable number of casualties, and a large number of beds—widely distributed —were set aside for them. It was thought that many of these beds would be filled immediately after the outbreak of war and that private practice would largely disappear. But the war did not begin according to plan. Hence, nothing else has gone according to plan, and so new plans to meet the actual situation have had to be made. The time-lag has naturally been attended by much impatience and dissatisfaction. Many of our London hospital staffs have had to undergo the disillusionment of enforced leisure, and criticism has grown in volume.

Those in the whole-time service complained that private practice had not disappeared, and that in the public interest they should be allowed to undertake it despite their whole-time contracts. Private practice, according to many not called up for whole-time service, had disappeared and they were unable to live without paid employment. Another complaint was that the Ministry's reference in the contract to private practice was vague and confusing. Some consultants had been enrolled but not called up; others had been called up but not enrolled. Some, who had been officially called up, found that the Ministry did not accept responsibility for paying them. From the Provinces came the complaint that the sessional rate of pay was difficult to apply. The Ministry was naturally the focus of criticism. The Central Emergency Committee was held responsible for the restrictive conditions of the whole-time appointments, although in fact it had no responsibility for and did not expect this extensive recruitment to whole-time service. Group Officers were blamed for decisions taken not by them but by their employing body. But perhaps the real explanation is that the German Chancellor did not follow the course clearly demarcated by the military experts during the recurrent crises between 1933 and September 3, 1939.

It soon became clear that complete revision of the organization in the light of experience gained in the first few months of war was necessary. That the first attempts failed was not surprising in view of the fact that what was offered was the release from whole-time service, on the first proposal without pay, and on the second at one-third of the whole-time salary for a liability of service for four-sevenths of the medical officer's time. At this stage the Central Emergency Committee of the B.M.A. decided to assume the responsibility for making to the Ministry of Health detailed recommendations for revision of the whole service. It established a special Advisory Emergency

Hospital Medical Service Committee, which, in addition to representatives of the Central Emergency Committee, included the Presidents of the three Royal Colleges, London and provincial Group Officers, a representative of the London County Council medical staff, and representatives of consultants enrolled in the service. This Committee, under the chairmanship of Sir Robert Hutchison, rapidly completed its investigations and little more than a fortnight ago submitted its proposals to the Minister himself. We are now able to announce that the Minister has generally accepted these proposals, which are fully described in the War Notices in this week's *Supplement*. Briefly, the reorganization involves the creation of a Class A establishment of whole-time officers to consist in the main of administrative and house officers, and of practitioners of the standing of registrar or chief assistant. It is intended that, where consultant services are at present provided by Class A officers, these may in future be provided by consultants and specialists on a part-time basis, each practitioner enrolled in this group receiving a salary of £500 per annum with adequate travelling expenses, remaining liable without additional remuneration for spells of additional service according to the demands of the moment. Class B enrolment will largely disappear, except where the employment of practitioners on a sessional basis is necessary to supplement the services of salaried clinical officers. With this exception the general method of remunerating the hospital staffs, hitherto recruited to Class B, will be by a *per caput* payment for medical services on an occupied bed basis, this payment to pass to a staff fund for distribution among the staff. The full details of the revised scheme are worthy of careful study. It deals also with the payment of house officers and the method of recruiting them; it provides for continual consultation between the Ministry and the new Advisory Committee; it defines the patients within the scope of the Emergency Medical Service. The success of the reorganization depends largely on the willingness with which medical men now under whole-time contract for a minimum period of one year relinquish those contracts in favour of the part-time contract which will shortly be offered to them. This offer, by the way, will be made not only to those who have been enrolled and called up but also to those who have been enrolled but not called up, and to that not inconsiderable group who have been giving their whole-time service but have not yet been enrolled.

The Central Emergency Committee and its Advisory Emergency Medical Service Committee have good reason to be grateful to the Minister for his prompt consideration and acceptance of the revised proposals. It recommends to the profession the acceptance of a plan which goes far to remedy some very real grievances.

CLARIFYING THE PITUITARY

Dr. H. B. van Dyke's second volume on the physiology and pharmacology of the pituitary body[1] is in effect a critical digest of the experimental literature which has appeared since the publication of the first volume in 1935. The need for such a guide is shown by the fact that approximately 750 articles appear annually on the subject. It might be alleged that the quantity is more conspicuous than the quality, but it would be fairer to describe the present phase as one of consolidating in detail the advances previously made. Nevertheless, some notable advances have been made in clarifying certain aspects of the complex functions of this organ. Dr. van Dyke's provision of a brief summary of his opinion on recent work at the end of each chapter is most helpful in enabling the reader to assess such advances. On the anatomical side he calls attention to the fact that the complex blood supply of the pituitary includes a portal system to the glandular part. He thinks that there is little basis for postulating any chemical influence of pituitary hormones on the diencephalon, but ample evidence of nervous influences operating in the reverse direction, of which the release of gonadotrophic hormones through nervous action is an outstanding example. In this connexion it is of great interest to learn that in birds and certain mammals stimulation of the optic nerves by light conveys impulses to the diencephalon which influences this release and consequently the date of the mating season. In animals without such seasonal variations such stimuli do not play an evident part. The fact that morphological changes following gonadectomy can be corrected by oestrogenic or androgenic substances affords experimental support for the clinical use of the former at the climacteric. In human beings the chorionic villi of the placenta produce enormous quantities of luteinizing hormone until gestation is complete or the foetus dies. Chorion epithelioma and hydatidiform mole produce a hormone chemically identical with that of normal pregnancy. The complex nature of the influence of pituitary hormones on lactation is shown by the failure of injection of lactogenic hormone to initiate lactation after ablation of the pituitary. It is a point of considerable biological interest to find that this hormone can be assayed by its stimulating effect on the growth of the pigeon's crop glands, showing the close homology between them and the mammary glands.

Turning to the association between the adrenals and the pituitary, it appears that the morphological and functional maintenance of the cortex of the former, including the sex-determined "X zone," depends on secretions from the latter; the adrenotrophic anterior pituitary hormone also seems to play a part in the metabolism of fat, causing fat to be transported from the tissue depots to the liver. This is curious, since it has been known for some years that the posterior pituitary secretion, pitressin, has a similar action. Our knowledge of the role of anterior pituitary hormone in carbohydrate metabolism continues to grow, and the antagonism between it and insulin is now well established. In the absence of the latter the former exhausts carbohydrate reserves and leads to dangerous ketosis. Yet on the other hand the anterior pituitary appears to be necessary for the normal absorption of dextrose from the alimentary tract. We are indeed reaching the point at which the pituitary appears to intervene at every phase of metabolism throughout the body, justifying its description as the master gland. It is increasingly clear that it may also be described as the central transformer of nervous into chemical energy, just as the nerve endings are the site of a similar transformation at the periphery.

"Q" FEVER

A number of cases of fever occurred in Brisbane in 1935 which presented features suggestive of a distinct clinical entity; similar cases had first been noticed in 1933. Derrick,[1] who investigated the outbreak, found that the illness was of acute onset with generalized malaise, intense and persistent headache, fever, and relative bradycardia. The temperature rose rapidly, usually remaining between 102° and 104° F., although sometimes there were large daily remissions. Two main types of illness were distinguished: in one the fever lasted six to nine days and terminated with a definite crisis resembling urban or murine typhus; in the other the fever was much more prolonged, and ended by gradual defervescence with occasional recrudescence. The fever, which was in no case fatal, differed from the typhus group in the absence of characteristic rash and, especially, in the consistently negative response to the Weil-Felix test with different strains of *B. proteus*. Photophobia was often present and sometimes congestion of the conjunctivae suggestive of leptospirosis, but all tests for this infection were negative. The relative absence of localized respiratory symptoms and the sporadic distribution were against a diagnosis of influenzal disease, and specific tests excluded the enteric and brucella groups of infections and all the commoner animal diseases. During the investigations inoculation of the patient's blood or urine produced in guinea-pigs a characteristic non-fatal fever of from four to six days' duration followed by long-lasting immunity to further inoculation. Guinea-pigs killed during the febrile attack had enlarged spleens, but other abnormalities were few, and as no organisms could be seen or cultivated it was thought that the infecting agent might be a virus. Burnet and Freeman[2] of Melbourne investigated this possibility and produced characteristic pathological effects by transmitting the infection to mice. Mice killed seven to ten days after inoculation showed enlargement of the liver and spleen, which contained large intracytoplasmic microcolonies of rickettsia-like organisms. These organisms take the form of Gram-negative tiny rods about 1 μ long and 0.3 μ broad, although occasionally long forms are seen. By Castaneda's method most of these organisms stain blue, but less so than psittacosis bodies, while some may be pink; with Giemsa they are reddish purple and in heavy infections easily recognizable. They are only found in intracytoplasmic accumulations in the infected animals and are not capable of growth in standard biological media. They survive in, but do not produce characteristic lesions of, the chorio-allantois of the developing chick; cultures in chick embryo in Tyrode's solution develop relatively slowly compared with viruses, and continue to grow in severely damaged tissues.[3] The organisms are with difficulty filterable through relatively permeable (0.7 μ) gradocol membranes. Infected tissues remain virulent for many weeks when stored in the refrigerator, and the infecting agent appears to be resistant to glycerol. In size, shape, staining reactions, intracellular habitat, and cultural and pathogenic properties the organism resembles a rickettsia, and the name *Rickettsia burneti* has been proposed by Derrick,[4] although Wilson[5] and Brumpt[6] are doubtful whether it should be classed as a rickettsia. The organism is present in the blood of patients during the febrile period, and may be present in the urine in the later stages and during convalescence. In routine diagnosis normal and immune guinea-pigs are inoculated. By differential centrifugation of the spleens of infected mice rickettsia suspensions have been obtained and are agglutinated by sera from the patients and experimentally infected animals; rising titres are found during the course of the disease and the method has obvious diagnostic value. Monkeys and dogs[7] are susceptible, rats are mildly so and develop inapparent infections, while rabbits are insusceptible. None of the susceptible animals are thought to play any part in the natural spread of the disease, and its epidemiology is obscure. Most of the cases occurred in meat-workers and dairy farmers, and it is thought that there may be a reservoir in some animal with a blood-sucking parasite as a vector. This mechanism of transmission has been suggested as an explanation of a number of accidental human infections during experimental work. These infections seemed definitely to be associated with experiments in mice, and it is suggested that in one group[9] the mite *Lyponissus bacoti* may have been responsible for the transmission, but in the other[10] infection probably occurred, possibly through some skin abrasion, by direct contact with infective mouse tissues. In an endeavour to find some natural reservoir of infection many bullocks, sheep, and pigs were examined without the organism being recovered. On the other hand, four out of thirty sera from bandicoots in South Queensland agglutinated at titres of 1:10 or more suspensions of the specific organism. The fevers of the Queensland coast have long been a complex problem, but the careful work described here seems at least to have disentangled one of them, and although the picture is still incomplete the investigators are to be warmly congratulated on their results.

STILBOESTROL

Since we first referred[1] to the actions of the synthetic oestrogenic substance known as stilboestrol discovered by Dodds, Golberg, Lawson, and Robinson,[2] much clinical and physiological work on the substance has been carried out. In this *Journal* Winterton and MacGregor[3] then reported that stilboestrol given by mouth or intramuscularly relieved post-menopausal disorders, amenorrhoea, senile vaginitis, leucoplastic vulvitis, and dysmenorrhoea as effectively as injections of oestrone. Simultaneously Bishop, Boycott, and Zuckermann[4] recorded that stilboestrol caused "oestrone withdrawal bleeding" in amenorrhoea and an oestrous vaginal smear in post-menopausal patients. Uterine proliferation in the monkey, similar to that following administration of oestrone, was also observed. These findings have been amply confirmed by other clinicians.[5,6,7,8,9] Whereas English workers found that the toxic effects of stilboestrol (chiefly nausea and vomiting) were present in only a small proportion of cases and were of a temporary nature, Continental workers considered these symptoms to be more serious; Varangot,[9] for example, states that only a few of his patients could tolerate a course of treatment lasting more than a month. The number of patients treated with the new drug is, however, as yet too small for any conclusion to be reached on this question. It is evident that there is much individual variation in tolerance. On the biological side, the observation of Dodds, Lawson, and Noble[10] that stilboestrol causes oestrus in rodents, sensitizes the rabbit uterus to the action of progesterone, and produces mammary growth in the guinea-pig has been confirmed,[11,12,13,14] and further similarities between the actions of the natural and synthetic products have been published. Thus oestrone depresses anterior pituitary function; Folley and Watson[15] have shown that the action of prolactin on the crop-gland of the pigeon and lactation in guinea-pigs and rats is inhibited by stilboestrol, which also inhibits lactation in women.[3] According to Noble[16] the drug depresses the diuretic, gonadotrophic, and growth-promoting functions of the rat's pituitary. The pharmacological effects of oestrone and stilboestrol are also alike, since Dawson and Robson[17] have demonstrated that they both inhibit the spontaneous contractions and tone of the isolated rabbit intestine *in vitro* and abolish its response to motor drugs such as adrenaline, histamine, etc. The castration cells of the castrate rat's pituitary are abolished by administration of stilboestrol.[14,18] Both the synthetic and the natural oestrogenic substance have a protective action against the necrosis in the tail of the rat brought about by injection of ergotamine or adrenaline.[19] This effect led Cobet and Ratschow[20] to give stilboestrol to patients with Raynaud's disease and other circulatory disorders. Their results were favourable, and they suggest that the action on menopausal flushes is direct. The only instance so far reported of failure to reproduce the effects of stilboestrol with oestrone is that of Mühlbock,[21] who could not inhibit the capon comb-growth stimulated by testosterone by simultaneous application of stilboestrol. This finding is, however, partially contradicted by the report of Kreitmair and Sieckmann[11] that stilboestrol diminishes the comb size in the cock but not in the capon. It is thus apparent that at the moment no differences have been observed between the actions of the natural oestrogenic hormones and the synthetic product.

STAB WOUNDS OF THE ABDOMEN

There can be no question that penetrating wounds of the abdomen call for laparotomy, since it is always possible that viscera or blood vessels may have been injured, and if such injury is not promptly repaired there is the obvious risk of peritonitis or of gross intraperitoneal haemorrhage. Writing on stab as distinct from gunshot wounds, L. T. Wright, R. S. Wilkinson, and J. L. Gaster[22] of New York point out that these may be divided into stab wounds of the abdomen and stab wounds of the abdominal wall; the mortality from the former is around 33 per cent., and from the latter is either low or altogether absent. Difficulty may arise, however, in deciding whether a wound has actually penetrated the coelomic cavity or not. Although in most cases it is true to say that at the time of admission to hospital there is adequate clinical proof of intra-abdominal injury, there is a border-line group which may cause anxiety. At Harlem Hospital it was at one time the custom to wait and attempt to ascertain clinically whether penetration of the abdomen had occurred or not, but the more recent practice of operating for every stab wound has been followed by a reduction in mortality for all types of case. Operation consists in dividing the abdominal wall down to the peritoneum and exploring the wound track to decide whether the peritoneum has been penetrated or whether there is haemorrhage within it. The peritoneum is not opened unless it is found to have been wounded or unless it obviously contains much blood. If a patient admitted with a stab wound is badly shocked he is given intravenous fluid by the slow-drip method. *X*-ray films are taken of both the chest and the abdomen, as pneumoperitoneum may be present and the chest may have been entered as well as the abdomen. The authors state that under no conditions should spinal anaesthesia be used for the exploratory operation, because if the intestine is perforated the augmented peristalsis increases the escape of intestinal contents into the peritoneal cavity. They favour either open ether or a combination of nitrous oxide, oxygen, and ether. If the large bowel is penetrated where it is mobile, as in the sigmoid or transverse portions, they exteriorize the injured part. In 184 cases consisting of 130 penetrating wounds of the abdomen and fifty-four of the abdominal wall, there was a total mortality of 13.5 per cent. These authors believe that suturing without drainage should not be done, and employ drainage in the majority of their cases of penetrating wounds.

ATMOSPHERE IN JAPANESE TEXTILE WORKS

In a report published by the Japanese Institute for Science of Labour, Drs. Sinzi Katuki and Hirosi Sukegawa describe the atmospheric conditions observed by them in seventy-eight spinning and weaving factories at Osaka. In the cotton-spinning factories the temperature was above 80° F. for six months of the year, and was sometimes 95° during August, while the air was 70 to 80 per cent. saturated with moisture in a few of the workrooms, though usually about 60 per cent. saturated. In the weaving sheds the conditions were worse, the air usually being 75 per cent. or more saturated, as well as having a temperature of 90° (in August). The conditions were no better in the silk, woollen, and hemp-thread factories investigated, so it follows that they were extremely trying for the workers. In was found that marked differences existed in the atmospheric conditions of the workrooms in various factories, partly the result of the structure and equipment of the buildings. In one instance it was found that the humidity of the air in a weaving factory was induced by blowing in steam instead of spraying cold water, and in general the managers of the factories showed lack of understanding and indifference, while the technical staff did not appear to pay any attention to the health and efficiency of the workers. A detailed examination by Dr. Yogi of the output from a spinning factory showed regular variations during the course of the year, dependent chiefly on the environmental temperature. The feeling of fatigue experienced by the female operatives at a cotton mill was investigated by means of a questionary, and it appeared that in August 24 per cent. of the weavers had a feeling of tiredness at 11 a.m., and 43 per cent. at 4 p.m. The corresponding figures for December were 6 and 13 per cent. An investigation of the temperature "comfort zone" showed it to be about 72° in summer and 66° in winter, so it is evident that in summer the operatives seldom experienced comfortable working conditions.

MEDICAL STAFFING OF FIRST-AID POSTS

The Central Emergency Committee has since the beginning of the war been in constant touch with the Ministry of Health on the subject of the staffing of first-aid posts. It was urged upon the Ministry that in the interests of efficiency a medical officer should be in complete charge of each first-aid post instead of only being responsible for the training of first-aid personnel, as he is at present. The peace-time arrangements in regard both to scope of responsibility and to remuneration were looked upon as inadequate. At the outbreak of war many medical men attached to aid posts, disregarding the limited range of their responsibilities, gave a large part of their time, in some cases the whole of it, to bringing to a high standard of efficiency the posts to which they were attached. They did this without waiting to be assured that they would be properly remunerated for this work. Subsequently the British Medical Association asked the Ministry that the whole issue of the war-time duties and payment of these medical practitioners should be placed on a proper basis, and the Minister promised a representative deputation that the matter should be fully considered. His reply is now available and is set out in the war notices on page 227 of this week's *Supplement.* It relates to posts, fixed and mobile, in vulnerable areas only. It is now agreed that a medical man shall be in complete charge of his first-aid post, continue to undertake the collective training of personnel, and have new responsibilities in connexion with general maintenance and administrative control. Local authorities will be authorized to pay to the medical officer in charge a salary of £75 a year, in addition to the sessional fees for attendance owing to an actual air-raid on the locality of the post. This replaces the previous arrangement whereby the rate of payment was twenty guineas a year. In non-vulnerable areas, however, the twenty-guinea payment will continue in operation. Further, it is agreed that where medical officers were required to attend their aid posts at the outbreak of war the payment of sessional fees will be authorized up to the receipt of Circular 1869 issued on September 9, 1939.

We regret to announce the death of Sir William Prout, K.C.M.G., formerly physician to the Hospital for Tropical Diseases, London, and senior consulting physician to the Colonial Office; also of Mr. Naughton Dunn, lecturer on orthopaedic surgery in the University of Birmingham and honorary surgeon to many orthopaedic institutions.

Professor E. D. Adrian, M.D., F.R.C.P., F.R.S., has been appointed a member of the Medical Research Council in the vacancy caused by the death of Professor John Mellanby, M.D., F.R.S., last July.

As Australia is at war the sixth Australasian Medical Congress (B.M.A.), which was due to be held in Perth in September, 1940, has been postponed indefinitely.

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation

TRAUMATIC SYNOVITIS AND INJURIES TO THE LIGAMENTS OF THE KNEE-JOINT

(EXCLUDING MENISCUS INJURIES)

BY

G. R. GIRDLESTONE, F.R.C.S.

Synovitis of the knee is recognized by the enlargement, warmth, and tenderness of the joint; there may be a soft crepitation on movement, with pain and resistance before the normal limits of flexion and extension are reached, and the joint is usually held a little flexed.

Acute traumatic synovitis of a knee-joint may be due to: (1) a direct contusion of any part of the knee-joint; (2) a sprain—that is, the stretching or tearing of ligaments by a forced movement in any direction beyond normal limits; (3) overuse or unaccustomed use—for example, strenuous football or ski-ing after inadequate training; (4) a fracture involving the joint (to be dealt with in the next article). Chronic traumatic synovitis may follow continued excessive use of a normal joint or ordinary use of a joint which is poorly aligned for strain or weight-bearing.

Diagnosis

It is necessary to exclude a ligamentous sprain or rupture, a fracture, and an internal derangement before we can diagnose an uncomplicated traumatic synovitis. The ligaments are first tested and the exact locality and extent of any damage noted. If the injury has been at all severe radiographs (antero-posterior and lateral) are taken in order to exclude fracture, including the uprooting of a tibial spine.

An internal derangement is evidenced by the history of something going out of place and immediately locking the joint—that is, limiting its full range: a subsequent sensation of something slipping into place again is almost pathognomonic. Occasionally the displacement is so quickly followed by replacement that neither "locking" nor "unlocking" is noticed. The lock associated with internal derangement is quite different from the stiffness associated with muscular spasm or with fluid- and peri-synovial infiltration; though when there is much limitation of movement and swelling after injury a lock cannot be discovered. Indeed, it is often impossible for anyone, faced with a hot swollen knee a day or two after a severe sprain, to say certainly, or even probably, whether a meniscus has been damaged or not. But it is one's experience that, in general, the more severe the ligamentous damage the less likely are the menisci to be damaged. If the ligaments are badly sprained the menisci themselves usually escape, though their attachments to the lateral ligaments may well be torn. The menisci suffer from rotary movements on an axis, associated with the maintenance of axial compression by intact ligaments rather than the non-axial strains which stretch and tear the ligaments. It is, however, often impossible to be sure, but it is bad practice to diagnose or even to suspect cartilage damage without something very suggestive in the history, symptoms, or signs.

Localization of Damage.—Having come to the conclusion that one is dealing with an uncomplicated case of traumatic synovitis of the knee, it is of the greatest value to ascertain exactly what has happened, and to localize the pathological condition underlying the synovial reaction. The success of treatment, judged by rapidity and permanence, rests on the exact recognition of, say, a local bruise or infiltration round a ligament, which, though exquisitely tender and so painful as to make walking impossible, may be dramatically cured by injection of a local anaesthetic with massage and active use. In another case a heavy blow on the articular margin of the tibia may cause a reaction of the joint so severe as to establish traumatic arthritis and prolonged trouble unless it is immediately and completely put at rest for just a few days. Careful palpation and the trial of various strains will usually disclose the nature and situation of the injuries.

Principles of Treatment

First among the principles comes the recognition that all joints have an ample and delicate sensory innervation. The nerve endings in the subsynovial tissues serve to protect the joint against overuse (witness the neurotrophic joint), and the sensory spindles in the ligaments give warning of dangerous strains. This fully protective nerve supply explains the supreme need for *rest* once the joint tissues have become inflamed. The second principle concerned is that of *movement*. In dealing with a perisynovial or pericapsular infiltration associated with some severe injury there is an indication for early movement in order to avoid the organization and contracture of the granulation tissues into adhesions. The third principle concerns the preservation and restoration of muscular power and tone.

At first sight these three principles would appear mutually antagonistic, but if rest is made the rule, and movement the exception, in the form of a single, very gentle, and slow active movement through the greatest possible range, the inflamed tissues will not be irritated. It should be needless nowadays to point to the great superiority of active movements over passive by calling to mind the relaxation of the opposing muscles that follows active flexion and extension. Full rotary movements of the knee are beyond the control of the supine or sedentary patient. Their evolutionary value is to enable the body to turn and swerve on the fixed tibia and thus to escape the clutch or tackle of the foe. Then, again, the muscles can be kept in order by faradic stimulation and by contractions without movement, even by movements of the limb as a whole without movement of the knee.

We can then solve the dilemma set up on one side by the golden rule of rest for painful irritated tissues supported by Hilton, Thomas, and Robert Jones, and on the other by the desire to avoid adhesions, with delay or even impairment of function. If the ligaments are stretched or torn they need protection by posture or by splintage. In most cases the difficulty is easily overcome by an intelligent mixture of rest, movement, and massage: (1) Rest and, if need be, protection by splintage—for example, a broad aluminium or plaster-of-Paris gutter. (2) Single, very gentle, coaxed active major movements:

the masseuse should finally carry out the rotary movements of the tibia very gently and slowly. (3) Effleurage of the perisynovial tissues and surrounding areas directed toward emptying lymphatics and reducing the cellular infiltration in addition. In some cases graduated massage and active use rapidly restore normality. In a few instances the extra-articular injection of planocaine 2 per cent. into a tender and painful area, singly, or repeated daily for a few days, may allow the patient to be active and make all the difference in speed of recovery due to the absence of reflex and disuse atrophy.

Organized "Adhesions"

In a rather different category are the cases of synovitis seen at a later stage when there is already limitation of movement by organized adhesions; in these, preparatory physical treatment, followed by gradual active and passive movements, is indicated. The sedative effect of the infra-red ray or diathermy or plain radiant heat may be a valuable daily introduction to gradual manipulative movement. Manipulation under anaesthesia may be needed.

Chronic Synovitis

The knee in particular is dependent upon the integrity and strength of its muscles and ligaments, and chronic synovitis is peculiarly liable to persist after acute synovitis of the knee where the condition of the muscles has not been especially regarded. Although the original cause may have disappeared, synovitis is still present and kept up on account of the lack of muscular and ligamentous tone. A mild vicious circle exists. This is dealt with by impressing upon the patient the principles of (*a*) avoidance of strain, (*b*) the necessity for complete rest of the whole limb supported throughout its extent, and (*c*) active natural use, first for only two or three minutes at a time, many times in the day. Every means should be taken to improve local circulation by massage, diathermy, active movements, and exercises. The correct dosage of rest and exercises is assured if the muscles are gaining and the fluid losing day by day. The use of elastic knee-caps should be restricted to periods of fairly strenuous activity during the later stages of convalescence—for example, a rugger match—before the knee and its guardian muscles and ligaments are fully taut.

Rupture of Ligaments

The medial collateral ligament may be sprained or even completely ruptured by any powerful force opening the inner side of the knee. The tear is usually above the level of the joint near the upper attachment, which may be pulled away. Its wide attachment to the tibia is very seldom torn.

In moderate cases (sprains) the ligaments are pulled rather than completely ruptured, and treatment will vary with the degree of laxity and with the associated damage to the quadriceps and the vastus internus in particular if the damage concerns the medial ligament. A few days in bed with the joint slightly flexed over a pillow to relax the ligaments may be necessary to begin with. This should always be associated with massage, together with faradic treatment of the vastus internus and active muscular contractions of the quadriceps as a whole. As soon as the reaction of the joint is over, the patient is allowed up, but must be strictly told to wear only strong leather shoes and the heel on the side of the injury is wedged up—half an inch in the male and a quarter of an inch in the female. The patient can then walk on even surfaces with careful muscular control.

Treatment in severe cases (complete rupture) begins with the application of a plaster cast, unpadded except for a circle of felt to protect the patella. The knee is set at an angle of 175 degrees. A haemarthrosis may be aspirated before application of the cast, a lateral puncture into the suprapatellar pouch being the easiest, and the skin puncture sealed with collodion. The plaster cast extends from the great trochanter to just above the ankle-joint. Walking and leg-raising exercises are encouraged after the first day. For a really severe injury such as complete rupture three months of immobilization is necessary. But in many cases a long knee-cage can be substituted for the plaster after six or eight weeks.

The external collateral ligament is less often injured. Again the ligament does not rupture in the middle, but near one or other bony attachment; or its fibular attachment may be pulled off.

The cruciate ligaments may be torn or avulsed by extreme hyperextension, lateral angulation, or dislocation. The commoner causes are extreme hyperextension—as when at rugger a runner's impetus carries his body on with his weight-bearing leg held firmly by a tackler—or a backward displacement of the flexed tibia on the femur in a motor accident. To test for the integrity of the cruciate ligaments the patient sits opposite the surgeon with the knee flexed to a right angle and the foot firmly supported on the ground between the examiner's two feet. Then the examiner grips the head of the tibia and tries to force it backwards or forwards under the condyles of the femur (see Fig.). Forward movement of a sliding nature indicates laxity or rupture of the anterior cruciate, and backward sliding signifies a posterior cruciate ligament lesion.

Testing the cruciate ligaments.

The treatment consists in immobilization at an angle of 170 degrees for two or three months in a hip-to-ankle plaster, allowing and encouraging active hip, ankle, and foot movements from the start and weight-bearing as soon as the acute symptoms subside, usually at the end of a week. After the plaster a hinged bucket calliper is employed. Everything depends on developing exceptional muscular strength and tone by intensive gymnastic exercises. Even in old cases muscular control may be sufficient to discount great ligamentous instability, and may enable the patient to lead an active life. Such an attempt should always be made before considering operative reconstruction of the cruciate ligaments by fascial grafts, arthrodesis, or the permanent use of a long knee-cage.

Dislocation of the Patella.—This may be purely traumatic or be predisposed by knock-knee. The dislocation has generally been reduced at once. The diagnosis is made from the history and the site of tenderness. The treatment consists in the development of the quadriceps by active exercises and faradic stimulation. If the dislocation is recurrent there is need for expert choice of the best operation in regard to the particular case.

Dislocation of the knee is usually obvious; it will be revealed by radiographs if the enormous swelling obscures everything. Injury to nerves or vessels should be looked for and noted. Reduction is possible only under general anaesthesia; difficulties may be presented unless displacements of patella or hamstrings are recognized and dealt with first. If there is much effusion, aspirate under full aseptic precautions and observe for a week, immobilizing the leg on a slung Thomas splint; afterwards allow the patient to walk in a complete plaster cast at 170 degrees for eight weeks. This is followed by active physical treatment and the temporary use of a long knee-cage if necessary. The result is generally better than the prognosis.

EYE CASUALTIES IN THE WAR

BY

ROBERT DAVENPORT, F.R.C.S.

Medical Commandant, St. Dunstan's

At the outset of the war in 1914 no special arrangements were in force for either war-blinded men or the segregation of serious eye lesions in specialized hospitals.

Through the enthusiasm and energy of the late Sir Arthur Pearson St. Dunstan's was founded, and No. 2 London General Hospital organized by the authorities to receive and treat the men before passing them to St. Dunstan's. St. Dunstan's has trained and cared for its charges since 1914, adding new cases each year to its numbers, and building up an organization which is world-famous. With the ageing of the men the need for a home for the sick and those recovering from illnesses or operation increased, and in 1938 St. Dunstan's opened its new home on the Downs by the sea near Rottingdean. In it was put all that time and experience had shown to be of value to the blind, whose comfort, physical and mental, was provided for in every possible way.

Many months before September, 1939, the Council offered the home to the Government for adaptation as a hospital for the serious eye casualties of the fighting services in the event of war. The offer was accepted and plans were completed for conversion, staffing, and addition to the existing building.

St. Dunstan's by the Sea

As a result there was available on the outbreak of war a modern, very suitable building to which agreed ophthalmic personnel, surgical and nursing, was posted. The existing dormitories were readily turned into excellent wards by the minimum of necessary plumbing and wiring, and the existing treatment room adapted as a temporary operating theatre, the necessary equipment for which was already bought and on the spot. Rather more than 130 beds in four open wards, and in two corridors of two- and four-bedded rooms are available, and beds and equipment are in reserve for the conversion of lounge-room space into two more wards, so that somewhere near 200 cases can be housed.

Plans and specifications for a new operating theatre block were ready, and work was started on this necessary addition during the first week of the war, and the unit is expected to be ready for use by the end of November. A fly-over bridge carries the corridor to the block, which comprises changing rooms, anaesthetic lobby leading to two theatres, dressing room, and sterilizing room. Experience of the last war suggested that general, facial plastic, and nasal sinus surgery would need to be provided for, and one theatre is equipped to this end, although both will meet the demands of either ophthalmic or other surgery. With lighting restrictions in mind and the avoidance of glass no windows exist in the block, which is artificially lit throughout, warmed, and air-conditioned by modern means. The windowless block fits in well with the requirements of both ophthalmic and E.N.T. surgeons.

The block is tucked against a high chalk bank, but its exposed sides are protected from splinters by steel sheeting and its roof by sandbags. Where the new corridor leaves the existing building a small but efficient *x*-ray department is being fitted up, bringing it into close contact with the theatres. The equipment for this department and the theatre block is of a very high order, and this factor and the beautifully designed and fitted "wards" will mean that serious eye casualties sent to St. Dunstan's will find it an admirably sited, comfortable, and efficient hospital, fully prepared to do all that is possible for repair of their wounds. In addition to the resident ophthalmic surgical staff a panel of consultants has been arranged so that all branches of work may be dealt with, and to add to the existing nursing personnel, specialized and auxiliary, there is held a list of V.A.D.s available for duty when required.

For those whose sad lot can only be that of blindness there is ready the whole organization of St. Dunstan's. Such men will be retained for the training, technical and psychological, which is directed to the founding of a useful and happy life under the disability of blindness.

USE OF STORED BLOOD FOR TRANSFUSION

SOME PRECAUTIONS TO BE TAKEN

We have received the following communication from Drs. H. F. Brewer, M. Maizels, J. O. Oliver, and Janet Vaughan, Medical Officers in Charge of the Emergency Blood Transfusion Depots at Luton, Maidstone, Sutton, and Slough, set up by the Medical Research Council on behalf of the Ministry of Health.

Since the outbreak of war considerable use has been made of "stored blood" for the treatment of civilian patients needing transfusion. Reports that stored blood has a somewhat greater tendency than fresh blood to cause reactions appear to have led to slight apprehension in certain quarters. We believe that at least some of these reactions may have been due either to faulty technique in the preparation of apparatus, the withdrawal, storage, or administration of blood, or to the use of unduly haemolysed blood, and that they should not be taken as condemning "stored blood" of itself. Blood has been distributed to a number of hospitals from the four Emergency Blood Transfusion Depots for London and the Home Counties, where the methods of collection and storage have been those outlined in the memorandum recently issued by the Medical Research Council. The reports returned have been uniformly satisfactory, although one observer, while appreciating the immediate restorative use in collapsed and exsanguinated patients, suggests that the tonic and anticoagulant value is less than that of pure blood.

Complete records of 160 miscellaneous cases—medical, surgical, and obstetrical—are available. They were given in all 219 pints of blood and were treated in forty-one different hospitals. The maximum amount any one patient received was six pints given as a continuous drip. Blood varied in "age" from a few hours to three and a half weeks. Group O blood was used in the majority of cases, but Group A and Group B blood were also provided on request. Slight rigors were recorded in ten cases, but in several such instances inquiry showed that the blood had been given cold. In three cases there was transient jaundice; one patient passed red cells in the urine after transfusion, but the medical officer in charge was doubtful whether this could be attributed to the transfusion. No case of haemoglobinuria was recorded. No fatality proved directly attributable to the transfusion of stored blood has occurred.

We would like to stress the importance of the following significant points if optimum results in the use of stored blood are to be obtained:

1. The anticoagulant solution should be prepared with freshly distilled water from a clean still, and it should be filtered and autoclaved immediately.

2. All apparatus must be scrupulously clean. In the case of the rubber tubing a stiff wire carrying a swab or narrow elongated brush (for example, a 0.22 rifle-barrel cleaner) should be passed throughout its length, since mere washing under the tap is insufficient to remove small adherent pieces of clot. Rubber tubing freshly obtained from the manufacturers *must* be washed to remove the French chalk with which its inside is coated.

3. Strict surgical asepsis should be observed whilst actually collecting blood.

4. Storage should be carried out at 2° to 4° C.

5. Blood showing undue haemolysis should not be used. A zone of discoloration due to haemolysis extending above the corpuscle layer up into the supernatant citrated plasma for 1/2 to 1 centimetre or less (this occurs very occasionally with blood over seven days old) may be allowed, but greater degrees, including complete tingeing of the plasma, should be a definite contraindication to use.

6. Corpuscles and plasma may be mixed before the transfusion by as little and as gentle agitation as possible.

7. The blood should be warmed to body temperature before use; *the avoidance of overheating is equally important.* The highest temperature advised is 104° F.

The elimination of grouping errors as a cause of reaction is assumed.

L.C.C. SERVICES IN WAR TIME

The hospital and medical services of the London County Council and the efforts which are being made to carry on normal work in addition to the demands of the emergency are the subject of a statement issued by the heads of the departments concerned.

Hospitals and Special Units

At the beginning of the war all admissions to adult convalescent homes and hospitals had to be suspended, but one convalescent home—Princess Mary's, Margate—which had been evacuated and scheduled, is now resuming admissions, the Ministry of Health having intimated that it does not require any beds to be kept empty. Owing to evacuation of expectant mothers, the maternity units at the Council's general hospitals have been reduced from twenty-one to fourteen. The radiotherapeutic units for cancer at Lambeth and Hammersmith hospitals are in full operation. Stocks of radium have been put in a place of safety, but radium treatment will be available for cases in which it is considered essential. The admissions to the plastic surgery unit at St. James Hospital were suspended, but partial facilities have now been resumed. Additional plastic surgery units are being established under the Government scheme at certain emergency hospitals outside the metropolitan area. The mental observation wards continue to function normally, but at the other special units the numbers of patients under treatment have in some cases been considerably reduced as a result of evacuation. The puerperal fever unit at the North-Western Hospital is continuing as usual. Admissions to the fever hospitals and sanatoriums are continuing, but there are fewer cases. Five courses in fever instruction for medical students are at present proceeding.

Approximately 20 per cent. of the beds which had been allotted for casualties can now be utilized also for civilian sick. When the patients under treatment exceed this number, application is made to the group officer for some patients to be transferred to hospitals in outlying districts. Hospitals have been classified into five groups so that a reciprocal arrangement exists whereby any hospital can apply to another in the same group for any assistance it may need. Special arrangements have been made for a blood transfusion service within the Council's hospitals in addition to the one provided under the national organization.

Nursing, Midwifery, and Ambulance Services

The scheme for the training of nurses for the war period introduced by the General Nursing Council provides that in each sector all the hospitals, including fever hospitals and mental hospitals, shall be considered as one institution in each category for the training of nurses. Where possible, sister-tutors are to be evacuated with the trainees from vulnerable areas. The time spent by the trainees at the casualty clearing station is to be strictly limited, and arrangements are made to ensure that each nurse obtains the requisite experience in the various branches, if necessary by transfer from one hospital to another.

In order to cope with the anticipated increase in home confinements, due to reduction of maternity hospital accommodation, thirty additional temporary midwives were taken on by the Council, but the services of sixteen have already been dispensed with as the expected pressure in certain districts has not been realized. The Council's fixed establishment of domiciliary midwives is eighty-one. About 124 midwives from the Council's maternity hospitals have been drafted to the reception areas to assist in the confinement of evacuated expectant mothers. The number of confinements in London attended by the Council's midwives during the fortnight ended October 14 was 246; the number attended during a peace-time fortnight in August was 194. There has been a substantial increase in the number of confinements booked for the next two months.

The immediate effect of war conditions upon the ambulance service was to reduce the number of calls for general (that is, non-accident) cases and to increase those for accidents. On the outbreak of war the ambulance service was augmented in order to deal with the heavy increase in the number of casualties which might be expected if London were bombarded from the air. Many calls have been received as a result of accidents arising from the lighting restrictions.

Venereal Diseases and Tuberculosis Schemes

The L.C.C. venereal diseases scheme is being administered as completely as a reduced staff will allow. With the exception of that at Great Ormond Street Hospital all the clinics are functioning, and it is reported that the attendances in most cases are larger than were expected. At the Whitechapel Clinic during the first week of war attendances dropped from a pre-war level of about 1,900 to just over 1,000, but during the first week of October the attendance was 1,434.

The necessity for providing beds for war casualties compelled the evacuation of a large number of tuberculous patients; others were discharged at their own request. The total number so evacuated or discharged was about 1,500. The effect of the evacuation on the Council's special tuberculosis hospitals was to reduce the number of patients to 720 in seven institutions where the beds normally available number 1,400. The reduced number of beds necessitates a very careful selection in order that the best use may be made of the accommodation. There is, however, sufficient provision for patients with a favourable prognosis. Those not requiring specialized residential treatment and who have suitable home conditions are not being accepted for treatment in present circumstances. There is no waiting list for suitable patients, and a certain number of empty beds is at the disposal of the Council. The borough dispensaries are functioning more or less normally, except in a few cases where the service is curtailed. Provision has been made whereby all patients receiving artificial pneumothorax treatment are handed the necessary particulars in a sealed envelope, to enable the treatment to be continued, whatever the area to which they may remove.

Mental Hospitals

One of the Council's mental hospitals has been closed for mental patients and is to be used entirely as an emergency hospital. Nine others are being used in part as emergency hospitals. The Maudsley Hospital, which deals with early cases of mental disorder suitable for treatment on a voluntary basis, has been closed because of its situation in the danger zone. The medical and nursing staff of the hospital have been distributed between the neurological units at Sutton and Mill Hill. It is hoped that the out-patient department of the Maudsley may be reopened before long, and a proposal is being discussed for the admission to the neurological units at Sutton and Mill Hill of a few patients who otherwise might have had treatment in the Maudsley Hospital itself. The out-patient clinics originally conducted by members of the Maudsley staff at three of the Council's general hospitals are still functioning.

It is mentioned as a matter of some interest that during the week immediately following the declaration of war the number of patients admitted to the mental hospitals on reception orders was 100, whereas in the corresponding week of 1938 the number was 62. Since the end of the week following the declaration of war, however, the average number of admissions has been 19 per cent. less than the pre-war average. Probably the sudden increase at the beginning of September was attributable to nervous tension, supplemented no doubt by a proper anxiety on the part of relieving officers to get the observation wards in London as free as possible of patients likely to be in danger if enemy activity should begin. Doubtless the clearance made during the first week is reflected to some extent in the falling off of admissions in subsequent weeks, but the postponement of expected trouble probably has also operated, and it may be that voluntary evacuation has removed from London some persons who might have been in need of care.

Mental Deficiency

The Mental Deficiency Acts are being administered in London as fully as possible. At the outbreak of war all examinations of and inquiries into mental deficiency automatically ceased. It has since been ascertained, however, that the Board of Control expects the administration of the Mental Deficiency Acts to be maintained, and it has been necessary to recall certain staff (medical and lay) to carry on essential work. Accommodation in the Council's institutions for the residential care of defectives is congested by reason of the overcrowding necessary to make room for emergency hospital beds, but it is considered that the Council should be able to provide for urgent new cases. Some 4,000 defectives are still under supervision in their parents' homes in London. The occupation centres were closed on the outbreak of war.

The work of examining blind persons under the Blind Persons Act ceased at the outbreak of war, and it has now been considered necessary to resume. For this purpose medical and lay staff have been recalled from the hospitals.

Since the early days of evacuation teachers in the reception areas, dealing with children from vulnerable areas, have been concerned at the growing inadequacy of the clothing which the poorer children brought with them. Summer dresses and suits and underwear, and thin shoes, have suffered seriously under the wear and tear of country life, and many of the children's parents are unable to make good the deficiency. The National Union of Teachers has made a practical contribution to solving the problem by making a grant of £1,000 for the purchase of clothing for the most necessitous cases. This money will be administered by the Save the Children Fund, which for thirteen years past has been collaborating with the National Union of Teachers in the distressed areas.

MEDICAL ASPECTS OF CONCENTRATION CAMPS

The Government White Paper[1] and newspaper summaries of it have given the world some idea of the conditions of life in the concentration camps for political prisoners in Germany before the war. To find parallels to these conditions it is necessary to go back to exceptional periods of unrest among Oriental or savage peoples. The documents in the White Paper are closely corroborated by much other independent testimony, and an interesting sidelight from the medical point of view is contributed to the *Catholic Medical Guardian* for October by a German doctor who was confined in the camp at Dachau.

The beginning of the imprisonment for many victims was, he says, a long journey in a train, into the compartments of which they were driven by the boots and rifle-butts of their S.S. guards. Twenty were crowded into a space made for ten and the doors and windows closed. On arrival at the camp they ran the gauntlet of two lines of guards armed with bayonets and clubs. They were then kept standing at attention on the parade ground for hours with no food or water or opportunity to attend to the calls of nature. Some had their ears permanently damaged, and some had blood-suffused eyes from beating on the head. Thereafter they were forced to work at the severest manual labour day after day, and the chief object of their guards seemed to be to inflict as much torment as possible. The drinking of water was forbidden throughout the day; the loads were calculated to be beyond the strength of the workers; the guards kept up a rain of kicks and blows. Prisoners who broke down were sent to the punishment squad. Heads were bare in high summer; clothes were continually wet in winter.

Diet and Punishment

The diet supplied on the average between 1,200 and 1,500 calories a day. The usual morning allowance was a quarter of a litre of black unsweetened acorn coffee, with no nourishment value. The prisoner took to work such bread as he might have saved from the day before. His evening meal was usually soup, containing 300 grammes of potatoes, cabbage, or beans, with 300 grammes of black bread. Occasionally the issue was supplemented by 50 grammes of black pudding, or by a little jam, cheese, or syrup. Fat was almost completely absent; pulse of various kinds was common. Sanitation was relatively satisfactory in Dachau, but in Buchenwald it was abominable. Though dysentery and enteritis were common, the latrines could only be used at certain hours of the day. Clothing and shelter were miserably insufficient.

In addition to the individual brutality of the guards, formal punishments included flogging, suspension from trees, and solitary confinement in darkness. Flogging was standardized at twenty-five lashes with a steel rod or ox penis on the buttocks, after which the prisoner must stand at attention facing a wall for twelve hours without eating or drinking. Huge haematomata developed around the wounds, and fever, whether of resorption or suppuration, followed. For tree-hanging the prisoner had his hands tied behind his back. At first the pain was agonizing, owing to the strain upon the brachial plexus and the cutting of the chains into the skin; the body gradually stretched owing to the elasticity of the intervertebral disks, and the sensation was that of being torn asunder by the legs. The acutely painful phase was followed by paraesthesia and then by a sensation of paralysis; the muscles then became lifeless and the backs of the hands oedematous. The suspension usually lasted an hour and a half, and for days afterwards the hands and feet were stiff and unfeeling.

Psychological Features

On the psychological side, says this writer, neurosis is endemic, and takes the form of anxiety, ruthless egotism, or despair. The ordinary prison neuroses are rare, as the captives are mostly innocent of crime. Queerly enough, physical neuroses, especially of the gastro-intestinal tract, improved in spite of extremely indigestible food. The author therefore thinks it a safe generalization that the best cure for this class of nervous disorders is "authoritative and imperative suggestion therapy." The psychical injury which does not express itself in physical symptoms must, however, be incalculable. The author makes some reflections on the possible effect which their occupation may have on the minds of the youths who are specially selected and taught the technique of cruelty to defenceless men which is a necessary qualification for the S.S. guard. It is a melancholy thought that 7,000 young men are posted to Buchenwald at a time and that any tendencies to sadism they may have are given full opportunity for development. Parties of Hitler Youth are taken through the camps, and one of the functions of these institutions seems to be to brutalize the German youth of military age. The student of morbid psychology would find an ocean of material in unexpurgated accounts of these camps which for reasons of decency cannot be published. The colossal work of undoing the spiritual harm that is being wrought among victims and guards alike baffles the imagination.

Medical Treatment

Generally speaking, this writer found medical treatment perfunctory. At the worst the sick were driven to work and left to die where they dropped. Occasionally obvious complaints like a "struma" or hydrocele were treated and the patient allowed lighter work. Duodenal ulcers, weak hearts, active tuberculosis, and diabetes were disregarded. Patients in hospital were left entirely to the mercy of the orderlies or of fellow prisoners doing supervision duty. A certain amount was done on the surgical side: palmar phlegmons were cut out, and compound fractures of the hands and feet caused by accident or violence were treated by amputation. A civilian dentist gave some treatment at Dachau, but in Buchenwald not even extractions were performed; periosteal abscess and caries were extremely common. Innumerable dirt diseases, such as impetigo, furunculosis, erysipelas, eczema, and infective fungoid diseases, were rife, and, owing to the lack of vitamins and rest, wounds healed with difficulty. The sick, even those unable to walk, were dragged to roll-call twice a day by their friends. A common complaint was oedema of the backs of the hands and ankles. In Dachau large numbers suffered from tenosynovitis. In Buchenwald hundreds of prisoners caught an acute itching dermatitis of the edge of the pinna, due either to a fungus, silica dust, or allergy produced by the nettle-fibre blankets. It yielded to painting with a zinc solution. There was, of course, a wide variety of disease not attributable to the camp conditions, but a very large number of acute cases were fatal—perforated appendix, ileus, cancer, and pneumonia. In the opinion of the author 80 per cent. of the deaths could have been prevented by proper medical attention.

Moral Fortitude

A few items are recorded on the positive side. Some prisoners were able, by submission to the discipline and by developing the habit of enduring privation, to school and strengthen their characters. The White Paper mentions the *Bibelforscher*, members of a religious sect who were almost as badly treated as the Jews, but whose courage and religious faith were remarkable and who professed themselves ready to suffer to the utmost what they felt God had ordained for them.

Hunger and work appeared to agree fairly well with some of the diabetics, who although they received no insulin showed no sign of coma. Some of them had lost as much as 80 lb. and still felt fairly well. Almost all sufferers from psoriasis were strikingly benefited. Colds were rare. All prisoners dreaded the camp hospital with its appalling death rate, and the will not to be ill must have strengthened their weakened organisms.

The question that remains in the mind after reading these terrible reports is why those in power should find it necessary to expend so much trouble and ingenuity in heaping gratuitous torment on thousands of helpless people.

Local News

FRANCE

[From our Correspondent]

War-time Organization of Medical Practice

The decree-law of September 12 places all those doctors who are not already at the disposal of the Ministry of National Defence at the service of the Ministry of Public Health. In other words, all French doctors, men and women, come under the national defence scheme and are in a sense mobilizable if not actually mobilized. There are approximately 30,000 doctors in France; between 25,000 and 26,000 are in practice and the remainder are attached to certain special services or have retired from practice. Those doctors who remain civilians but who may be called on to go anywhere to fill gaps created by the calling up of their colleagues for army service may well experience difficulties in adjusting themselves to new conditions. It is indeed inevitable that this gigantic reshuffle should create much searching of heart, not least among the doctors who are serving in the army at 70 francs a day and who are naturally wondering what is happening and what will happen to the practices they have left. In these circumstances it is fortunate that there exists a mutual aid society, Sou Médical, to which some 9,000 doctors belong. In peace time it defends the professional and material interests of its members, and now, in war time, its staff of experts is busy solving also the war-time problems of its members.

Hospital Reform

The new law governing the public hospitals in France is a brave attempt to bring into one comprehensive scheme a tangle of public and philanthropic hospital activities dating from many generations back. For centuries gifts and legacies for the benefit of the sick poor have been administered with an independence inspired by a parochial rather than by a national outlook; hence the faults of overlapping and of lack of co-ordination. When the status of the public hospitals was legally defined in 1851 the inmates were the indigent sick, precisely those persons for whom charitable legacies were intended. Now, with hospital treatment sought by almost every class, the need for a fair distribution of hospital charges between various bodies, central and local, has become imperative. The new law introduces certain necessary reforms and codifies the rules and regulations. Principles are laid down governing the selection of patients seeking admission to hospital, and the administrative bodies responsible for the functioning of the public hospitals are reorganized, attention being paid to the representation of the medical profession and the insurance societies on the administration committees of hospitals with more than 200 beds each. Provision is made for co-operation between hospital administration and the teaching of medicine. For the better distribution throughout the country of hospital facilities, all plans for erecting new hospitals and modifying old ones must be approved by the Ministry of Public Health. Small local hospitals and certain institutions in the large towns will, however, be exempt from the paternal interference of the central authority. Facilities will be provided for the suppression of those hospitals and allied institutions whose conduct has not been found to be in conformity with modern standards of hygiene. There is also to be a tightening up and unification of the rules governing the appointment of the medical staff of the public hospitals.

Professor Leriche on Amputation Stumps

In *La Presse Médicale* for September 13 and 20 Professor René Leriche of Strasbourg comments disconcertingly on the shortcomings of the amputation stumps of the last war. About 16 per cent. of the 80,000 patients amputated in the period 1914–18 had to be re-amputated, sometimes more than once. "Retouching" was necessary in 31 per cent. of the total, and as for the amputations of the lower limbs 50 per cent. of the patients had to be operated on afresh for the satisfactory adjustment of artificial limbs, etc. A few of the secondary operations were necessitated by the development of osteitis or painful scars, but in the opinion of Professor Leriche the chief trouble was the inability of the operating surgeon to think in terms of modern prosthetics. When the operator follows the dictates of the most orthodox textbooks, showing a brilliant mastery of technique but encountering the disapproval of the prosthetic surgeon and of the patient himself some months hence, it is the operator and not the prosthetic surgeon whom Professor Leriche blames. He reviews the various amputations of the limbs in the light of the experiences of the last war, and shows how they have robbed many a classic operation of its prestige. Chopart's disarticulation, for example, has been found to be worthless in 95 per cent. of cases, and the same may be said of many another operation sanctified by textbooks.

Reports of Societies

FAULTS OF MEDICAL LITERATURE

Sir Robert Hutchison's Lecture

The David Lloyd Roberts Lecture was delivered before the Medical Society of London on November 16 by Sir ROBERT HUTCHISON, President of the Royal College of Physicians, whose subject was " Medical Literature."

The lecturer began by glancing at the vast amount of contemporary medical literature. It had been estimated that there were over five thousand medical periodicals in the world. In this country there were about 130, and here the yearly crop of medical books was over 400. The mere question of storage was itself a problem. In the library of the Royal Society of Medicine room had to be found for 3,000 new volumes each year, taking up shelving 60 ft. in length and 8 ft. in height. More serious was the effect of all this proliferation upon the interchange of knowledge. It was increasingly difficult to find the needle in the haystack. Facts might be said to be buried rather than recorded. It was almost physically impossible for anyone to follow Bacon's aphorism: " When a man addresses himself to discover something he first seeks out and sees before him all that has been said about it by others." Science seemed likely to be suffocated in its own secretions.

After recounting the familiar jest about stacks of unopened journals in consulting rooms, Sir Robert Hutchison said that current medical literature could not be permanently ignored with impunity, and he quoted Osler as saying, " The doctor who does not use books and journals, who does not need a library, who does not read one or more of the best weeklies and monthlies, soon sinks to the level of the cross-counter prescriber, and not alone in practice but in those mercenary feelings and habits which characterize a trade." All the busy practitioner could do was to tear out from his weekly journal those articles which interested him and had a direct bearing on his work and file them. In that way, with proper indexing, he could build up a useful collection. If in addition he got every year such a publication as the *Medical Annual* it should not be difficult for him to keep reasonably up to date. The contributor to medical literature needed something more—a clue through the labyrinth —and the *Quarterly Cumulative Index* was an excellent guide.

When the required articles had been found they had still to be read and abstracted, a laborious business which nowadays required a considerable knowledge of languages. He looked with no great favour upon the preparation of bibliographies and abstracts by professional librarians, who, however skilled in the business, had no medical training and could not be expected to know the relative value of different papers nor the points which should be picked out. The work of the literature hunter would be easier if there were more periodical publications of the type of the German *Zentralblätter* and *Jahresberichte*. The ideal would be an international clearing house in which the whole periodical literature of the world would be sifted by experts and summaries made of such papers as contained any original as opposed to merely repetitive or didactic matter.

Measures for Stemming the Flood

But the root of the difficulty—the immense bulk of raw material to be dealt with—would still remain untouched. What was it that prompted doctors to write? The motives were mixed: some reasonable and creditable, others less so. Good reasons were the necessity for putting on record new observations or results of experiments and the impulse to teach. Bad reasons were the desire for prestige and priority. He remembered at a meeting of the British Medical Association many years ago Lawson Tait holding up a copy of the *Journal* and saying that he divided it " into the intra-professional and the extra-professional advertising portions." That was grossly unfair. After all, the only way in which a young man could let it be generally known by his colleagues that he possessed special knowledge or skill in any department of work was by contributions to the professional journals. One must draw the line, however, at the publication of the same paper in more than one journal and at the equally reprehensible practice of sending out reprints wholesale.

Another motive for writing which was of doubtful validity was the desire for " self-expression "—a form of mental exhibitionism. No doctor would surely desire a better epitaph than the one recorded of a member of the surgical staff of the London Hospital in the eighteenth century, that he was " guiltless of any contribution to medical literature." Sir Robert Hutchison equally deprecated ceremonial orations, presidential addresses, and memorial lectures, such as he was then delivering. " Surely there are better ways of remembering the dead than by boring the living."

He suggested a strict birth control in regard to new journals. The amalgamation of existing journals might well be carried out in many cases. Some journals might be suppressed altogether, among them those which appealed only to a local patriotism. There were five such local journals in England alone, and others in Scotland. Superfluous journals led to superfluous writing, and editors were driven to tout for contributions, whereas it was the writer who should woo the editor. The ideal current medical literature for this country would consist of one good weekly journal catering especially for the general practitioner, which would contain articles mainly clinical in character, but also critical reviews and abstracts of the work published in the more specialized periodicals here and abroad. In addition each special branch of medicine should have a journal, but not more than one, appearing at longer intervals for the publication of original work in that sphere.

Stricter editing was also desirable, involving the refusal of many articles that at present found their way into print, and the cutting down of others. Almost everything was too long—lectures, speeches, sermons, and books. Powerful astringents might be required to check the verbal diarrhoea which afflicted so many writers, but it was the editor's business to administer them.

On the Writing of Books

The over-production of books was as great a nuisance as the multiplication of journals. The publishers were largely to blame. In their rivalry with their competitors they easily persuaded young would-be authors to write for them, and recouped themselves for their many failures at the expense of the more successful. It would be a great gain if, instead of issuing expensive and elaborate textbooks, publishers would provide more concise, fully documented monographs giving a complete account of present knowledge in a limited field.

Sir Robert Hutchison also criticized the dullness of medical literature, the excess of facts and comparative absence of ideas, generalizations, and hypotheses, so much recording and so little reflection. The dullness was curious considering that the subject-matter was so interesting.

> "A medical textbook might well be like one of those omnibus volumes of 'Detection, Mystery, and Horror,' for, after all, diagnosis is detection, disease is often mysterious, and, heaven knows, our work is full enough of horrors, but, as it is, the average textbook is about as readable as a telephone directory. Take, for instance, the biography of a red blood corpuscle from its birth in the bone marrow, with its capillary wanderings and its moving adventures by flood and field to its normal gradual old age and burial in the spleen or to its tragic end in a haemorrhage. It might be made a vivid Odyssey, but how dull it all sounds in a textbook of physiology—as arid and sterile, as dry and dusty as the sands of the Sahara."

Medical writers also fought shy of humour. They did not agree with the Virgilian tag that in order to speak truth it is not necessary to pull a long face. Yet a writer had never really mastered his material until he could jest about it.

The lecturer complained that one of the unfortunate results of the increasing specialization of knowledge was that the writings of workers in one department were often hardly to be understood by those outside it. Many papers on medical psychology, biochemistry, or iatromathematical subjects might, so far as he himself was concerned, just as well be written in Chinese. In addition to being prolix and obscure, medical literature exhibited only too often an absence of any sense of style or even of grammar. The average of medical writing was probably not so high now as it was last century. Certainly there were no textbooks like those of Michael Foster, Fagge, or Osler, and the modern multiple productions which had succeeded them had lost the individual touch. Much of the didactic writing of old days was in lecture form, and lectures, although the modern publisher did not favour them, were usually more readable than the formal textbook. One reason for slovenly writing was dependence on the stenographer and the dictaphone. A deeper reason was a defective literary and linguistic education. The great models of English prose were probably less read by the younger generation, and a literary diet of newspapers, detective novels, and the productions of scenario writers was no substitute for them. It was deplorable that in an examination of the standard of the M.R.C.P. it should have been found necessary to drop Latin and Greek because almost no candidate in recent years had ever attempted the comparatively simple translations from these languages, while very few showed even any knowledge of German. It might be said that style was of less importance than matter, but that was too superficial a view. As Allbutt said: "The man of science ought best to know that style and matter can no more be dissociated than skin and bone; but if we write clumsily, loosely, or disjointedly our thoughts are accordingly."

At a special meeting of the council of the Medico-Legal Society recently held, the following decisions were arrived at: (1) To suspend the ordinary meetings of the society for the time being, but to review the situation from time to time in the hope that it may be found possible to hold occasional meetings or to resume the normal activities of the society. (2) To cancel the annual dinner which was to have been held in December next. (3) To continue the publication of the *Review* and the annual subscription of £1 1s. until the end of 1940, both these matters to be again reviewed before the expiration of that period. An emergency committee has been appointed with all the powers of the council and with power to add to its number from members of the council.

Correspondence

Anaesthesia in War Time

SIR,—Your leader on anaesthesia in war time (*Journal*, November 11, p. 958) must appeal to all practical anaesthetists, and more so to those specialists who have been teaching postgraduates and students since the last war. You do not, however, stress one fact—the difference between work at the base hospitals and that near the front. The former should be similar to that in the general hospitals in ordinary civil life, and can easily be disposed of by appointing a specialist anaesthetist to, say, every 500 beds, with several juniors to help him. Even so, it is possible to criticize some of the arrangements at these improvised hospitals in such matters as uncovered exits from the theatres, the complicated apparatus provided, and the enormous cylinders of gas and oxygen (potential bombs).

At the front anaesthesia must be different. Conditions prevent the storage of innumerable cylinders of explosive gases. The wounded are shocked but have not suffered from prolonged sepsis and interference with their carbohydrate diet, and are generally heavily doped with morphine; such cases are notoriously easy to anaesthetize, requiring but little anaesthetic to produce the light anaesthesia which is all that is necessary. Such an anaesthesia is easily obtained by ether or chloroform on an open mask, or by air blown through a couple of Junker or Boyle's bottles in tandem containing ether and chloroform. A steady stream of air can easily be obtained by hand or foot bellows attached to a net-covered rubber bag inflated against pressure. Air as a vehicle for ether and chloroform is not so good as N_2O and O_2, but is very efficient, easily used, and safe.

As you so pertinently remark, everyone attempting to give anaesthetics nowadays should possess and be able to use his own bronchoscope. Ether, or even chloroform, and air without positive pressure are easily given by the intratracheal route with very simple apparatus and without the use of cylinders. These remarks are not intended to apply to those special C.C.S. which came into existence before the end of the last war dealing with abdominal, chest, or head work; specially skilled anaesthetists should be attached to these, and they will each have their own methods of dealing with such work.

Avertin is portable and easy to prepare and use. Very little ether is required to produce anaesthesia, but it requires experience to obtain the best results after the use of opiates.

A word of warning about the intravenous barbiturates: some of them contain sulphur; many of the septic cases will be given prontosil or sulphapyridine; as everyone knows, these compounds and sulphur are incompatible, but the presence of sulphur in some barbiturates is not so generally understood.

Your article is full of common sense and will be read with satisfaction by many who, like myself, are not afraid to use chloroform under war conditions, or, indeed, in the comparatively few suitable cases at all times.—I am, etc.,

London, W.1, Nov. 14. Z. MENNELL.

SIR,—As much of my time during the last war was devoted to the administration of anaesthetics I have been greatly interested by the leading article on anaesthesia in war time in the *Journal*. The article raises many points of interest and some issues to which the immediate attention of the profession should be drawn. May I briefly discuss the issues raised as they occur.

1. If a general practitioner is to be called to a work whose scope is far beyond his peace-time duties he should so prepare himself that his anaesthesia is both safe and good; if he cannot get immediate practical experience he should at least in spare moments study some not-too-bulky book upon anaesthetic practice and the modifying physiological forces of anaesthesia and the nature of anaesthetic drugs.

2. How far modern refinements in apparatus are superior to the anaesthetic equipment of 1914–18 I do not know, but

the technique of anaesthesia must still be much the same, and ether, either open or closed, must still be regarded as the method of choice, removing the fear of primary syncope, secondary syncope, and reflex syncope

3. I believe the dangers of chloroform, though really true, have been exaggerated partly owing to very faulty administration, especially during the early stages of induction—how often one has seen this drug literally "poured" on to the mask! But in view of possible civilian casualties we must remember that it is still the anaesthetic of choice in children under the age of 6 years.

4. The disfavour shown nowadays towards C_2E_3 is rather curious in view of its suitability for children between the ages of 6 and 10 years, for old people, and the powerful or alcoholic subject who responds so badly to open ether.

5. In the use of anaesthesia in cases of shock no mention is made of what used to be taught as a highly satisfactory method of induction—namely, closed ether.

6 A point which might be kept in mind, especially in connexion with first-aid posts, is the highly explosive nature of ether and the importance of avoiding the presence of a naked light or flame, especially in these sand-bagged days.

7. Closed ether given from a Hewitt inhaler seems to me as safe as any anaesthetic could possibly be if properly given—an item to be remembered in connexion with first-aid posts.

8. I wish that all who teach and demonstrate the science of anaesthetics would put up three large "N.B.s"—namely, (*a*) remember the significance of and difference between the conjunctival and corneal reflexes; (*b*) remember the importance of air in all anaesthetics; and (*c*) never forget the evil of conversation and a mind astray.—I am, etc.,

AUSTIN PRIESTMAN,
Medical Officer of Health and
School Medical Officer.

Folkestone, Nov. 14.

SIR,—The reading of your leading article on anaesthesia in war time in the *Journal* of November 11 (p. 958) recalls to my mind a simple, agreeable, and relatively safe method of administration of a chloroform-ether mixture that I was in the habit of using frequently many years ago. It was originally introduced into this country, I believe, by Dr. W. J. McCardie of Birmingham. The principle is as follows. Into an ordinary Clover's inhaler is poured a mixture of 1 part by volume of chloroform to 2 parts of ether. A rubber bag can be used for a short time during the period of induction only. The strength of the mixture is controlled solely by the rotation of the cylinder, and the face-piece is not removed at all during the operation except for necessary refilling. There is no rebreathing and coughing is reduced to a minimum.—I am, etc.,

Guildford, Nov. 16. H. F. PARKER.

SIR,—In view of recent correspondence on the danger of chloroform anaesthesia and of your leader in the *Journal*, it may be of interest to note the all-inclusive statistics of deaths under anaesthetics contained in the Annual Reports of the Registrar-General for Scotland. In that for 1936, Table 30, page xciii, the following figures are given:

DEATHS UNDER ANAESTHETICS (SECONDARY CAUSE)

Ether alone 35, in various combinations 34	= 69
Chloroform and ether 30, in various combinations 1	= 31
Chloroform alone 14, in various combinations 2	= 16
All other anaesthetics—volatile, local, basal, etc.	= 49
Total	165

Regarded superficially these figures do not seem to justify the claims made for the safety of ether and the danger of chloroform. Exact analysis is, of course, impossible in the absence of knowledge of the frequency of administration of different anaesthetics and of the selection of anaesthetics for types of patients or of cases.

The reports for the years 1931–6 show little variation in the total number of deaths from anaesthetics, but indicate that deaths from chloroform have tended to fall while those from ether have tended to rise. Presumably this has resulted from a less frequent use of chloroform and a more frequent use of ether. If this is true, however, it would indicate that the chief factor in deaths under anaesthesia is not the choice of the anaesthetic but the type of illness and of patient.

Perhaps some of the anaesthetists or "the detached observer" of your leading article would care to comment on these figures.—I am, etc.,

Loanhead, Midlothian, Nov. 13. W. HAMILTON.

Treatment of Gas Gangrene

SIR,—In an interesting letter (*Journal*, November 11, p. 973) Mr. W. A. Cochrane refers to the value of radiographs in the diagnosis of gas gangrene. I should like to call attention to the beautiful photographs by Dr. Agnes Savill and Miss Vera Collum which illustrate a paper I read in the Section of Surgery of the Royal Society of Medicine on December 13, 1916 (*Proc. roy. Soc. Med.*, 1917, **10**, 29). The paper was based on an analysis of 107 cases of gas gangrene, of which a large number came from the battle of the Somme on July 2, 1916. In it I made the observation that some help in coming to a decision as to treatment might be obtained from a minute study of the *x*-ray plate; and commented on the advisability of treatment by incision in early cases and by excision of an affected muscle when necessary, amputation being reserved for mass gangrene. Thanks to the kind co-operation of Dr. Weinberg and M. Séguin of the Pasteur Institute I was able to employ a potent polyvalent serum (*B. perfringens, Vibrion septique, B. oedematiens*) in some cases with strikingly successful results. It happened sometimes, however, that after the gangrene organisms had disappeared death took place from streptococcal infection. It seems probable that had sulphapyridine (M & B 693) been then available a fatal issue in these cases might have been averted.

In the diagnosis of gas gangrene the characteristic putrid odour is unmistakable, and has since enabled me to recognize the presence of a gas infection in a neglected maternity case. In a typical case progressing to a fatal termination the lemon-yellow coloration of the skin, a subnormal temperature, haemorrhagic vomiting, and dyspnoea are present. The patient may talk naturally, eat well, and is generally conscious almost to the end.

May I make a strong protest against the plaster-of-Paris treatment of infected wounds suggested by Dr. Trueta. Some of the very worst cases I had under my care had been encased in plaster-of-Paris, and arrived with the swollen tissues bulging above the plaster. Any pressure should be avoided, and the one flaw in the Thomas splint lies in the pressure from the shoulder or thigh ring.—I am, etc.,

FRANCES IVENS-KNOWLES.

Killagorden, Cornwall, Nov. 15.

Gas Injuries to the Eye

SIR,—I welcome Dr. Redmond Roche's letter in your issue of November 18 (p. 1019) relating to my correspondence on the above subject which appeared in the *Journal* of November 11 (p. 972). It gives me an opportunity to clarify the confusion that apparently exists in the minds of many regarding this subject, and which is so clearly reflected by the nature of Dr. Roche's letter.

First, a clear differentiation must be made between immediate treatment and that of the established injury. This letter is concerned solely with immediate treatment, and under active service conditions.

Secondly, it must be presumed that correspondents on the subject possess an elementary knowledge of the properties and action of mustard gas. The confusion which apparently has arisen is due, I feel sure, to lack of knowledge of the fundamental principles involved. It is manifestly impossible in the space of your correspondence columns to deal with the subject at any length. I will, however, outline a few of the salient features of a mustard-gas lesion of the eye, so that it may be easy to understand the rationale of the treatment advocated.

Very briefly, mustard gas is a liquid which volatilizes slowly. It is a cell poison, local in its action, and is absorbed into the lipoid of the tissues with *extreme* rapidity. In so far as the cells of the cornea are concerned the action of this gas may be described as instantaneous—a statement which is based on the following experimental findings. If drops of liquid mustard gas are simultaneously placed on the cornea of both eyes of an animal and one eye is immediately thoroughly irrigated, with everything to hand under the most advantageous conditions to carry out "first aid," while the other eye is left for Nature to deal with, the lesions of the cornea in both eyes, when examined macroscopically the next day, are indistinguishable from each other. Histological changes have been shown to occur within a very short space of time after contact, and progressively develop. This progressive development of the lesion is one of the features of the gas and consequently makes it such a valuable chemical warfare agent. When we are able to defeat this subtle action and prevent a lesion developing mustard gas will cease to be used in war.

Other points which require particular emphasis are the period of delay which always occurs before the injury becomes evident and the absence of pain during this period. The actual latent period will depend mostly on the concentration of the gas and the duration of exposure. Lack of appreciating this peculiar action has, perhaps, led many to suggest a line of treatment who with a deeper knowledge of the subject would not otherwise have done so. Research workers all over the world have been assiduously studying the problem of the immediate treatment of mustard-gas lesions for years. Many avenues have been explored and it is hoped that this work will continue, but so far no therapeutic agent has been discovered that will counteract the action of the gas on the delicate tissues of the eye once the cells have been penetrated. There is no first-aid treatment that can compete with Nature's rapid and complete removal of unabsorbed mustard gas—reflex action of the lids and immediate flow of tears—as shown by laboratory experiments. Further, no therapeutic agent will influence the development of a lesion in those cells of the cornea already affected. The damaged tissues are devitalized, which is another prominent feature of the poisoning.

For these reasons immediate treatment must be palliative. It should be aimed at allaying irritation ("suicidal pain," Dr. Roche might note, is not a feature of a mustard-gas injury), counteracting spasm, and above all preventing septic invasion of the devitalized tissue. This may best be achieved by the use of perfectly bland sterile lotions and, following this, the instillation of a drop of sterile liquid paraffin to prevent the lids sticking together and so to permit free drainage from the eye.

Dr. Roche will find this treatment, together with the points I have outlined, detailed in all the official manuals on the subject, and also in my article in the *British Encyclopaedia of Medical Practice,* vol. **5**. Greater detail in so far as the eye is concerned is discussed in an article by me in *Modern Trends in Ophthalmology,* which is at present in the press. Publication of this latter book has been delayed owing to the war, but reference to my article, and in particular to the experimental findings mentioned above, was made by Mr. Arnold Sorsby in a paper which he read in opening a discussion in the Section of Ophthalmology at the B.M.A. meeting held at Aberdeen this year.—I am, etc.,

War Office (A.M.D.7),
Nov. 17. L. T. POOLE.

SIR,—Considering the importance of mustard gas in the event of aerial activity, it is surprising that no attempt seems to have been made to obtain a "pool" of experience in this devastating injury. It would appear advisable to issue definite instructions as to treatment in order, at least, to prevent further damage from unwise interference. I would like information from those who have treated many cases regarding the following points:

1. Lavage by saline, sodium bicarbonate solution, and similar lotions is only possible at an early stage before swelling. Even so, how can it remove an oily liquid? Surely the only fluid capable of removing any excess must itself be oily. Irrigation has been impossible in the few cases I have seen, but these were not early. Surely irrigation increases spasm.

2. For spasm and pain sterile atropine appears useful. Should it be a routine? If so, between which ages?

3. Cocaine appears contraindicated entirely. What of holocain and similar drugs?

4. Dionin would appear ideal considering the hyperaemia produced by it and the tremendous devitalizing action of mustard gas, but many patients complain bitterly of the irritating burning pain following instillation of dionin.

5. Should ointment be used? Does it hold up secretions or not? The only agreed fact appears that bandaging is undesirable. Surely it is advisable to have some really authoritative teaching on these points in place of theoretical discussions. Can't we do anything for the pain?

Dr. A. Francis's experience (*Journal,* November 11, p. 972) with "dielectric oil" is most suggestive, while Professor J. H. Burn's information (November 11, p. 972) regarding the use of cod-liver oil by the German Army Medical Service is surely indicative of German thoroughness. If we have anything definite as the result of our own research it would be interesting and useful to have it made available for all.

So far official instructions in the publications I have read seem more in the form of vague suggestions, tending to imply that eye injuries from enemy action in the air are of slight importance. At the present moment symptoms are still arising from mustard gas of the last war. It must be remembered that any irritation produced may subside for nearly half an hour before the acute inflammation begins. What can be done in this important latent stage?—I am, etc.,

Lytham St. Annes, Nov. 11. WILLIAM WILSON.

SIR,—In the absence of any indication that either oils or salines neutralize mustard gas, their relative merits would seem to be a biophysical problem. From this viewpoint it would be interesting to know whether osmotic influences can affect the movement of a substance which is in solution in the tissue lipoids; and, similarly, whether the application of, say, castor oil will result in the transference of lipoid-dissolved substances from the tissues to the castor oil. If this latter possibility were true, irrigation of the conjunctiva with oils would be indicated.—I am, etc.,

Nov. 13. R. B. TERRY.

Fatal Pulmonary Embolism in Fractured Neck of Femur

SIR,—In connexion with the excellent article on fractures of the neck of the femur by Mr. Philip Wiles (*Journal,* November 4, p. 920), I would draw attention to five fatal cases of proved pulmonary embolism from treatment of basal and trochanteric fractures in old and elderly female subjects which have come under my notice in the last two years. In these subjects the complication took place in the usual types of basal and trochanteric fractures—that is, in those with lateral rotational displacement of the distal fragment and in the comminuted impacted type.

In considering how this condition of embolism might have been anticipated and prevented in these cases, one feature of significance appears to have been that treatment was undertaken about the same time in each case—namely, a week to ten days after the accident. If a thrombus is present, this seems to be the dangerous period for dislodgment. Two of the fatalities actually occurred in the operating theatre before any attempt to administer an anaesthetic or to reduce the fracture had been made. Both patients complained of breathlessness and of a feeling of restlessness and oppression on the way from the ward to the theatre, death taking place in a few minutes after being lifted from the trolley to the table. The other three patients all died a few minutes after gentle reduction of the fracture under a general anaesthetic while the surgeon was waiting to inspect the post-reduction films prior to immobilizing the limb.

At necropsy the damage to the bone, the extent of the extra-osseous injury, and the size of the haemorrhages which had taken place were far greater than might have been imagined probable or possible. Thrombosis of the circumflex veins was present and extended into the femoral and external iliac veins. The lifting of two of the patients out of bed and then removal to the theatre was enough in itself, therefore, to cause the condition of fatal pulmonary embolism.

It should be emphasized that all the cases were in elderly and old women of 65 years and over. In these cases lifting and moving of the patient and/or the attempted manual reduction of the fracture are particularly dangerous at a period of a week or ten days following the accident. It may be submitted that, if interference is to be contemplated at all (and this point in itself must be carefully weighed in the individual case) in basal fractures occurring in the elderly, then it should be undertaken at once, before thrombosis has occurred, or only after some weeks, when danger of moving a thrombus is past. In the elderly, early gentle traction in a Thomas splint as described in the article, or in Jones's hip-abduction frame, would seem to be the safest method if, in spite of the risk, it is decided that displacement is to be corrected. I have no personal experience as to whether pulmonary embolism is a serious risk in the treatment of basal and trochanteric fractures occurring in the young or middle-aged adult.—I am, etc.,

Edinburgh, Nov. 8. W. A. Cochrane.

Treatment of Fractures

Sir,—I have read with interest Mr. R. Watson-Jones's letter on this subject (*Journal*, October 21, p. 826) and must agree with him that the method described by Professor Trueta for the treatment of infected fractures cannot be regarded as revolutionary. The principles of the treatment of infected fractures—excision, cleansing, drainage, non-interference with the wound, and immobilization of the limb—remain the same. The fact that a closed plaster cast is applied does not exclude drainage. I have been using Professor Trueta's method for about ten years, but have not had the opportunity of making observations on such a large scale. In some cases I cut a window in order that the superficial gauze covering of the wound can be changed to avoid the smell becoming too offensive. In spite of the window, healing of the wound and union of the fracture were never delayed. In my opinion the success of the treatment depends on proper immobilization of the limb and non-interference with the wound after the initial dressing.—I am, etc.,

London, W.1, Nov 14. E. Goldschmidt.

Traumatic Dislocation of Patella

Sir,—Having myself twice suffered from this very painful dislocation, the article by Mr. E. P. Brockman (*Journal*, November 11, p. 963) prompts me to relate my experiences, particularly as I find that there is very little information about it in the standard textbooks.

The first occasion on which it occurred was at school on the rifle range, and was due to a forcible rotation of the knee-joint while falling prone. I have very little recollection of the actual process of reduction, but remember that it was done in a sitting position. The second occasion was quite recent, and was due to tripping over a hassock in the dark. After two very painful and unsuccessful attempts at reduction in the recumbent position, my wife was able to reduce it quite easily by gentle extension on the foot accompanied by internal rotation, as soon as we realized that I had to sit up in order to relax the quadriceps. I found that the only way in which it was possible to sit up was to force myself up by pressing with both hands behind my back on the floor. Any attempt to sit up without using the hands of course makes matters worse by tightening the quadriceps, and is, moreover, exceedingly painful.

It is my impression that a great deal of the pain in this dislocation is caused by quite understandable attempts on the part of the patient to sit up to reach his injured knee, and in part also by external rotation of the tibia on the femur from the pull of the displaced patellar tendon. This pain is quite sickening, and similar, I imagine, to that experienced in injuries to the menisci, and is possibly caused in the same way, under the stress of the rotation.—I am, etc.,

Wivenhoe, Essex, Nov. 11. Walter Radcliffe.

A Drop-wrist Splint

Sir,—Mr. John Sainsbury, in his letter in your issue of November 18 (p. 1021), wastes his time in criticizing one of the illustrations to my short article in the *British Medical Journal* of November 4 (p. 914). I admit it would have been better to have shown the apparatus fixed to a case of drop-wrist, but the photograph was taken quite recently and no such case was available at the moment. Therefore a normal subject was used and happens to have taken a very energetic hold of the end of the splint. The illustration was meant to show only the method of fastening the splint and not the poise of a paralysed wrist. I think this is indicated in the letterpress.

In actual application to a crippled hand the bases of the middle phalanges rest on the wooden roller, the essential elevation of the first phalanges being thus provided, while the fingers remain only slightly curved as in the normal position of rest. Anyway, the proof of a splint is in the wearing thereof, and this splint was found to be efficient, comfortable, and economical in nearly a hundred cases at Summerdown and the adjacent Officers' Convalescent Hospital, and met with success also at many other centres.—I am, etc.,

J. S. Kellett Smith,
Cheltenham, Nov. 18. F.R.C.S., D.M.R.E.

Treatment of Varicose Ulcers

Sir,—There being a considerable vogue for the treatment of varicose ulcers by occlusive dressings, the following experience of mine (albeit that of a humble general practitioner) may be of interest in seeming to indicate that this method may have its disadvantages (in any case the damming up of foul stinking discharges seems to me to be unhygienic and repulsive).

The patient, a woman of 50 and weighing close on 15 stone, came under my care suffering from multiple varicose ulcers on both legs, which had been treated with strips of elastic adhesive bandage, each strip being just sufficient to cover the ulcer. She also told me that before using the strips her doctor had treated her by elastic adhesive bandages applied to the whole of the leg but without any improvement. When I saw her she was in bed and the ulcers were still covered with the occlusive strips. Both legs were reddened and oedematous and excessively tender. In the calf of the left leg was a fluctuating swelling from which a considerable quantity of pus was later evacuated. In addition she had a number of boils, one excessively large and painful being in the left axilla and another in the right groin. Her temperature was 101.5° F. No glycosuria. On removing the occlusive strips several ulcers were disclosed which showed no signs of healing but which exuded considerable quantities of foul-smelling pus. The ulcers were irrigated daily with "sanitas" fluid diluted 1 in 6 (later increased to 1 in 4) with alternate irrigations of warm hypertonic saline. The boils were treated by incision followed by fomentations with cataplasma kaolin. By the second day of treatment the temperature had fallen to normal and the redness and oedema of the legs had largely disappeared. In three more days the floors of the ulcers were covered with healthy granulations and thereafter healing was rapid. The abscess in the calf of the left leg, however, caused some trouble, necessitating incision under an anaesthetic and drainage, followed by packs of 1 in 1,000 flavine in normal saline. The considerable quantity of pus contained in the abscess yielded in culture an almost pure growth of *Staph. aureus*. The patient was thereupon given uleron—two tablets t.d.s. for five days—and the condition promptly cleared up, and she made a good recovery with complete healing of the leg ulcers.

The above experience seems to show that in treatment of varicose ulcers (especially if multiple) by occlusive dressings there is a definite risk of systemic infection and abscess formation from the damming up of septic discharges.—I am, etc.,

Leamington Spa, Nov. 6. J. R. A. Davies.

Use of Radium in War Time

SIR,—I have read with much interest the article on "The Use of Radium in War Time" in your issue of November 11. The authors certainly go far to show the ultimate grave danger to life from the retention in the system of exceedingly minute quantities of radium. In support of their views they give a considerable number of references. On analysis one finds that these refer to workers who have been employed for years in occupations in which they habitually used radium, particularly those who licked brushes in order to point them in the painting of luminous dials, etc., or to injections direct into the circulation. The excretion of radium is also considered and is apparently rapid, though not complete, as a certain degree of radio-activity persists.

The facts as stated are not in dispute, but exception must be taken to the assumption that the conditions of the cited clinical and experimental work are in any way comparable to those that would be produced if a bomb made a direct hit in which radium was involved. In these conditions those who were immediately around the radium would suffer the same dispersal as the radium. For the survivors, if any, it would be a case of one and only one dusting; a very different risk to the daily exposure of occupation or the actual injection of radium into the blood stream.

In the quoted literature there is an instance of a physicist being powdered by the explosion of some radium, but there is no record that he suffered ill effects from this extremely severe dusting.* Probably nobody was so exposed to the radium risk as Madame Curie in her primitive draughty workshop with its leaky roof and smoky stove, yet she lived for thirty-six years after the discovery.

Are there no records of people showing changes in the bones or dying from aplastic anaemia, other than those employed in radium work, to support the view that radium scattered into the air by direct hit would be such a frightful menace to all around? Can no records be produced of the deaths of surgeons who have inadvertently damaged or broken needles in the course of their work? Are there no instances of deaths among those who have searched the ashes of incinerators or who have dug the city refuse heaps to recover lost and often much-damaged needles? To the best of my knowledge no such records exist. The assumption, therefore, that the references quoted have any direct bearing on the problem of the use of radium in war time seems to me to be unjustified by experience.

Nobody would doubt that the hiding away of large quantities of radium, especially in soluble form, is expedient if only because of its intrinsic value; but for relatively small quantities that might be dispersed into the air from a direct hit on needles or plaques the danger to life seems more hypothetical than real, especially if we allow for the fact that the lungs are capable of eliminating practically the whole of the inhaled dust within a relatively short time. The chances of the retention of a particle of radium dust from one dusting must be exceedingly remote.

I asked an authority on shells what were the chances of a direct hit on a source of radium if a given area was being bombed from the air. He ventured a figure in the neighbourhood of 1 in 5 million. Suppose that, with this remote chance of a direct hit in mind, a number of needles were actually disintegrated, again bearing in mind the improbability of the destruction of such light yet strong little tubes as radium needles. What would be the dilution of the radium in the dust at a distance compatible with the survival of any who happened to breathe it? How much of this contaminated atmosphere would they breathe before they fled out of it or before the dust settled? If this series of probabilities was expressed in figures the danger to life would be so infinitesimal that it would not be worthy of a moment's consideration as a war risk.

The conception that the contaminated site would become untenable for all time seems to me to be unjustifiable; doubtless this would be so as regards delicate scientific apparatus, but as a risk to human life it is quite a different matter. In mining for radium there appears to be a definite risk to workers that ultimately leads to a percentage of deaths from pulmonary disease, but a contaminated area from a bomb explosion would contain so little radium that it would not be worth disturbing by mining. Moreover, a "clucking hen" (Müller Geiger counter) would quickly determine the presence of any concentration that was worth attention. If grass was grown over the contaminated area it would prevent the possibility of dust.

The danger of *irradiation* from radium diffused over a wide area is one that could easily be assessed by measurement. We know that radiations are subject to the inverse square law, and surely the danger from this source must be fantastically remote. I am told that under a housing estate there is a quantity of radium in the dump on which it is built, and in one of the western cities of the U.S.A. there is a concrete-pavement in which a relatively large quantity of radium lies buried. No known ill effects have occurred from these sources of potential danger.

While accepting that radium, if it becomes fixed in the system even in minute quantities, may be a source of danger to life, it seems to me that the risks from war conditions in this respect are not based on foundations that justify the precautions (and consequent disuse of radium) that have been in force since the outbreak of war.—I am, etc.,

Oxford, Nov. 17. A. E. B.

* Since writing the above I have learned that this man, constantly employed in radium work, died about five to six years later.—A. E. B.

Prophylaxis of Influenza and Cancer

SIR,—The value of any of the multiplicity of remedies recommended for the prophylaxis of influenza and colds could be judged better if administered well before the expected peaks of outbreaks and epidemics, as some weeks are needed before any rise of immunity can be produced by prophylactic agents.

Owing to one group of my cancer patients showing the first signs of primary or recurrent malignant disease a few weeks after influenzal attacks I have recently made a new study of the series of influenzal epidemics and outbreaks since 1890, and have suggested that a two-phase modification of Brownlee's theory can account for all the phenomena of influenzal waves.[1] In recent years the peaks of the waves have been in February, June, and October (though they may show before long a backward drift, as has been traced in the years just after the last war). As the peaks are usually preceded by some weeks of rising death rates, practitioners who intend to try any of the remedies advocated should begin their tests soon, before the expected January rise starts.

There is on the market now at least one influenzal virus vaccine, combined with catarrhal vaccines (Parke, Davis and Co.), and results with this and similar virus brands will be of great interest. Also Shope's studies of swine influenza in the United States[2] showed that considerable protection was given by heat-killed vaccines of the bacilli which had been found associated with the virus; so some immunity might be expected to result in patients from some of the brands of catarrhal vaccines *when administered at the most effective time*. The latter proviso has been lacking in a number of the tests made with bacterial vaccines.

In addition to virus and catarrhal vaccines other remedies may be given with the aim of raising immunity; one of the best attested of these so far is serocalcin, which has been under clinical trial for six years.[3] A month's trial of this remedy is said to give a four-months immunity to influenza and "colds." Certain vitamin products and ultra-violet ray treatments also are among those which have a probable immunizing value.

The similarity in the periodicities of influenza and cancer which I have traced[4] is of the greatest interest to theory and practice: it supports the virus theory of cancer: and in the attempts to prevent cancer recurrences, in addition to radiotherapy given beforehand to sites likely to show recurrences, the effects of influenzal virus and bacterial vaccines, and other possibly immunizing measures, are being tested.

[2] *J. exp. Med.*, 1937, 66, 169.
[3] G. Tippett and MacLeod Yearsley, *Med. Pr.*, 1939, 202, 254.
[4] *Brit. J. Surg.*, 1938, 26, 113.

The relation between influenza and cancer has been found lately not to be confined to the clinical group already mentioned, in which recurrences (or a primary) followed a few weeks after influenzal attacks, but my analysis of the dates of recurrences in any given year has shown that a great proportion of these have run concurrently with, or a few weeks after, the influenzal "periods," as detailed in the paper on influenzal periodicity.[1] This is a very interesting and unexpected finding, suggesting that the relation between the influenzal and the neoplastic viruses may be quite a close one. It suggests that efficient prophylactic measures for cancer, as for influenza, may be not long delayed.—I am, etc.,

London, W.1, Nov. 18. J. H. DOUGLAS WEBSTER.

Cancer and Pernicious Anaemia

SIR,—I endeavoured in a letter to the *Journal* of June 16, 1934, to expound a theory of cancer based on the supposition that it is a deficiency disease.

Since 1934 no real evidence has come to light that cancer is due to virus infection. Much time and money have been spent on this line of investigation. To my mind a drive should be made along new lines, and I would like one new line to be that cancer is caused by a deficiency in the body of the person attacked by this disease, and that in all probability the deficiency is of a substance that is essential to the normal formation of a certain type of cell. Also that this substance, "*x*," may become "fixed" from time to time in single cells, and that if and when this substance is used up by that cell and there is no further supply forthcoming, that cell will die. In order to prevent its death this cell starts reproducing.

By way of support for my theory I would suggest that pernicious anaemia is a form of cancer. If pernicious anaemia is a cancer then we are well on the way to discover a substance that will control each and every individual type of cancer severally. We can control pernicious anaemia, therefore we can control one type of cancer. All I can do now is to try to point out why I think that pernicious anaemia is a cancer. No doubt many will scoff at this suggestion, but before they do let them think of the cases of pernicious anaemia that died before liver treatment began and the clinical picture these cases used to present.

Now for the comparison between cancer generally, on the one hand, and cancer of the marrow, or, as we know it now, pernicious anaemia, on the other.

Cancer	*Pernicious Anaemia*
1. Hereditary tendency.	Both hereditary and familial tendency.
2. Cancer is a disease of the middle-aged or elderly, affecting the sexes about equally. It is sometimes met with in young adults and rarely in children.	Pernicious anaemia is a disease of late adult life and affects the sexes about equally, rather commoner in men than in women. It is sometimes met with in young adults and even rarely in children (Muir). Only 9 per cent. under age of 40.
3. Progressive and leads to fatal termination with remissions without any form of treatment.	Progressive and fatal with remissions without any form of treatment.
4. Prognosis very bad. Death ranging from six weeks from onset to over two years without treatment.	Prognosis very bad without treatment. Osler's opinion is that average life with remissions is one year.
5. Histologically the cells of cancer are directed to proliferation.	The cells of the marrow are directed to proliferation, although the blood picture has tended to mask this from our eyes in that the blood cells actually decrease in number.

Up to the present time the average worker on pernicious anaemia has concentrated on the blood picture as arrived at by blood count. The fact that there is diminution in the number of cells circulating in the blood tends to hide the fact that this is not really the true state of affairs as to the actual number of red cells, normal and abnormal, in the body as a whole. Now in the bone marrow there are important changes. The fatty marrow in the long bones and in the short bones is now all marrow of a dark red colour (this, of course, towards the termination of the disease). According to most writers on this subject this marrow contains not only gigantoblasts but megaloblasts and large numbers of erythroblasts. The whole change may be regarded as a marrow hyperplasia of megaloblastic type.

It has been said that this is a degeneration of cells, but I feel that this is really in the nature of an embryonic regeneration of cancer cells. These cells are imperfectly formed because they are lacking in the substance "*x*" and are undergoing rapid proliferation in search of it. They are easily destroyed on reaching the blood stream owing to their unstable form, and so we find the picture of anaemia and the deposits of iron in the various organs.

Considerable hyperplasia of marrow takes place in the confines of the bones, and the picture post mortem could quite easily be interpreted as a cancer of marrow.—I am, etc.,

Christchurch, Hants, Nov. 12. EDWARD F. HUNT.

Treatment of War Wounds

SIR,—The publication of Professor Trueta's admirable book has aroused wide interest and much criticism. The book, while emphasizing the necessity for well-recognized principles of rest to the bone and soft parts, opens a further line of thought. A point which struck me was Dr. Trueta's insistence on the use of dry gauze instead of vaseline pack, as in Winnett-Orr's method. Perhaps the importance of this minor detail can explain the better and more astounding results obtained. Vaseline by its viscid nature prevents the absorption of calcium from the plaster to the wound. Dr. Trueta quotes Kline, and has emphasized that the vicinity of the plaster should supply enough calcium. A condition of local excess of calcium is thus produced which has three effects: (1) it encourages the union of fracture; (2) it helps in the production of non-pyogenic bacteria which antagonize the pyogenic; and (3) it has a general wholesome effect.

As long ago as the last war (1914-18) Baer observed the beneficial effect of maggot therapy, which Stewart believed to be due to exudation by the maggots of calcium carbonate, and he recommended dressing wounds with this.—I am, etc.,

London, W.2, Nov. 12. B. B. BHATIA.

Vein-seeking

SIR,—I have read with interest Mr. F. Ronald Edwards's description of his "vein-seeker" in the *Journal* of November 11 (p. 957). Exactly the same effect can be obtained by the following method, which has the advantage that no special instruments at all are needed.

The needle, fitted to a sight-glass, is connected by rubber tubing to a drip-bulb and the whole filled with saline or citrate. The tubing is then closed by a screw clip about two inches away from the sight-glass, and the drip-bulb is connected to the bottle of blood. The rubber tubing between sight-glass and screw clip is then compressed in the same way as the rubber teat on Mr. Edwards's vein-seeker. The needle is inserted under the skin, the pressure on the tubing is released, and blood will be seen to enter the sight-glass as soon as the vein is entered.

If a second bottle of blood is needed the drip-bulb can easily be changed over to a new bottle. Intravenous anaesthetics or stimulants can be injected into the rubber connexion between sight-glass and drip-bulb.—I am, etc.,

Medico-Legal

MEDICAL MAN CHARGED WITH WIFE-MURDER

Defence of "Dissociated Personality"

Verdict: "Guilty but Insane"

At Nottingham Assizes on November 16, 17, and 18, before Mr. Justice Singleton, Dr. Leonard Phipps Lockhart, of Beeston, aged 41, medical officer to a large industrial undertaking, was charged with the murder of his wife, Mary F. L. Lockhart, at their home on September 2. Dr. Lockhart was found guilty but insane, and was ordered to be detained during the King's pleasure.

Mr. P. E. Sandlands, K.C., and Mr. T. R. F. Butler appeared for the prosecution, and Serjeant A. M. Sullivan, K.C., and Mr. T. N. Winning for the defence.

The Facts of the Case

For the prosecution it was stated that on September 1, the day of the invasion of Poland, Dr. Lockhart and his wife, who were a devoted couple, were noticeably apprehensive about the war, the wife especially. That evening, to a friend who complained that his wireless set did not give good reception, Dr. Lockhart said, "You can have mine," and gave it to him. Next morning a manservant employed by Dr. Lockhart, on arriving at the house, was warned of gas, and found the doctor and his wife in the study lying near a gas fire. Mrs. Lockhart was dead and the doctor unconscious, but he recovered in hospital. An envelope was found giving directions to the servant about notifying the solicitor and other matters. On Mrs. Lockhart's arm was a puncture and in the bedroom a hypodermic syringe which had contained sodium evipan. A post-mortem examination of the woman's body showed that there was evipan in the liver. The necropsy also showed that death was due to carbon monoxide poisoning. There was no evidence of struggle or violence.

Evidence was given by Dr. A. Somerville of Beeston, who said that after the manservant's discovery he was summoned to the house and found that Mrs. Lockhart had then been dead for six or eight hours. Dr. Lockhart could not have been under the influence of the gas for very long, or he too would have died. In reply to a question, he said that he doubted very much whether a hypodermic injection could have been made other than with the consent or at least the knowledge of the woman. Dr. J. H. Donovan of Nottingham General Hospital said that on admission Dr. Lockhart was found to be suffering from carbon monoxide poisoning. On recovering consciousness he asked when his wife was coming to see him and was greatly distressed when later he was told that she was dead. He said that the last thing that he remembered was giving his wireless set to a neighbour. This witness in reply to a question said that he thought a healthy person might succumb to carbon monoxide from a gas fire in half an hour.

Case for the Defence

Serjeant Sullivan, in opening the case for the defence, said that it was for the prosecution to establish that the accused was guilty of murdering his wife, and, if so, that it was a conscious act. Mrs. Lockhart died as a result of carbon monoxide poisoning, but the case was confused by the fact that she had previously, with her own consent, received an injection of evipan at some time long enough before her death for it to circulate through the system and reach the liver. She did not die from the effects of the evipan, nor did the injection in any way accelerate her death.

There was evidence that both husband and wife went to bed on the night of September 1, but after that they did not act together, because the most significant factor in favour of the accused was that when Mrs. Lockhart was found she had been dead for some hours, whereas Dr. Lockhart was still living, although in a state of deep unconsciousness. This might be an attempted suicide by Dr. Lockhart, but there was no evidence of agreement to die together. It seemed probable that, Mrs. Lockhart's death having taken place about 1 a.m., Dr. Lockhart awoke at 7 a.m., and, finding his wife missing, went into the study, found her lying dead, and possibly tried to revive her and, failing to do so, attempted suicide.

If the accused was responsible for the death of his wife there arose for consideration in this case a mental or psychological phenomenon which presented difficulties of the most unusual kind. It was not a defence of insanity that he proposed to make; it was a defence of unconscious action, not arising from insanity at all. Some of the most eminent medical men in the field of psychiatry would be called to support this defence. The work of the accused necessarily brought him in contact with leading members of his own profession, and the expert evidence to be called would be given by those who knew him before this event occurred. Counsel went on to develop the argument for the existence of a condition in which the personality for a period long or short no longer controlled bodily actions—in which the automatic powers of the body were left in charge without any exercise of the personality. The appalling suffering and strain of the last war brought this condition of dissociation into prominence, but it was far more common than many people appreciated because it was only in a small proportion of cases of dissociated personality that any act of a startling or criminal nature was performed. In the great majority of cases of "fugue" the mechanical operation of the subordinated portion of the brain sufficed not only to keep the man alive but to carry him through operations even of an intricate kind with apparent intelligence and purpose and with nothing to suggest inadequate control.

The defendant's story began in August, 1918, when, while serving in the army, he suffered concussion from a bursting shell. While he was being lifted into an ambulance a blank came, and when next he remembered anything he was back in the tent where his company had been the night before the attack, and of what occurred between those two incidents he had no notion. A little later, still serving in the war, he had a similar experience, and afterwards, having taken up an appointment at the Royal Devon and Exeter Hospital, he again had a blank period, as a consequence of which he left and took up other work. When therefore his memory ceased to function on the night of September 1 it was an index, from previous experience, to a dissociation of personality. It was not the carbon monoxide poisoning which caused the lapse of memory; the lapse had already occurred. The defence therefore urged that a man whose mind was dissociated from his personality was not responsible for acts which he might perform mechanically; he was not insane, but unconscious, and even if it were found that he had terminated the life of his wife the verdict should be "Not guilty."

Dr. Lockhart's Evidence

Dr. Lockhart, in the witness box, described his experience in the great offensive of August, 1918, when his platoon, with the exception of himself and another, was wiped out. The last thing he remembered was being put on a stretcher and carried by German prisoners, and when he came to himself again he was in the assembly tent, with no recollection of how he had got there. On another occasion, while inspecting positions with his commanding officer, both of them got stuck in the mud, and again there occurred a total blank in his memory. In 1924 he was appointed resident medical officer at the Royal Devon and Exeter Hospital, and as part of his duties he had to administer anaesthetics. He had never given volatile anaesthetics by himself before, and he found his right hand trembling, and after that he could remember nothing else. On the advice of the senior physician of that hospital he decided to leave and go in for research work, not into active clinical practice; he was for a time at St. Thomas's Hospital and then became Delépine Research Fellow in Preventive Medicine and Bacteriology at the University of Manchester. Later he entered the employment of Boots Pure Drug Company to carry on bacteriological research and to look after the welfare of the staff, but the welfare work soon assumed prominence and he was responsible for a staff of about 22,000. His work was not domiciliary, but he co-operated with the workpeople's own practitioners. He was a member of a number of organizations connected with industrial medicine, and was also in charge of the medical side of the local A.R.P. He put his heart into his A.R.P. work, but was doubtful of his own adequacy.

After saying, in reply to a question, that his marriage was a perfectly happy one, Dr. Lockhart was questioned as to certain dispositions he had made in a letter to his manservant dated September 1. He said that both he and his wife had been concerned for the future welfare of this servant in the disintegration of social life which they feared might follow if war came. Explaining a phrase in a letter to the servant, "If anything should happen to us both . . .", Dr. Lockhart said that he was the only resident doctor in the part where he lived, and he and his wife, who was a V.A.D. nurse during the last war, intended to work together in the area, which was a vulnerable one. The manservant had served them very well, and they wished to make provision for him. On the same day that he wrote the letter to the manservant he posted an application for Membership of the Royal College of Physicians, his application being under the by-law which excused examination by putting in published work, and he wrote to his sponsors, Lord Dawson and Sir Arthur Hall, informing them that he had done so.

Dr. Lockhart then described the events of the fatal evening. It was not true that he made a gift to his neighbour of his wireless set. He lent it to him for the night. As he entered his house that evening he heard his wife call to him, but he remembered nothing more until he woke up in hospital puzzled by what turned out to be a blacked-out bedside lamp. He had no idea at all that he was connected with his wife's death. He was visited in prison by Dr. F. H. Brisby, medical officer of Leeds prison. There happened to be a faulty gas fire in the room where the interview took place, and some smell of gas. Dr. Brisby asked him whether he remembered on the night in question turning on the gas, and he replied that he did not, but after Dr. Brisby had left, thinking over his visit and the connexion between his remark and the smell of gas, he became disturbed, and an image began to arise in his mind of his wife's body, which was very cold and limp in his arms, and of a strong smell of gas. The images bore no relation in time or sequence to one another, but he also had the impression of the body lying somewhere in the attitude adopted by a patient who was being given an intravenous injection. This recovery of memory was associated with a feeling of terror that mutilation should have come to his wife as a result of war. He had an attack of convulsive sobbing, and Dr. Brisby was again sent for. He added that he had never at any time contemplated suicide, nor had his wife.

In cross-examination he was questioned as to the hospital incident in 1924, and he explained that although he felt he could not give volatile anaesthetics, it was not due to a shrinking from responsibility so much as to a great anxiety for the unconscious patient. It was suggested to him that the various documents he had left for the manservant betokened an extravagant precaution, but he said that they were prepared in view of war emergency, not with the purpose suggested by the prosecution, and that he was by habit of mind extremely cautious. He was responsible, for example, for a quarter of a million units of tetanus serum, and his precautions had to be extreme. Asked whether he remembered a tourniquet on his wife's arm, he said that he did not, but he recollected the hand being in the position which indicated that the tourniquet was there. A notice, "Keep out; gas (study). Fetch police." which was found by the manservant on arriving in the morning was not within his recollection; he could not recall either writing it or placing it in the hall. A previous witness, an air raid warden, had stated that Dr. Lockhart had visited his post twice on the night of September 1 to complain about lights; Dr. Lockhart said that he could remember only the earlier visit. With regard to the syringes, forceps, and other apparatus which were found, some of them on a stool in the bedroom, he said that these were part of the kit which he and Mrs. Lockhart had got together for an A.R.P. emergency bag.

Nurses' Evidence

Miss Matthews, nursing sister at the Royal Devon and Exeter Hospital, testified that she was at that hospital in 1924 when Dr. Lockhart was there, and she remembered that he told her he had a great dislike of giving anaesthetics. She heard that he was supposed to have had a mental collapse, and she did not see him afterwards. Miss Ellen Rabett, theatre sister at the same hospital, said that Dr. Lockhart gave anaesthetics on several occasions. One afternoon when he was doing so he complained of not feeling well and looked rather distraught. He agreed to her suggestion that he should go to his room. He had said on other occasions that he was not very certain of himself, and did not like the confinement of the theatre. On the day in question he was very much perturbed and did not seem to understand what he was doing. He had muddled the bottles in which the anaesthetics were kept.

Medical Evidence for the Defence

Dr. Millais Culpin, professor of medical industrial psychology in the University of London, said that he had known Dr. Lockhart for six or seven years. His opinion as to his responsibility for his acts on the night of September 1 was based on the assumption that he was speaking the truth as to his loss of memory.

"This is a condition with which I have previously been very familiar in the war in patients suffering from mental disturbance. They have been under great emotional stress, which they have resisted, and have reached a point at which the emotions overcame them and the ordinary stream of consciousness was suspended. In that condition they performed acts which were quite foreign to their ordinary personality, and when this period ceased they have had no recollection of it. That observation is based upon the fact that I use a particular technique which enables me to restore the memory for the period when their ordinary consciousness was suspended."

Asked whether the partial recovery of the memory as spoken of by Dr. Lockhart was confirmatory or contradictory of the witness's opinion, Professor Culpin said that his description fitted in precisely with what happened when memory was restored—the rush of emotions and ideas which had been shut aside hitherto now took possession of his consciousness. The period of suspended consciousness might in his experience last for hours or weeks, or even in a few cases for years.

What is it that carries him off?—Some urge which he had not previously allowed to take possession of his consciousness—some urge or set of emotions which he has hitherto excluded or tried to exclude.

Is the existence of such a condition rare or common?—It is more common than people think, even in civil life.

Much more frequent, you think, since the last war?—I have no means of comparison.

Have you seen a number of cases which you think are attributable to the war?—Yes, and some independently of the war.

Can such a condition come on gradually?—There may be premonitory warnings, but the victim would not appreciate or understand them as a rule, though his actions would indicate the approach of such an attack.

The witness said that he judged from what he had heard that the accused had a pretty bad shell shock, but the unusual feature about it was that he returned to his duty, whereas most men ran away. His attitude towards the administration of anaesthetics threw some light on the subject. With regard to the letter addressed to the manservant on September 1, if he had seen that letter, knowing the accused, he would have felt alarm, he would have felt that something was going to happen, but he would not have read into it the conscious intention to commit suicide. Asked by the judge whether he regarded the writing of the letter as showing that Dr. Lockhart was not in his normal state through strain or illness, he said that he did; it was the letter of a man who had no clear idea what was in front of him. The fact that on the same day as the letter to the manservant he had applied for the M.R.C.P. substantiated his opinion; the application was the act of an ordinary healthy man looking forward to the future. Professor Culpin was asked whether in the condition he had described the man would be capable of forming an intention to kill his wife, and replied that he would find himself doing it without thinking about it

Would he be capable of forming a judgment as to the propriety of his action?—He would not think of it.

The judge said that the question was not answered, and after a pause the witness said that it was difficult to answer, but he could picture something taking place almost automatically, the bodily action being controlled by the set of emotions and ideas which had taken possession of his consciousness.

In cross-examination the witness was pressed as to what proof there was that a man who said he could not remember events was speaking the truth. He said that he had been doing this work for years, and it was his business to know whether the emotional reactions were genuine or not. If they were genuine, it was a proof to him that the forgetting was also genuine. Asked to explain a phrase he had used, "the reason was in abeyance," he said that it was another way of expressing the fact that other emotions and ideas had taken possession of the consciousness to the exclusion of reason. There were many forms of this separation of consciousness, of which somnambulism was one.

The judge asked about the significance of the note which was left in the hall, giving warning of gas.

If it be written by one who had anything to do with the turning on of the gas it shows a complete association of ideas?—It shows that that part of him did realize that something had happened.

There was something which was dangerous, so that if he is prepared to be responsible for it he is seeking to warn others of the danger?—Yes.

It is not quite a dissociation of ideas; it points to a desire to protect other people coming to the house?—I agree, and I could not account for it. It does point to a stage in which he realized something.

Some memory?—Yes, of the outside world.

The witness said that it was well known that Dr. Lockhart was a man of great scruple, and it was possible that at this stage the good part of him took possession once more. The judge also asked whether, on discovering his wife dead in such circumstances, the natural thing would be to run for help. The witness replied "No," and recounted his first interview with the accused, when he asked him what were the worst things he remembered in the war, and he replied, "Boys on barbed wire having their guts shot out." At the second interview he spoke of the stress of the "bloody A.R.P.," imagining countless situations and problems. In the recovery of memory there came a sense of terror lest mutilation should happen to his wife, and the night following recovery he had dreams of his wife and of war and mutilation. He judged that the accused's mind was occupied with a terrible fear, and it was under that fear that he did what he did.

Dr. R. D. Gillespie, physician for psychological medicine at Guy's Hospital, said that he saw Dr. Lockhart in Lincoln prison three weeks previously. If the evidence given in court as to loss of memory and the incidents in the Army and at Exeter were accepted, he would conclude that on the night of the tragedy the accused was in a dissociated state, by which he meant that there was a break in the continuity of his consciousness. While people were in that condition they were capable of purposeful acts of an elaborate nature. In most cases the persons affected went through life without doing anything abnormal, judged by ordinary standards. On the evidence given he considered that the accused was a person susceptible to this peculiar mental state. Asked whether there was anything in the nature of mind disease involved, he said that it was a type of mental disorder; memory and judgment were for the time being seriously impaired or in abeyance, though some kind of will prevailed, otherwise no action could be carried out. The warning note against gas was a difficulty, but probably there was not always a complete break in continuity between the normal and abnormal states: the note might have been written during an interval of consciousness, and the subsequent forgetfulness was not against that hypothesis.

Dr. J. R. Rees, director of the Tavistock Clinic, and at present consultant for psychological medicine to the Army, had known the accused for some years as an eminent man in his own branch of medicine. He had always thought him to be a tense and highly strung person, inclined to be carried away by ideas. He accepted what the accused said as to his loss of memory, and he formed the opinion that at the time of the tragedy he was in a mentally dissociated state. Personality in such a condition might be completely or partially altered. Criminal characteristics appeared in only a small percentage of cases. On cross-examination Dr. Rees said that before loss of memory there must have been a period of strain and tension, and to Mr. Sandlands's suggestion that strain and tension were common to many people at that time Dr. Rees retorted that breakdown was common too; he himself had had two cases in one day.

Apart from that common strain, the only thing that really affects you is that the acts complained of were inconsistent with the normal character of the accused?—Yes, I agree.

Lord Dawson's Evidence

Viscount Dawson of Penn testified that he had known the accused personally for two or three years, and for a longer time by reputation, and had had an opportunity of forming an opinion as to his character and capacity. Dr. Lockhart had served on the Medical Committee of the National Fitness Council. He was a man highly intelligent and full of enthusiasm, speaking sometimes almost with a religious fervour and having to be called back to deal with the details of the moment. Lord Dawson had formed his opinion on the case from the history as given in the witness-box and from a visit to the accused in Lincoln prison. Every physician knew how difficult it was to evaluate what a person had to say about himself, and doctors acquired considerable skill in judging the accuracy of such statements. He had taken a good deal of trouble to find out how far Dr. Lockhart's memory was affected, and he came to the conclusion that his memory of the essential parts of this tragic incident was lacking. With regard to the letter to the manservant, considering Dr. Lockhart's morbidly over-anxious temperament, which moved quickly from anxiety to terror, and from terror to imbalance, he was not convinced that he remembered that letter very well. He judged him to be suffering from dissociation between the higher and the lower levels of the brain. The accused conformed to a type well known to those who had made a study of automatic states. The patients were mostly people who performed foolish, sometimes insane, acts; it was only a minority who were guilty of anti-social conduct. Asked what he meant by an automatic act, Lord Dawson replied that he meant an act which was purposive, executive, and at times extraordinarily elaborate, but which took place without the person knowing what he was doing, and the memory of which, in most instances, did not persist. He would class the present among such cases, always remembering that it had a criminal implication. Asked whether Dr. Lockhart would realize the nature and quality of his action, Lord Dawson said that the higher levels of the brain were concerned with the greater part of the "knowingness," and without that "knowingness" he would not be able to evaluate what he was doing, nor would he have the power of choice, nor a proper control over his conduct, nor the means of knowing what his conduct should be.

In cross-examination Lord Dawson said that the executive side of the mind might remain intact while the "knowing" side might be suspended. Questioned as to the warning notice, he said that it might indicate a partial appreciation of what he was doing. In his judgment this lapse or abeyance of "knowingness" did not maintain a steady level; it would return and recede. The judge pointed out that the preparations for the anaesthetic must have been fairly considerable. Surely a man could not carry out all these details without knowing what he was doing? Lord Dawson admitted that the action was complicated, but such things had been known before. Dr. Lockhart had taken up evipan because he wished to avoid volatile anaesthetics, and had become adept in its use in his research work. The judge said that the prosecution had put forward the theory of a suicide pact. Would this mean that both parties were in a state of "unknowingness"? Lord Dawson replied that it was impossible to answer for the wife.

Evidence of Prison Medical Officers

Dr. F. H. Brisby, medical officer of Leeds prison, who was called by the prosecution at the request of the defence, said that he was asked to supplement the observations of the prison medical officer at Lincoln. He visited the accused on November 10 and 11. At the first interview the accused told him that he had completely lost his memory regarding the events on the evening of September 1 after he returned home and heard his wife calling him. At the second interview he told him that he had had in the interval what might be described as an emotional storm. From a remark which he (Dr. Brisby) had made, linked up with a smell of gas from a faulty stove in the room, he said that some memory had returned to him. His mind was in a complete turmoil, with terror predominating, and this terror was largely centred on the wife. Asked whether he noticed a change of demeanour between the first and second interviews Dr. Brisby said that the first time he saw Dr. Lockhart there was a distinct air of detachment about him and he discussed the case impersonally. On the next day there was a great change. As a result of the two interviews he formed the opinion that the accused was of an unstable type, and with acute apprehension and mental stress acting on his unstable mentality his mind on the night of September 1 became unhinged so that he would not know whether his acts were right or wrong. The judge asked the witness's view of the kind of loss of memory which had taken place, and he replied that he thought that an impression of a very painful nature had been received; something absolutely incompatible had happened, and he had simply blotted it out, not allowing it to enter his conscious field. This could only arise through the man's disordered state.

In cross-examination he agreed that states of dissociation were not uncommon, although anti-social acts in such states were rare. The normal dissociate behaved more or less like a normal man of low intelligence. In a state of dissociation a man might appear to be absolutely normal in his different personality or he might be an abnormal person and commit a crime. There were many degrees of dissociation, and it might be mass or transient.

Dr. F. E. Norris, medical officer of Lincoln prison, said that he had had Dr. Lockhart under his close observation since September 5. He agreed generally with Dr. Brisby's conclusions. The mechanism of dissociation was a matter of theory, and he did not agree entirely with the picture of dissociation drawn in this case. The impression had been given that the higher orders of the mind had been cut off from the lower, but his idea of what happened was that dissociation was not so much between the different levels of the mind as between the conception of the mind at all his levels and the associated ideas. He thought there was a narrowing of consciousness rather than a cutting off of the higher consciousness. He agreed that the present was a typical case of its kind, that the emotional storm was genuine, and that the accused would not be able to exercise judgment as to right and wrong.

Counsel's Closing Speeches

Serjeant Sullivan, in his closing speech for the accused, said that although this case had presented an interesting problem to the medical world, there was no proof that this man had anything to do with the termination of the life of his wife. It was only on that assumption that the medical evidence became important. Insanity meant that a man had a perverted memory and judgment, and that, instead of appreciating the true nature and quality of his acts, he might conclude that an act which was utterly wrong by all proper standards was an act of virtue. The defence in this case was that the personality of the accused was not operating at all during the period in question; there was no vicious operation of memory, judgment, or will; these were suspended for the time being. There was a difference between having a mental judgment which operated in a wrong way and having no capacity for judgment at all; the one was insanity, and the other was unconsciousness of what was done. The same words and phrases had to be used to explain many gradations and differences in mental states. Assuming that the accused was found to have caused the death of his wife while in an unconscious state, he had now recovered his personality, and counsel suggested that the true view upon the medical testimony was that it was not his personality which had been acting at all, but an unconscious—or, to use Lord Dawson's word, an unknowing—series of actions, elaborate, purposeful, and apparently rational in the sense of being thought out. If that view were taken the verdict should be simply "Not guilty."

Mr. Sandlands, for the prosecution, said that facts had been brought forward from which no other inference could be drawn than that this unfortunate man was responsible for the death of his wife by administering an anaesthetic so that she should not know the terror of approaching death, and then turning on the gas fire and arranging a canopy over her head so that the gas should be inhaled. The preparation of the documents which were left for the manservant showed that the accused was fully conscious of what was being done. The court had been asked to believe that the letter to the manservant stating that, among other things, he could live in Dr. Lockhart's house had no connexion with the events of the fatal night, but surely it meant that some happening was contemplated which would leave the house intact although it might destroy the lives of Dr. and Mrs. Lockhart. Why was it that the documents were taken from the bag and put in the hall where the manservant could find them? Was this consistent with the idea of the suicide of Mrs. Lockhart and the horror-stricken husband finding her in the morning? From the evidence of the three psychologists it was clear that they thought the accused to be suffering from a disorder which made his reasoning powers so defective that he was incapable of appreciating the nature and quality of his act or, if he did appreciate it, that he was unaware that he was doing wrong. The two prison medical officers had said that dissociation was due to a mental disease, that he must have known what he was doing, but the control was by a diseased mind: it was not a case of absence of control but of wrong control, and he asked the jury to take the merciful view that at the time these acts were committed the unfortunate man did them because of defective reason due to disease of the mind.

The Summing-up

Mr. Justice Singleton began his summing-up, which occupied two and a half hours, by complimenting the prosecution and the defence on the fairness with which the case had been conducted. He also commented on the fact that although many distinguished physicians had been to see the accused man, yet it was the prison medical officer who by a chance remark was able to restore certain portions of his memory, and the judge added that those in the criminal courts knew how concerned prison medical officers were for the welfare of those who came into their hands.

The prosecution's point was that the facts suggested an agreement to commit suicide. He explained the law on suicide pacts whereby a survivor was held to be guilty of murder. Assuming the jury was satisfied that Mrs. Lockhart died at the hands of the accused man or as the result of a suicide pact, Serjeant Sullivan had still contended that the verdict should be "Not guilty," and had put forward the defence of unconscious action. He had spoken of the accused man as being an automaton, and the jury must ask themselves how far these ideas carried them in a case of this kind. Learned counsel had spoken of the rare and interesting phenomena which this case had presented to the medical profession. It might be that that was so, but they could only take cognizance of the evidence as to the facts which was presented to them. No great amount of help was obtained by considering that the case might be nearly like some other, or comparing it with the case of a sleepwalker. The sleepwalker did something when his mind was completely away, and if in his sleepwalking he fell through a window, and perchance killed someone by his fall, most people, he thought, would hesitate before describing it as murder. But they had to confine their attention to the evidence in the particular case. Lord Dawson seemed to go further in regard to the doctrine of unconsciousness or "unknowingness" than the mental experts, but at the end of his evidence he said that Dr. Lockhart had some appreciation of what he was doing. When the evidence was examined was it possible to say that there was anything like the unconscious act of an unconscious man? The judge referred in particular to the arrangements made for the administration of the anaesthetic and the preparation of the documents which were left for the manservant. Could these be regarded as the acts of an automaton or unconscious individual? There was evidence on which the jury could find, if they thought proper, that at the time he committed the act he was insane or was not responsible for his actions. No one contended that the accused man was insane to-day. Every man was presumed to be sane and to possess a sufficient degree of reason to be responsible for any crime he might commit until the contrary was proved—in other words, a man was not found insane on suspicion. To establish a defence on the ground of insanity it must be clearly proved that at the time of committing the act the accused was labouring under such a degree of mental disorder as not to know the nature and quality of his act, or, knowing it, to be unaware that he was doing wrong. If the jury reached that conclusion the verdict must be "Guilty but insane at the time of committing the act."

The judge dwelt at some length upon the evidence for at least a certain dissociation of ideas. He himself regarded the warning notice as to gas as the most important document in the case. Was there any dissociation of ideas in that? Was that the writing of a man who was an automaton? On reviewing the evidence of the psychologists it seemed a little dangerous that a jury should have put before them on their expert evidence a demand for a verdict of "Not guilty" because of what was said to be unconsciousness or "unknowingness."

The jury were absent for twenty minutes and then returned a verdict of "Guilty but insane." The order of the court was that Dr. Lockhart "be kept in custody as a criminal lunatic in such place as shall be directed until His Majesty's pleasure be known."

EXPECTATION OF LIFE IN WAR TIME

By the Fatal Accidents Act, 1846, if the wage-earner of a family is killed through negligence the widow and children may be awarded damages against the offender. The amount of the damages depends on the pecuniary loss suffered by the household. Mr. Justice Oliver decided in a recent case* that in arriving at the damages it is proper to take into account the possibility of the man being killed in the war. A man aged 31 years was killed in a motor-car accident through negligence. From a chemist's apprentice he had become manager of one of Messrs. Boots' branches, and was in the running for a position that might have brought him a thousand pounds a year. On the other hand, the judge pointed out, the court must consider that he might have been killed in a war, either through fighting in it or through an air raid. The additional war risks applied to his case even though he died before war broke out. Considering also the possibility that the widow might marry again, his Lordship awarded her £2,250, her small son £500, and her daughter £250. Damages in this case were, by agreement, assessed under the 1846 Act, but similar principles would doubtless have been followed if the court had been assessing the deceased's expectation of life under the Law Reform Act, 1934, which allows damages to the estate (not the dependants) of a person who is killed by negligence.

Obituary

P. D. WARBURTON, M.R.C.S., L.R.C.P., D.P.H.

Surgeon, West of England Eye Infirmary

The sudden death on November 9 of Mr. Percival Dillon Warburton at Exeter came as a painful shock to a wide circle of friends both within and outside the medical profession, and his loss will especially be felt in B.M.A. circles in Devon and Cornwall in view of his conspicuous work for the Association for many years.

Born at Retford in 1885, he was educated at Wesley College, Sheffield, and he received his medical education at Sheffield University and later at the London Hospital. He qualified M.R.C.S., L.R.C.P. in 1911, taking the Sheffield D.P.H. in 1914; and at the Royal Infirmary, Sheffield, he successively held the posts of house-physician, house-surgeon, and ophthalmic house-surgeon. He joined the Regular R.A.M.C. in 1913, being seconded to complete the house appointments at Sheffield; and on the outbreak of the last war he reached Belgium in October, 1914, as M.O. to the 1st Battalion, South Staffordshire Regiment, but was afterwards attached to No. 13 General Hospital, Boulogne, as a surgeon. In 1914 he had passed out of the R.A.M.C. College with distinction in pathology and bacteriology. After serving in France and Belgium till 1918 he was early that year sent to India, where he became D.A.D.M.S. with temporary rank of Lieutenant-Colonel, and was also chosen for the appointment of specialist in prevention of diseases at Secunderabad. Retiring from the Army in 1921 he returned to England and came to Exeter, where he immediately engaged in ophthalmic practice. In 1922 he was appointed assistant surgeon to the West of England Eye Infirmary, and in 1932 succeeded Mr. Ransom Pickard as a full surgeon, becoming widely known in this specialty. He also held the surgical registrarship of the Royal Devon and Exeter Hospital, and in 1925 was appointed medical officer in charge of the venereal clinic there.

Warburton was a keen and active member of the B.M.A., which he joined in 1917. In 1925 he became honorary secretary to the South-Western Branch, an office which he was still holding at his death; and in him the Branch loses a quietly efficient and conscientious worker for the Association whose place, especially on the Branch Council, will be hard to fill. He was also a member of the Central Ophthalmic Committee for the eight years preceding the taking over of the functions of that committee by the Ophthalmic Group Committee. Warburton was a man of taste, culture, and wide interests, in fact a man of the world; and he was always ready if necessary to speak his mind honestly and fearlessly, though never with any trace of personal rancour. Being himself of a modest and retiring disposition he particularly resented anything in the nature of what he considered unnecessary display; and in committee, as in affairs in general, he frequently made valuable contributions, thanks to his power of forming sound and intuitive independent assessments of problems and underlying motives. He was a lover of Devonshire and of country life and an enthusiastic sportsman of varied interests: a dry-fly fisherman, a golfer, a keen lawn tennis player fortunate in the possession of a beautiful hard court, and a member of the Tiverton Hunt, of which, usually accompanied by his children, he was an ardent follower for many years. Moreover, in his student days he was a keen soccer player, being a member of the Sheffield Wednesday team in the early years of that club. In 1919 he married, in Bombay, Marjorie, daughter of the late Mr. A. H. Tozer of Theydon Bois, Essex, and of Lloyds, London, who survives him. He also leaves two sons and a daughter, and to the family the deepest sympathy goes out in their sad and premature loss. Popular without ever courting popularity, all who knew Warburton could not fail to note during the last six months how altogether exceptionally deeply the present troubles of his country had affected his personal outlook and philosophy. F. A. R.

F. W. M. CUNNINGHAM, D.S.O., M.D., F.R.C.P.Ed.

Physician, Royal Sussex County Hospital

The sudden death of Dr. Frank Cunningham on November 10 brought a sense of personal sorrow to his many friends, and particularly to the community of the Royal Sussex County Hospital, where in every rank he was held in affection and esteem.

Educated at Glasgow Academy in his early years, he passed on to Fettes College, where he won a foundation scholarship, and thence to Edinburgh University with an open classical exhibition. It was to medicine, however, that he decided to devote himself, influenced perhaps by the advice of his distinguished uncle, Professor Dan Cunningham, who at that time occupied the chair of anatomy in the university. After graduating M.B., B.Ch. in 1907 he became junior house-physician to the late Dr. George Gibson, in whose classes he had won the prizes in clinical and theoretical medicine, and thereafter was medical officer to the Royal Crichton Institution, Dumfries. He then came south and became house-surgeon and house-physician to the Royal Sussex County Hospital, where he formed those strong attachments which in after-years found their fulfilment in an appointment to the honorary medical staff and in a period of fine service which culminated in his becoming senior physician to the hospital. But before this he was to spend some years in the R.A.M.C., first in India and subsequently in the great war in France. He came over as medical officer to Sir James Wilcox's staff, and when the Indian contingent was withdrawn was given the command of the 73rd Field Ambulance with the rank of lieutenant-colonel. In this command he greatly distinguished himself and was awarded the D.S.O. with two mentions in dispatches. During the Armistice he served on the special commission on the reorganization of front area medical work. He retired from the Army in 1919 and started practice in Hove that year. Success quickly followed and he soon became one of the leading and most trusted practitioners in the town. After taking the M.R.C.P.Ed. he was elected in 1921 to the honorary medical staff of the Royal Sussex County Hospital, and later became M.R.C.P.Lond. and F.R.C.P.Ed.

The loss to the hospital he so greatly loved is a heavy one, for he threw himself heart and soul into all its activities, and even in the last year or two, when his former robust health showed some signs of failing, he never ceased to spend himself in its interests. Cunningham took his profession very seriously and it was always his aim to uphold its high tradition. With a wide outlook on life, he was essentially the sound, sagacious, and kindly physician and consultant, intensely concerned with his patients' interests and ever their friend as well as doctor. As an example of his devotion, the writer remembers with lifelong gratitude the many weeks of a life-and-death struggle during which his friend Frank Cunningham gave up his practice, lived in the house and watched over him night and day till all danger was past. Such was the man and such the devotion which earned him the trust and affection of many who now feel forlorn at his passing.

No review, however brief, of Cunningham's life would be complete without mention of his love of all kinds of sport. He was a keen follower of cricket and was a member of the committee of the Sussex County Cricket Club. Seldom, if ever, did he miss a rugger international at Twickenham, and many will miss his cheery presence in the band of friends who used to foregather there on these occasions. He was himself a hockey international player and "blue," a fine golfer, and an enthusiastic fisherman. Frank Cunningham's varied career and numerous interests no less than his straight and friendly character brought him the happiness of many friends, whose first thoughts and deep sympathy will go out to his widow. Him they will remember as one who lived his days generously, simply, and with modesty, as the best always do. H. N. F.

Dr. L. A. **Parry** writes: By the death of Francis William Murray Cunningham, Hove has lost a beloved and respected physician, who will be missed by a large circle of colleagues, friends, and patients. He joined the British Medical Association in 1916, and was a member of the Brighton and Sussex Medico-Chirurgical Society, being elected president two years ago, an office the duties of which he carried out with great distinction. Of late years he had, owing to ill-health, given up general practice, with the exception of some of his old patients. He to the last kept on his work at the Royal Sussex County Hospital, to which he was very devoted. A memorial service was held at All Saints, Hove, on November 13, which was attended by a very large number of his medical and other friends. Dr. Cunningham was an essentially honest and straightforward man, loyal in his friendships, hospitable and generous, always available to his colleagues. The profession in Hove know they have lost a loved and distinguished doctor—one whom they all admired and trusted.

Dr. **Alec Landale Clark**, who died on November 5 as the result of a road accident, had practised for some years in Gilbert Street, London, W. Son of the late John B. Clark of Broughty Ferry, he studied medicine at Edinburgh University and graduated M.B., Ch.B. in 1923, and then served as clinical assistant and house-physician at the Edinburgh Royal Infirmary. While in practice in Mayfair he worked as clinical assistant at the West London Hospital, the Hospital for Sick Children, Great Ormond Street, and the Hospital for Women, Soho Square. "E. B." writes from Edinburgh: As one who had known Landale Clark from his earliest undergraduate days I would add a few words in memory of one who will be missed by many. "Lal" Clark, as he was known to his intimates, had a host of friends both within and without the profession. His was a very happy disposition; he radiated happiness and he had a kindly thought for everyone. Brought up as a delicate child upon whom every care was lavished, it was interesting to watch the development of his personality. Gifted with a beautiful singing voice and a lover of music, one wondered whether he would take medicine seriously. But any doubts which may have existed were speedily dispelled, for as a house-physician, and indeed throughout his life, his profession and his patients were always, with him, the first consideration. He was a man with high ideals, and his sense of duty dominated his outlook. Lal Clark had a flair for doctoring, for he combined the faculty of picking out the clinical essentials with an unusual depth of understanding and a very genuine charm of manner which gained for him the confidence and the affection of his patients. His partnership with the late Jim Brunton Blaikie in one of the busiest practices in Mayfair was a singularly happy association.

The Services

NAVAL COMPASSIONATE FUND

At the quarterly meeting of the directors of the Naval Medical Compassionate Fund, with Surgeon Vice-Admiral Sir Percival Nicholls, K.C.B., K.H.P., in the chair, the sum of £149 was voted to the applicants whose cases were considered.

"INDIAN MEDICAL SERVICE: A HANDBOOK"

Major A. N. Chopra has published a handbook for the I.M.S., giving all rules and regulations for service therein, which should be most useful to all members, not only to those joining as new recruits, but also to older and more experienced officers.[1] In successive chapters it gives, with appropriate references, the rules for recruitment, conditions of service, courses of instruction, pay, leave, including study leave, travelling allowances, passages to Europe, the Funds, and pensions. Seventeen appendices complete the work, giving the actual text of various Government Orders, the most important of which are No. I, the Royal Warrant of Service, No. XI, conduct rules for all Government servants, and No. XII, dress regulations; also rules for selection for promotion, attendance at senior courses of instruction, procedure when called on to give evidence in courts of law, private practice—all things which it is necessary for an officer to know, but which it is sometimes difficult to find at short notice when reference to authority has been required. It may be said without hesitation that the work is a most useful one, which should be in the possession of every officer of the I.M.S. On page vi is given a list of abbreviations used. Many abbreviations are used in the text which are not included in this list. Fortunately, most of them are easily interpreted. What most strikes a senior whose recollections go back some sixty years is the great rise in advantages—for example, pay on entry, £650, instead of £286; grant of study leave, and of free passages; and the opportunity of retiring on a gratuity after five years' service. On the other hand, the cost of living has considerably increased, and no doubt service in India is not so pleasant as it was half a century ago.

Universities and Colleges

UNIVERSITY OF OXFORD

Applications are invited for the Nuffield Professorship of Orthopaedic Surgery, and should reach the Registrar of the University not later than December 16. The stipend is £1,200 per annum and £600 as clinical director of the Wingfield-Morris Hospital; private practice not allowed; age limit 60. Residence is required during forty weeks in each academic year. Further particulars may be obtained from the Registrar.

UNIVERSITY OF LIVERPOOL

The Council of the University of Liverpool, on the recommendation of the Senate, has conferred the title of Professor Emeritus on Sir Robert Kelly, M.D., F.R.C.S., who occupied the chair of surgery from 1922 to September, 1939.

UNIVERSITY OF ABERDEEN

The Senatus Academicus of the University of Aberdeen has decided that students on military service will be allowed, when they return to civil life, to resume any fellowships, scholarships, or bursaries whose tenure may have been interrupted.

UNIVERSITY OF WALES

Welsh National School of Medicine

The following candidates for the degrees of M.B., B.Ch. have satisfied the examiners at the examination indicated:

Medicine.—R. T. Bevan, H. R. Hudd, C. W. D. Lewis, Silvia M. D. Mehta, Enid M. Powell, Mary M. Williams.

Medical Notes in Parliament

In the House of Lords on November 16 the Royal Assent was given to the National Loans Act, the Prices of Goods Act, and the Chartered and Other Bodies (Temporary Provisions) Act.

The Bastardy (Blood Tests) Bill, which was waiting for Committee in the House of Lords, on recommitment, lapsed with the prorogation.

Sir Francis Fremantle presided on November 16 at a meeting of the Parliamentary Medical Committee. Dr. Salter brought forward a report from a medical man who had been transferred from a London hospital to take charge in a home county of a public assistance institution which must prepare 1,600 beds against emergencies. This report made complaints of maladministration and said that questions about supplies had to be referred to the county medical officer, not to the sector officer. On behalf of the Parliamentary Medical Committee Sir Francis Fremantle placed these complaints before Dr. Elliot. It is understood that the Minister made arrangements for a special inspection. The same meeting of the Parliamentary Medical Committee endorsed the approach made to the Air Ministry to secure, with special regard to venereal diseases, the appointment of women medical officers to attend women attached to the Air Force. The Committee also decided to urge the appointment of mobile units to attend scattered units in Britain. It was remarked that local authorities would require assistance in dealing with venereal disease where Service personnel was scattered. A subvention was advocated for the films issued by the Social Hygiene Council. Mention was made of the circulation of anti-vaccination pamphlets among the civil population, and Sir Francis Fremantle's action in challenging this was endorsed. The Committee held that an authoritative contradiction of these pamphlets should be circulated by the Ministry of Health.

Before the Parliamentary Session ended by a prorogation on November 23 the House of Commons discussed unemployment and also the problems of evacuation and education in Scotland. A meeting of the University M.P.s' Committee was arranged for November 22.

E.M.S. and Specialist Services

Sir Ralph Glyn inquired on November 13 whether there was adequate specialist treatment available for persons threatened with blindness and attending Moorfields and other London hospitals, and whether Dr. Elliot would authorize immediate release of enough eye, heart, throat, and ear specialists to attend to their normal peace-time work.

Dr. Elliot said he knew no difficulty in providing adequate specialist treatment for ophthalmic cases. In general, there had not been interference with necessary treatment in the other types of case he mentioned. As to the position of specialists, he was discussing with a special committee the terms of service of specialist and other members of the Emergency Medical Service. He hoped to make a statement in the following week on the result of this consultation.

Emergency Powers for Universities

In the House of Commons on November 14 Sir Donald Somervell moved the second reading of the Chartered and Other Bodies (Temporary Provisions) Bill. The general purpose of the Bill, he said, was to enable modifications to be made in the constitution and electoral procedure of bodies incorporated by Royal Charter, statutory bodies, and universities and colleges, if such modification became necessary to meet war conditions. The Bill followed on the earlier measure dealing with Oxford and Cambridge, and gave the universities power to pass emergency statutes. These would be required to deal with such matters as the postponement of elections to office, the suspension of offices becoming vacant, and the suspension of conditions relating to candidature and tenure of office, scholarships, and so on. The Bill was read a second time.

Education in War Time

Mr. Lees-Smith opened, on November 16, a debate on education. He said one disastrous result of the present situation was that schemes for milk in schools, medical service, nursing service, dental clinics, and other services had practically come to an end. In the early stages of the war doctors were concentrated in the hospitals and the result was that services outside the hospitals were being starved. Dr. Haden Guest, in an earlier debate on evacuation, had shown that there were enough doctors and nurses available, properly distributed, to provide a nucleus for the hospitals, ready for emergency and at the same time to carry on the public health services, the medical services, and to provide a service of consultants.

Mr. Kenneth Lindsay, in a general statement, said the average weight of some of the evacuated children had increased by 3½ lb. Many were benefiting from the changed conditions; those in country areas were taller, stronger, better fed, they slept longer, and were more alert and easier to teach. Had there been an evacuation in 1914, 33 per cent. instead of 3 per cent. of girls' heads would have been unclean. In reception areas an adequate medical service was now operating. In neutral areas, wherever schools were opened, there was a normal service. In evacuation areas a skeleton service was operating, and with the reopening of schools it would be extended.

A circular advocating the wider use of communal meals for evacuated children would be issued shortly. The Government had agreed to meet overhead charges, and it should be possible to provide children with a good meal for 2½d. to 4d. Evacuated children who received free milk in their own areas usually continued to receive it in the reception areas. Many of the evacuated children whose parents paid for milk in their own areas also continued to receive it. There had been an inevitable falling off in the consumption of milk by children in the evacuation and some neutral areas where schools were closed pending the completion of air raid precautions. It was estimated that 150,000 children under 5 were now in reception areas, 41,000 of them unaccompanied by parents. Nursery schools of the orthodox type were not possible for them, and it was also felt that crêches and day nurseries would not meet the problem. A scheme for dealing with these children on different lines would be announced. Mr. Lindsay said there were about 900,000 children in evacuation areas, 1,700,000 in neutral areas, and 2,500,000 in reception areas.

Serious Casualties at First-aid Posts

Mr. Groves asked Dr. Elliot on November 16 whether his attention had been called to the fact that in Barcelona a system of aid posts and mobile units similar to that in this country had to be abolished because it proved impossible to prevent the reception of serious cases at these posts, from which they could not be evacuated to hospitals without fatal delay. He also asked whether the Minister's attention had been drawn to the further fact that the death rate was notably diminished by the abolition of aid posts and mobile units. Dr. Elliot said in reply that he had seen statements in the medical press to the effect stated by Mr. Groves. He was advised that the conditions as they existed at Barcelona were not parallel to those in this country. The instructions here were that the seriously injured were to be taken direct to hospitals and not to first-aid posts. He had no reason to believe that these instructions would not be observed. Many first-aid posts in England and Wales were situated at hospitals. First-aid posts were inspected by his medical officers in every region, and he was satisfied the facilities were adequate for dealing with the type of case for which the posts were intended.

Doctors and Gas Masks.—Sir John Anderson, on November 14, informed Mr. Bull that he had received one or two representations, and others had been made to the Ministry of Health, from local authorities for civilian duty respirators for midwives and doctors in evacuation districts. He could not undertake to extend the issue of special respirators and anti-gas equipment to persons outside the public air raid precautions services and the emergency hospital service.

Notes in Brief

The question of allowing an extra ration of butter, when rationed, to tuberculous persons, particularly children, is under consideration.

On October 28 the number of patients on the waiting list for admission to tuberculosis sanatoria and hospitals in Wales was 225, or, including patients discharged by reason of the Emergency Hospital Scheme and awaiting readmission, about 600. Hutted hospitals in Denbigh and at Chepstow are making steady progress, and subject to the requirements of the casualty service will be of assistance in the treatment of tuberculous patients.

Medical News

Professor Grey Turner, M.S., F.R.C.S., has been appointed a corresponding member of the Surgical Society of Buenos Aires and an honorary member of the Society of Hospital Surgeons of Santiago of Chile.

The *Journal of the American Medical Association* for October 28 announces that Dr. Evarts Graham, professor of surgery at Washington University School of Medicine, St. Louis, has been honoured by the creation of a lectureship in his name, and thus Dr. Graham's influence in the advancement of scientific surgery will be prolonged.

The programme of the Royal Institution (21, Albemarle Street, London, W.1) announces a course of three lectures on food production in war time, by Sir Frederick Keeble, F.R.S., on Tuesdays, November 28, December 5 and 12, at 2.30 p.m. The subscription for this course payable by non-members of the Institution is 6s.

The British Institute of Philosophy announces that the second of the series of free public addresses, entitled "The Deeper Causes of the War and the Issues Involved," will be given by Professor Gilbert Murray in the Assembly Hall (entrance in Craven Street, Strand) of the Royal Empire Society at 2 p.m. on Thursday, November 30. The series will be continued in January and February, on dates to be fixed, by Professor Ernest Barker, Sir Richard Gregory, F.R.S., and Sir Richard Livingstone. Cards of admission can be obtained from the Director of Studies at University Hall, 14, Gordon Square, W.C.1.

Professor H. V. A. Briscoe, D.Sc., will read a paper on "The Chemical Properties of Siliceous Industrial Dusts" at the Royal Society of Arts on Wednesday, November 29, at 2.30 p.m. Applications for tickets should be made to the Secretary of the Society, John Street, Adelphi, W.C.2.

The October issue of the *British Journal of Rheumatism* has a note stating that publication of this periodical will be continued, possibly in a restricted form and possibly also at less frequent intervals.

According to *Il Policlinico* (Sez. Prat.) of October 30, of the 38,000 German doctors about a third are with the army, and of the remainder 1,200 have been sent where they are particularly needed, especially Danzig, East Prussia, Kassowitz, and Silesia.

An Order was made on November 9 by the Ministry of Food (Great Westminster House, Horseferry Road, S.W.1) which permits any person to use until further notice the following oils for the purpose of the preparation of any medicine or medicament for internal or external use without the necessity for holding an individual licence as required by Article 8 (*d*) and (*e*) of the Oilseeds, Vegetable Oils and Fats and Marine Oils (Control) Order, 1939: Coconut oil, cottonseed oil, gingelly (sesame) oil, ground-nut oil, maize oil, olive oil, palm oil, soya-bean oil.

The Library of the Royal Society of Medicine will now be open until 8 p.m., and may later be open until 9 p.m. if there is sufficient demand for this.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

In England and Wales there was a considerable reduction in the incidence of diphtheria, and small decreases were recorded in Scotland, Eire, and Northern Ireland. With the exception of Northern Ireland, notifications in these countries were well below those of the corresponding week last year, but deaths are slightly in excess (Scotland excepted). There has been little fluctuation in the figures for scarlet fever, and the low case fatality indicates a continuance of the very mild type prevailing in recent years. Dysentery is on the increase both in England and Wales and in Scotland; in the former country no locality is particularly affected, but in the latter more than half the cases, 31 out of 50, occurred in Edinburgh, where there has been an unusual prevalence of the disease during the last six weeks. Though probably unrelated to the dysentery outbreak, the high and increasing death rate in Scotland among children under 2 years of age from enteritis and diarrhoeal diseases is worthy of mention. It may well be that the causative organism is not so readily recovered from fulminating and fatal forms of the disease, and some of the deaths are actually attributable to dysentery.

Acute Poliomyelitis in 1939

During the late summer and autumn, the usual period of seasonal prevalence of poliomyelitis in the northern hemisphere, large epidemics were encountered in various parts of Germany, in Hungary, Switzerland, Holland, and in some of the States of the U.S.A. Except in Hungary and Italy the disease did not reach the 1938 level, but in certain American States it was decidedly more prevalent. In Germany the numbers recorded during the summer and autumn were lower than in 1938, but were well above the median of the immediately preceding eleven years. The majority of the cases were in Schleswig and the Berlin area; of the total 1,130 cases reported between September 3 and 30 in Germany (including Austria and the Sudeten area), 227 (20.3 per cent.) were in the former district and 147 (16.7 per cent.) were in the latter and 40 were in the district of Potsdam. In the previous year Rhenish Prussia, the Palatine, and Württemberg were the principal epidemic foci. In Switzerland the disease was more prevalent during September and October than in the corresponding months of 1938, but the total number was well below the epidemic year 1937. Of the 287 cases reported between September 3 and October 28, 87 occurred in the canton of St. Gall and 66 in that of Aargau, both in the north-east of the country. In 1937 the districts of Berne, Zurich, Vaud, Lucerne, and St. Gall were most affected. In Hungary three-quarters of the cases reported in September and October occurred in the three departments situated along the eastern frontier: of the 331 recorded 68 were in Szabolc department, 44 in Bihar, 91 in Hajdu, and 44 in the town of Debrecen. In the U.S.A. between August 3 and October 7, 3,993 cases were reported, compared with 550 during the corresponding period of 1938 and 5,187 in 1937. Five States contributed about 58 per cent. of the total: New York 717 cases, Pennsylvania 244, Michigan 587, Minnesota 369, and California 374. Outside these States poliomyelitis was less prevalent than usual.

In England and Wales the situation has been more favourable than in 1938, when the disease was unusually prevalent in a few counties, notably in Essex, but never attained epidemic proportions. Between July 1 and November 4, 1939, 473 cases of poliomyelitis were notified and 43 of polio-encephalitis, compared with 1,068 and 77 respectively in 1938. London largely escaped: 64 in 1939 for the same period and 86 in 1938, even although the principal foci in both years were in counties into which Greater London has spread—in Kent to the south of the Thames in 1939 and in Essex to the north in 1938. Sporadic cases and minor outbreaks have occurred in various counties, but in none, apart from Kent, has the disease been able to establish itself. During the current week as many as eleven counties were affected, but only in three did more than one case occur—namely, Kent 5 (1 each in Bexley, Bromley, Gillingham, Maidstone, and Eastry); Surrey 3 (1 each in Leatherhead, Merton and Morden, and Wimbledon); Middlesex 2, both in Harrow.

No. 44.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 4, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for : (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for : (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases ; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			37			38	27			

* Includes primary form in figures for England and Wales, London (administrative county), and Northern Ireland.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The TELEGRAPHIC ADDRESSES are
EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*
SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Doctúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

A Historic X-ray Apparatus

Dr. R. T. GUNTHER, Curator of the Museum of the History of Science, Old Ashmolean, Oxford, announced in the *Times* of November 10 that his museum had lately received a portable *x*-ray apparatus of outstanding historic importance, for it was probably the first outfit of the kind to be placed at the disposal of army surgeons in war. In 1898 Captain E. G. Spencer-Churchill, then an undergraduate at Magdalen College, acquired a Wimshurst electrical machine, *x*-ray tube, and fluorescent screen, with which he showed his friends the bones in their hands. When, in 1900, he went out to serve in the South African War his *x*-ray equipment went out too, and was the only one then available in South Africa. Dr. Gunther would like to know from our readers whether there is any army record of an earlier *x*-ray apparatus being used in military surgery.

Fractured Femur in the Field

Dr. BERNARD CHAVASSE writes from Liverpool: The method of treatment referred to by your correspondents Dr. W. R. Wilson (*B.M.J.*, October 28, p. 896) and " D. W." (*B.M.J.*, November 18, p. 1028), who alludes to the description of it by Major J. B. Fotheringham (*Journal of the Royal Army Medical Corps*, March, 1939), is that which appeared under my name in your issue of October 5, 1918. I feel honoured that this method, which was slowly evolved under the conditions for which it was designed, has met with such distinguished and recent approval. The method is not a rival to the Thomas or any other proper splint. It is for application at the site of the casualty—separated from the regimental aid post (where a Thomas splint may be available) by what is apt to be a terribly long and rough journey. Only a stretcher and two stretcher slings are required. The rifle gives additional support.

Hygiene of Rubber Boots

" M.R.C.S." writes with reference to the inquiry by " Registered Medical Auxiliary " about a foot powder for soldiers wearing rubber Wellingtons: For the last forty years I have used rubber boots for all my shooting and fishing (except when wading). Blistering is prevented by making the feet a close fit in the boot by wearing two pairs of socks, or a pair of socks over stockings. This seems to prevent the feet getting over-hot in hot weather, and keeps them much warmer in cold. I also use an inner sole cut out of a thin sheet of cork. This sole can be taken out and dried after use. Of course the socks should be changed and dried—at any rate the outer pair, which seem to absorb most of the moisture. The boots need drying inside as far as possible. No doubt these precautions could not be taken in the field, but some form of inner sole and an extra pair of socks should do away with most of the risk of discomfort or injury to the feet. Any powder would probably form a cake with the sweat.

Obesity after Childbirth

" G. W. G." writes: Can any reader give me advice regarding a woman patient aged 30, who weighs nearly 16 st (height 5 ft. 6 in.)? One year ago she had a child, and since that event has put on 1½ st. The breasts are still full of milk, although the child has been weaned for ten months. She eats moderately and avoids most fattening foods. Apart from getting somewhat easily tired and being very worried about her figure she enjoys good health.

Muscular Twitchings

" H." writes: Can any of your readers suggest a treatment likely to control general twitching of the muscles—sometimes affecting all the muscles of the body? Calcium and parathyroid, luminal, and chloretone have been tried without effect. The patient is 80 years old.

Income Tax

Husband and Wife

" DELTA " has been called up for military service, and his wife, who is in the A.T.S., has also been called up, and is stationed some distance away. Can he claim that they are legally separated so far as income tax liability is concerned?

⁂ No. The precise point has not been before the courts, but the general argument in Eadie *v.* Commissioners of Inland Revenue—that absence by reason of duty, business, pleasure, etc., does not constitute separation—would be against the claim. " Delta " is, however, entitled to the additional personal allowance in respect of his wife's earnings—£45 for 1939–40.

Division of Partnership Assessment

X. took Y. into partnership on a 50 per cent. basis as from April 1, 1939, and the firm's assessment for 1939–40 was based on the amount of X.'s (sole) practice for 1938–9. Consequently his car expenses—£305—for that year were deducted in calculating the assessment, but, of course, no expenses were deducted on Y.'s account—he was not then in partnership. How should the assessment of £x be divided between X. and Y.?

⁂ There is no legal rule that covers the facts, and the partners evidently only want an equitable basis for division. Our suggestion is as follows. Compute the amount of expenses Y. will incur corresponding to X.'s £305—we will suppose it is £150—then add both amounts to £x and divide equally before taking off the expenses. The results will be: X.'s share, 1/2 of (£x + £455) less £305; and Y.'s share, 1/2 of (£x + £455) less £150. Unless Y.'s estimated expenses are taken into account in this way he will pay on more and X. on less than fairness suggests.

LETTERS, NOTES, ETC.

"Foreign Pharmaceutical Products"

Messrs. BALLANTYNE, CLIFFORD AND CO., Solicitors, 120, Fenchurch Street, E.C.3, write: We have been instructed by our clients, Messrs. H. R. Napp Limited of 3 and 4, Clements Inn, W.C.2, to write you with reference to the publication in your *Journal* of the booklet issued by the Association of British Chemical Manufacturers and the subsequent references to the same appearing in your issues of November 4 and 11. Our clients do not feel that the matter has been dealt with satisfactorily so far as they are concerned, although they are glad to note and appreciate your expression of regret for having published material which may infringe the registered trade names mentioned in the booklet. They desire us, however, to call your attention to certain matters which have not been specifically mentioned and without knowledge as to which, they feel, there is danger of your readers forming an erroneous view both with regard to them and the products. We refer to the fact that not only are these products manufactured by our clients in this country but that they have been so since their inception several years ago, and that they are and always have been marketed in cartons upon which is clearly indicated that they are made in England. Our clients feel sure that you would wish to prevent as far as possible any injustice to them arising from this unfortunate publication, and they hope you will insert this letter.

Corrigendum

The designation of Dr. John Sainsbury was incorrectly given under his signature at the end of the letter on " A Drop-wrist Splint " published last week at page 1021. It should have read " Late Medical Officer in charge Massage and Electrical Department, Special Surgical Military Hospital, Ducane Road."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY DECEMBER 2 1939

TREATMENT OF WAR FRACTURES BY THE CLOSED METHOD*

BY

J. TRUETA, M.D.

Late Director of the Department of Surgery, General Hospital of Satalunya, Barcelona

Advance in the treatment of compound fractures has always been secured by the experience gained in time of war. Only in wars are fractures sufficient in number to permit a study of all the problems involved. This was evident in the great war, the last great conflagration which preceded the war in Spain. In the twenty years that have elapsed since the end of the great war progress has, however, been maintained because of the increase of casualties due to road and industrial accidents. For this reason the outbreak of the Spanish War found the study of injuries more advanced than at the end of the great war.

Compound fractures in war may be produced by various projectiles: bullets fired from rifles or machine-guns, artillery fire, and aerial bombs. Injuries from aerial bombs are always more destructive than others, even gunshot wounds, so that in this paper I shall give special attention to air raid injuries because of the gravity of the lesions.

Treatment of open fractures is not merely treatment of the bone but of the wound. Bone should be considered as organic tissue which reacts similarly to other tissues, so that the fracture is only a wound of the bone. Treatment of the wound is then the principal part of treatment of open fracture.

At all times the treatment of open fractures has been directed towards two objects: (*a*) to avoid or to overcome the infections which jeopardize the life of the wounded or his fractured limb; and (*b*) to obtain the best possible reduction of the fragments, and by immobilization to secure consolidation of the fracture without deformity.

In all surgical works of the past these two aims have been prominent. In the writings of Ambroise Paré, for example, his preoccupation with these problems is evident. Against infection he recommends a paste containing turpentine, comparable to the use of antiseptics three centuries later, and for immobilization of the fracture he advocates splints, which are illustrated in his books. Paré was the first surgeon who opposed the custom of his time of cauterizing wounds by means of boiling oil with the idea of destroying the "poisons" produced in them. Like many other advances in surgery, this innovation came about by accident. He described it in the following words:

> "At length my oil lacked and I was constrained to apply in its place a digestive made of yolk of eggs, oil of roses, and turpentine. That night I could not sleep at my ease, fearing that by lack of cauterization I would find the wounded upon which I had not used the said oil dead from the poison. I raised myself very early to visit them, when beyond my hope I found those to whom I had applied the digestive medicament feeling but little pain, their wounds neither swollen nor inflamed, and having sleep through the night. The others to whom I had applied the boiling oil were feverish, with much pain and swelling about their wounds. Then I determined never again to burn thus so cruelly the poor wounded by arquebuses."

I will not waste further time with the history of the subject, but will discuss only the weapons we use against infection and deformity in open fractures.

AVOIDANCE OF INFECTION

Local Antisepsis

From the time that Lister applied to surgery the discoveries of Pasteur, antiseptics were considered the most efficient means of avoiding infection of wounds. The great progress which Lister's technique represented was not, however, generally accepted for many years, and Lister had great difficulty in obtaining recognition for the new methods, which were so opposed to the concepts in vogue in his time.

Beginning with Lister's carbolic acid and the mercury derivatives advocated by Koch,[9] trial of new antiseptic products has continued up to our own day. Each new antiseptic has been an improvement on the one that has preceded it, in both its bactericidal power and its lessened toxicity for the tissues of the body. Progress continued until the time of the great war, when Alexis Carrel introduced continuous irrigation with hypochlorite solutions. This was shown to be more efficient than any antiseptic used up to that time, because it united to its bactericidal power a very weak toxicity for the cells of the body. The reason for the efficacy of continuous irrigation with Carrel-Dakin solution was not properly appreciated. The good results were ascribed to its great bactericidal power, whereas the real reason was that its slight toxicity allowed the tissues to react against infection. This was confirmed by Sir Almroth Wright, who obtained the same or even better results from the use of hypertonic solutions which had no antiseptic power but which acted physically in promoting drainage. Post-war experience has shown the doubtful value of antiseptics as a means of preventing infection in wounds, and in my opinion the war in Spain has confirmed this.

Biological Antimicrobic Methods

The vogue for vaccines and serum, which some years ago was extensive, has also diminished. Apart from antitetanic serum and to a less extent anti-gas-gangrene serum, the use of sera for all other wound infections fails to produce effective antibodies because of lack of specificity.

Chemotherapy

Since the publication of the work of Domagk compounds of the sulphanilamide group have been widely used in the treatment of wound infections. This new method of treatment has been advocated with the same enthusiasm as was the introduction of the other forms of antisepsis. Apart from the complications, such as nephritis, anaemia, erythematous rashes, and petechiae, which are observed when these drugs are used for severe infections and in large doses, I do not share the enthusiasm which was expressed in a monograph published in Spain during the war by Drs. D'Harcourt, Folch, and Bofill (1938). I have not seen good results in severe infections of the limbs, though in pleuropulmonary infections and in some cases of meningo-encephalitis the results have been more encouraging. I believe it is necessary to use sulphanilamide compounds with prudence, never exceeding 6 or 7 grammes a day, and reducing the amount as soon as the drug is beginning to produce beneficial effects.

Excision of the Wound

Until the year 1897, when the German surgeon, P. L. Friedrich, published his experimental work on excision of contused wounds as if they were neoplasms, the factor of the vitality of the tissues as a decisive element in the struggle against infection was not given its due importance. Since then this principle has been appreciated, and in the great war it was finally accepted. No treatment against infection, such as antisepsis of the wound or the use of sera, is employed to-day without first excising all damaged tissues, particularly those deprived of circulation. The only variation has been in the selection of the tissues which must be excised most radically. Contrary to the opinion held during the great war by surgeons like Leriche, I believe that the greatest danger of infection lies not in bone but in muscles. Bone plays an almost passive part in infections and is only invaded secondarily after colonization of the organisms in the soft tissues. Dead muscle tissue is a favourable soil for the development of anaerobic infections, and for this reason must be excised meticulously. Small haematomata in the intermuscular spaces are good culture media which should be followed up systematically. Skin, on the other hand, provided it has a good blood supply, should be preserved, only the edges of the wound being resected with scissors. After the publication of Friedrich's work and the experience which followed it, but especially as a consequence of the great war, a new factor gained importance—namely, the time which elapses between the production of the wound and the removal of the devitalized tissues. As a result of the experience of the great war eight hours was considered the limit as the optimum time for operation before infection of the wound occurred. But this limit is not exact because it varies in relation to the degree of destruction of the tissues. I have been able to see in hundreds of cases an aseptic course in wounded patients operated on after eight hours, provided the wound was but little contused, as, for example, in wounds produced by bullets fired from a distance. On the other hand, in wounds from shrapnel, and especially those produced by aerial bombs, infection occurs much earlier, often in less than four hours.

Shock

Patients with compound fractures produced in air raids showed signs of shock immediately after infliction of the wound, but this shock generally disappears with appropriate treatment, especially morphine, lobeline, heat, and transfusion of blood. Rest, physical and psychological, also helps to revive these patients. To this primary or psychic shock is added secondary or true shock when the wound has not been properly treated within a few hours. In extensive wounds of the limbs I have been able to observe clinically, perhaps for the first time on a large scale, that true shock is the result of absorption of disintegrating tissues. After air raids in Barcelona it has been possible to operate radically on hundreds of patients with severe wounds of the limbs within half an hour, and sometimes within twenty minutes. After treatment of the primary shock a meticulous operation was performed, all the devitalized tissues being removed and the limb itself preserved wherever possible. When operation was undertaken immediately it was common to observe that secondary shock did not occur, nor did generalized infections develop. If true shock is to be avoided, I am convinced that operations for compound fractures with extensive wounds should be performed within the limit of two hours. In this I agree with Professor Manuel Bastos, who reached similar conclusions from experience in Madrid, where because of the proximity of the front it was possible to operate within this optimum period. Unfortunately, this limit of two hours cannot always be observed in the Army, because of the difficulty of transporting the wounded to the casualty clearing hospital, especially when the numbers are great and many have to be collected from between the two lines of fire. On the contrary, in bombarded cities the existence of civilian hospitals within the town allows immediate assistance to the injured, provided the organization is adequate.

Physical Methods: Open Treatment

Among the procedures aiming at sterilization of the wound by physical means, open treatment has been most widely followed, and has given the best results. Suggested during the great war by the German surgeon F. Schede (1915) and accepted immediately by Braun and later by Böhler, this method has produced excellent results. Schede used plaster casings with windows, as later did Böhler, while Braun only fixed the limb by a splint with the wound uncovered. The results that I have obtained by this technique have not been unfavourable, especially the promotion of healing under the slough, but it is of limited use in deep wounds of the limbs because retained secretions remain undrained under the slough. Only in severe trauma of the lower limb when there is doubt about the possibility of saving the limb is it necessary to watch the state of nutrition of the tissues for two or three days. In these cases it is advisable to employ open treatment, after immobilizing the limb correctly by continuous traction and a good splint, such as Thomas or Braun. This treatment, by exposure to the air, is better than the use of antiseptics, because it does not interfere with the natural defence mechanism of the body, while allowing the surgeon to watch the wound without the necessity for handling it. Also it is painless and simple. This technique, like the use of antiseptics, is employed only after complete excision of the wound—that is, after applying the principle of Friedrich.

Drainage

One of the factors which favour the development of infection is retention of discharge, especially when, as in all war wounds, colonies of organisms exist in the depth of the wound. Good drainage is essential, for a badly drained cavity allows the collection of fluid, at first consisting of blood, but rapidly changing to pus. In my experience the best drain proved to be sterile absorbent gauze introduced between the tissues in the direction of the muscle fibres. Sometimes counter-drainage by a rubber tube was inserted through the plaster into the most dependent part of the cavity.

Immobilization

It is well recognized that movement increases the dissemination of infection in the body and the absorption of toxins from wounds. This is probably due to interference with the local defence mechanisms through rupture of the small capillary and lymphatic thrombi by which the wound is isolated from the general circulation. Certainly it is true that a rigorous immobilization constitutes one of the most effective means of preventing and combating infection.

What do we understand by a rigorous immobilization? An immobilization which prevents movement of all the tissues, but especially the most vascular—that is, the muscles. This protection against movement can only be obtained by enclosing the extremity under a rigid casing, which while preventing all movement, even the most insignificant, permits a good circulation. The only known material which supplies this requisite is plaster-of-Paris. Experience in Catalonia is on this point convincing, as we shall see later. The only disadvantage of plaster is that it prevents examination of the wound at any given moment. Fortunately this examination is seldom necessary, but one must be quite dogmatic about the indications. In the upper limb, if the treatment has been correctly applied, progress is always satisfactory with the closed method, and gas gangrene and septicaemia are very rare. I have never seen these complications, even in patients treated by young surgeons with a limited experience. It is therefore not necessary to examine the progress of the wound. In the lower limb, thigh and leg must be considered separately. When operating on fractures of the leg, especially those involving the popliteal region or the calf, it is necessary to examine carefully both the circulation of the foot and the local circulation of the part, and especially the possibility of excising all devitalized tissues. When, in spite of this excision, there is still doubt about the vitality of the tissues that remain, or about the total circulation of the leg, it is essential to wait two or three days before putting on plaster, using instead open treatment with continuous traction which will permit frequent observation of the state of the circulation. In this way amputation can be undertaken without loss of time when it is apparent that the nutrition of the limb is insufficient. In the thigh the indications are similar, but with the difference that here the local circulation of the tissues surrounding the wound is more important than the general circulation of the leg, because the latter is more easy to assess. Here also if there is doubt one must wait two or three days, keeping the patient in bed with the wound open and the leg fixed by continuous traction. With this line of treatment it has been possible to save many limbs as well as lives, and to see gas gangrene disappear progressively from our hospitals.

I must consider here another question. Should these wounds be sutured or should they be left open? In this my criterion is absolutely definite. If suturing would produce the slightest tension in the soft tissues the wound must be left completely open. If there is any doubt about the vitality of the tissues, especially the muscles, then here too the wound must not be sutured. It will be readily understood that in wounds from aerial bombs, which constitute the greater part of my experience of war wounds, one seldom sees cases where suture of the skin is possible. On the other hand, in accidents of civil life suture can, under certain conditions, be performed without danger.

REDUCTION OF FRACTURES AND IMMOBILIZATION WITHOUT DEFORMITY

The only satisfactory method of obtaining reduction of fractures is by traction, initial or continuous. Reduction must be secured by the application of extension on the operating table. Each region has its own special technique. In the upper extremity it is possible in most cases to reduce the fracture by manual traction at the end of the operation. Occasionally in fractures of the humerus extension has to be made by transfixion with a Kirschner wire through the olecranon against counter-traction by means of a towel crossed around the thorax and fixed to the operating table. In fractures of the lower limb the deformity is reduced by traction, the details varying with the site of the fracture. To ensure proper reduction some form of orthopaedic table should be used. The purpose of the traction is to reduce the fracture and maintain it in reduction so that after the surgical treatment of the wound is completed a plaster cast can be applied.

Operation on the lower limb is performed with the fracture reduced by traction. In this way all the tissues are in their normal position, so that both bone and soft tissues are more easily explored. Traction is made progressively in such a way that reduction is complete at the end of the operation. This is one of the reasons why x-ray examination is unnecessary before the operation. All the tissues with a bad circulation are excised, the bone fragments are placed in a good position, and the cavity drained with gauze.

Immobilization with Plaster-of-Paris

This should be put on under the anaesthetic in all cases where it is possible, profiting by the good reduction of the fragments that has been obtained by the continuous extension. *The patient should never be moved from the operating table in order to put on the plaster.* The reasons for this are clear: reduction of the deformity would be lost, time would be wasted, and shock increased.

Plaster-of-Paris Technique

To obtain complete immobilization both of the bone and the soft tissues the plaster should be put directly on the skin without the interposition of cotton-wool or stockinet. Only the anterior superior iliac spine, the os calcis, and the tendo Achillis should be covered by a thin layer of cotton-wool. In a few very thin patients it may be necessary to cover lightly the bony points around the elbow. The use of cotton-wool under the plaster diminishes the immobilization of the soft tissues and, because it quickly becomes saturated with the discharge of the wound, it increases the smell, so that the plaster cannot be kept on as long as is necessary.

After-treatment

The plaster cast must be left in position as long as the smell is not excessive and the plaster does not become soft and wet. The patient nearly always runs a temperature for a few days after the operation, showing that a local fight against infection is going on at the site of the fracture. In a total of 1,073 patients treated in my clinic removal of the plaster for a true clinical infection was necessary in only 0.75 per cent. of cases. On these occasions it was found either that a cavity was badly drained or that cellulitis had developed.

Advantages and Drawbacks

The immediate benefits of the plaster treatment are absence of pain, rapid disappearance of shock, elimination of sleepless nights, and return of appetite. The absolute rest of the fractured limb promotes good normal union. The failures can all be attributed to faulty technique: the surgeon had either tried to save a limb with insufficient blood supply or had not excised enough bruised tissue.

The most common complications are cellulitis and lymphangitis. Diagnosis and treatment are usually easy. If in a case of fracture treated by the closed method there are a rise of temperature, loss of appetite, pain at the site of fracture, sensation of tension, and regional adenitis the plaster must be removed. Nearly always cellulitis, or more rarely a primary lymphangitis, is found. The usual treatment for cellulitis is carried out. The intermuscular planes are widely opened up, the whole of the affected area is exposed, and the cavity drained with sterile absorbent gauze. The plaster is renewed either immediately or at most two or three days later. I have had to remove the plaster from eight of my 1,073 patients for this reason.

Gas Gangrene

In the case which is developing gas gangrene the symptoms are immediately more striking. The patient says he cannot sleep, he has no appetite, his tongue is dry, he is restless, and from the first moment his pulse rate is raised. Locally there is increasing pain in the region of the wound, heat, and tension. The foot or the hand becomes rapidly cold, in a few cases with oedema, and the digits cannot move. With this combination of general and local symptoms the plaster should at once be removed and the wound opened up without waiting for evidence of gas beneath the skin. Bold resection of the skin and devascularized tissues with separation of the intermuscular spaces followed by immobilization has been successful in several cases transferred to my clinic for treatment.

This complication, which in my patients occurred once in 1,073 cases, generally develops within the first two or three days after the infliction of the wound. For this reason it is essential to be extremely vigilant during this time and not to encase in plaster fractures in which there is doubt about the vitality of the tissues. In open fractures treated by other techniques with the object of watching for the appearance of gas gangrene it is important also to diagnose the condition before bubbles of gas are seen, relying on the general state and the local signs. No time is lost, then, if vigilance is sufficient in the cases treated by the closed method; and, as I have said before, if the technique is correct the complication is rare. In the majority of cases of gas gangrene that I have seen either the limb has been preserved in the presence of vascular lesions that interfered with the normal circulation or the wound had been sutured.

Plaster Windows

I am convinced that making a window in a plaster case neutralizes all the value of the plaster treatment. Such an opening interferes with the local circulation at the site of fracture, sometimes producing great oedema, disturbs the immobilization of the soft tissues and, if the opening is large, the immobilization of the bone fragments. Those cases of compound fractures which cannot be closed under plaster because of anxiety about the vitality of the tissues are best treated by continuous extension with the Thomas or Braun splint.

Special Benefits of the Closed Method for the Treatment of War Fractures

The widespread use of plaster-of-Paris in Catalonia was brought about by the exigencies of war, but the reasons which compelled me to advocate this method were the following:

1. It is the best complement to the technique of local excision of the wound as a means of avoiding infection.
2. It allows immediate radical operation of fractures, because after the operation the patient can be moved without danger and evacuated long distances.
3. It permits a perfect drainage of the cavities of the wound because the plaster acts by suction of the discharges absorbed by the gauze. For this reason I do not use petroleum jelly, which diminishes absorption.
4. It avoids the dehydration and loss of heat that occur in large wounds if the open method is used, which induces a condition of shock.
5. If the plaster is correctly applied—that is, directly on the skin without the interposition of cotton-wool and with the limb in correct position—displacement of the fragments does not occur. Frequently the first plaster achieves the desired position, and at each change of plaster the fragments are maintained in the position that was obtained on the operation table. In other cases a better reduction must be secured after ten or twelve days when the danger of severe infection has passed, because the emergency of the first treatment did not permit one to leave the fragments in a sufficiently good position. This can be done (with x-ray control) at the base hospital far from the danger zone and without urgency.

Confirmation of the Value of this Technique

In the first place I must mention our results in Spain. Mine have been published in my book on the treatment of war wounds, and shortly Colonel D'Harcourt, chief surgical consultant to the Republican Army, will publish in an English journal the results obtained in 5,000 cases treated under his direction in the military hospital in Barcelona. As I have mentioned earlier, I had one case of gas gangrene in over 1,000 cases of compound fractures, and Colonel D'Harcourt had twenty in 5,000. It is necessary to take into account the fact that I was able to operate immediately in many of the patients, and that in others I was the first surgeon who handled them. Colonel D'Harcourt, on the contrary, was obliged to treat many wounded soldiers admitted to the military hospital in a bad condition after having been inadequately treated previously or treated on wrong lines. In view of the small number of cases of gas gangrene in the recent statistics of the Catalan hospitals there has grown up a doubt as to whether gas gangrene occurs in our country in the proportion in which it is found in other countries of Europe. On this point I can affirm, though I have no statistics available, that the number of cases of gas gangrene in our war was extraordinarily high, but they occurred only in places where proper treatment was not used. It is only necessary to glance at the *Revista de Sanidad de Guerra* to see the cases reported there. For example, in an article by Dr. V. Goyames on transfusion of blood in two hospitals in Madrid, sixty-one transfusions were given for gas gangrene. In Madrid also there was a hospital devoted entirely to the treatment of this condition. I have information that gas gangrene was a frequent complication among the wounded of General Franco's army, and appeals were made to certain countries to send quantities of anti-gas-gangrene serum for treatment. And both the Republican Army and the Army of General Franco fought on the same soil and under the same climate. I maintain, therefore, that if in Catalonia gas gangrene disappeared, this was due to the technique which our surgeons employed.

Confirmation and Opinion of Foreign Surgeons

As is well known, at the end of the war in Catalonia a retreat from the country of nearly half a million persons took place. Among these refugees were over 10,000 wounded, nearly all with wounds of the extremities, who went to France. Numbers were evacuated in the army ambulances, but many thousands went across the frontier walking with plasters that covered and immobilized open fractures. Several hospitals were organized in France attended by surgeons of "La Santé Militaire Française," who did all they could to deal with this unprecedented influx of wounded. During the early days of the retreat the French doctors were amazed by the arrival of thousands of soldiers—many on foot—in bad general condition due to fatigue and hunger, with plasters smelling offensively, under which were extensive wounds. Many amputations of urgency were performed because the surgeons feared the development of gas gangrene.

A short time later reports were presented to medical societies in different parts of France on the observations made by these surgeons, who previously had little experience of the closed method of treating compound factures. The general consensus of opinion was that the results were eminently satisfactory, serious infections being extremely rare.

Dr. M. Arnaud reported to the Academy of Surgery in Paris (May, 1939) the results he had seen in 800 wounded from Catalonia, the majority of whom had been treated by the closed method. He was surprised to see only one case of gas gangrene.

All the wounded who came to France during the evacuation of Catalonia arrived after many days of travelling from one place to another under the psychological and material conditions of an army in full defeat, which in every war always produce the greatest mortality. In spite of these bad conditions the testimony of these French military surgeons is proof of the value of this method.

I hope that this evidence will be sufficient to encourage my British colleagues, and I am sure that the result of treatment of compound fractures in the present war will be very different from that of the great war.

⁂ The discussion of Dr. Trueta's paper is reported at page 1106 this week.

ANAESTHESIA IN WAR TIME

BY

R. R. MACINTOSH, M.A., M.D., F.R.C.S., D.A.

Nuffield Professor of Anaesthetics, University of Oxford

AND

FREDA B. PRATT, M.D., D.A.

First Assistant to the Department of Anaesthetics,
University of Oxford

Although the anaesthetic problems peculiar to modern warfare remain unformulated, the basic principles of anaesthesia, whatever these problems may be, will remain unaltered. These principles are the maintenance of a clear airway, the recognition of the signs of anaesthesia, and the avoidance of an overdose of the anaesthetic drug. The problems will undoubtedly include (1) the supervision by the anaesthetist of several unconscious patients at the same time; (2) the anaesthetizing of shocked or exsanguinated patients, and of patients heavily morphinized; (3) the danger of fire and explosion if explosive gases (ether, vinesthene, or cyclopropane) are used; and, because of the physically depressed state of the patients and the lack of skilled anaesthetists, (4) the problem of applying restorative measures to patients *in extremis*.

Experience of the last war has suggested that air raids will result in casualties so numerous as to make their adequate treatment impossible. The medical practitioner with any surgical knowledge will be pressed into surgical duties, so that the few delegated to anaesthesia will be responsible for the supervision of more than one anaesthetized patient. In this task the anaesthetist will obviously be helped if he can call on intelligent though only partially trained assistants. To prepare for this a series of fifteen lectures on the basic principles of anaesthesia was given at Oxford at the outbreak of war. Among those who attended were dental practitioners (the B.D.A. was circularized locally and the response was encouraging), retired medical practitioners, and laboratory attendants experienced in anaesthesia in animals. A similar series of lectures could be arranged at any other large centre to ensure that in an emergency the anaesthetist could have the assistance of helpers with some knowledge of the care of the unconscious patient.

Choosing the Anaesthetic

Too much stress has been laid on the use of particular anaesthetic drugs for particular conditions. While it is undeniable that the specialist can attain refinements of anaesthesia with drugs such as cyclopropane and pentothal, this fact has overshadowed the truth that safe anaesthesia can be furnished by so-called old-fashioned means by comparatively inexperienced anaesthetists provided they apply a sound knowledge of the basic principles of anaesthesia. During the past few years there has been so much talk of new anaesthetic drugs and techniques that many doctors are hesitant about offering their services as anaesthetists in war time because they know nothing about "these new-fangled anaesthetics."

It cannot be emphasized too strongly to the occasional anaesthetist that safety in anaesthesia does not lie in attempting a multitude of techniques or in learning the actions of a wide range of drugs but in gaining experience in the use of one anaesthetic agent. The drug chosen is of minor importance provided it is administered skilfully. We know of hospitals in the United States in each of which a different type of anaesthetic drug is used almost exclusively. In one hospital in New York City nothing but spinal anaesthesia is employed for general surgical operations, including thyroidectomy and mastectomy. In another hospital cyclopropane only is used, while a third favours nitrous oxide, and in a fourth practically nothing but ether is employed. The anaesthetists of these hospitals extol the merits of the particular drug they use, yet it is striking to find a negligible variation in the gravity or number of complications caused by the anaesthetic either during the operation or in the post-operative period. The reason is that each anaesthetist has mastered his own particular technique. An inexperienced anaesthetist would soon encounter difficulties and dangers if he attempted similar methods. The specialist anaesthetist should be competent to provide any form of anaesthesia required. The occasional anaesthetist is recommended to use what opportunity he has to master one drug only—and that drug should be ether.

Merits of Ether

Whichever of the many techniques or drugs an anaesthetist may favour he will change to ether if he encounters difficulties which prevent him providing satisfactory operating conditions. This drug, discovered almost a hundred years ago, has never lost its pride of place as the safest and most reliable of anaesthetics. A further tribute to the safety of ether is that in other countries ether is administered thousands of times annually by nurse anaesthetists. Although these nurses have had special training there is no other anaesthetic drug with which they could be allowed so much freedom. Often the method is somewhat crude, but because of the safety of ether it can seldom be said that the life of the patient is endangered.

Induction with ether, if enough time is allowed, need not be unpleasant. If it is rushed, however, the feelings experienced by the patient are disagreeable and provoke resistance. If a quick induction is required an intravenous injection of evipan may be given. The technique of continuous intravenous barbiturate anaesthesia requires special training, is fraught with certain difficulties and dangers, and is not to be recommended to the occasional anaesthetist. A " one-shot " injection of evipan, however, is a simple affair, quickly learnt, and of great value. For an adult 0.2 to 0.5 gramme, according to the anaesthetic resistance of the patient, provides a pleasant and quick method of producing unconsciousness deep enough to allow ether anaesthesia to be superimposed. As soon as the injection is finished the administration of ether is begun, and it is continued as rapidly as the patient will tolerate it. Because of its rapid excretion the effect of the small dose of evipan is very transient. After a few minutes the depth of unconsciousness is attributable for all practical purposes to the ether used. Alternative drugs to ensure a rapid induction are vinesthene and ethyl chloride. Provided the practitioner is familiar with the use of chloroform a mixture of chloroform and ether may be employed. Whatever drug is chosen for induction a change is made to ether immediately respiration becomes automatic. Whether ether is given by Clover's inhaler, the " open " method or by bubbling air, oxygen, or gas-and-oxygen over or through ether matters little.

From personal experience (R. R. M.) in the hospitals in Spain during the Spanish War we learnt the difficulties of anaesthetizing unprepared patients, particularly since no nitrous oxide, oxygen, or in fact any anaesthetic material beyond a bottle of ether was available. These difficulties were emphasized in operations on the head and neck. Since atropine was not obtainable we were greatly handicapped by the secretion of a large amount of mucus. Atropine should be given before every operation in which ether is to be administered. If given subcutaneously it takes ten to fifteen minutes to act. Given intravenously it becomes effective almost at once. The only anaesthetic apparatus available was an outfit consisting of a laryngoscope and endotracheal tubes which we had taken with us.

The Endotracheal Tube

By passing an endotracheal tube and attaching it to an ordinary tin (such as a container for motor oil) in the top of which two or three small holes had been bored, a simple apparatus (Fig. 1) was made which enabled us to fulfil the essentials of anaesthesia for the repair of wounds around the head and neck region—that is, the maintenance of safe anaesthesia without encroaching on the part being operated upon. An almost identical technique was originally suggested by Flagg.

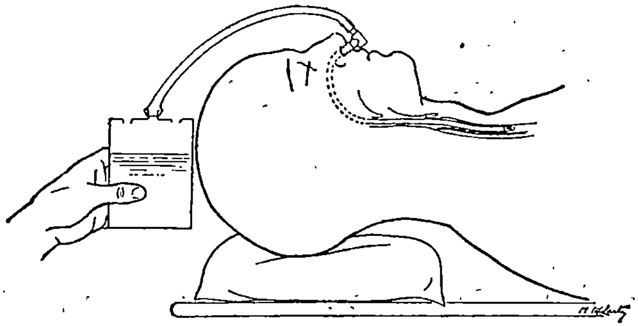

FIG. 1.

If the anaesthetist has time to spare, let him devote it not to learning how to administer different anaesthetic agents but to learning how to pass an endotracheal tube. The ability to do this will increase his sphere of utility enormously. Early experience should be gained in the post-mortem room. Later by passing a laryngoscope at the completion of any operation he can familiarize himself with the view of the larynx in the living. Exposure of the cords is facilitated by an adequate depth of anaesthesia, the preliminary spraying of the throat and larynx with cocaine, and the introduction of a support under the head in such a way as to flex the neck and extend the head (Fig. 2).

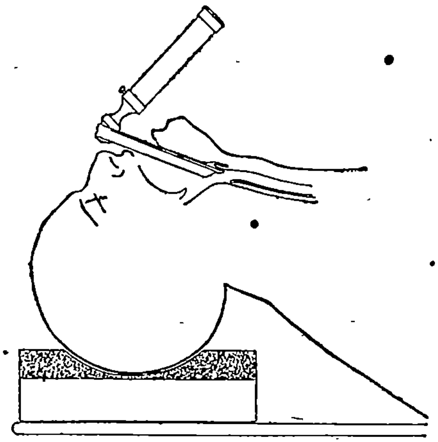

FIG. 2.—Position for laryngoscopy.

The importance of the maintenance of a free airway cannot be over-estimated. Once unconsciousness is reached this duty devolves on the anaesthetist. A free airway can generally be maintained by pressing the angle of the jaw forward so as to lift the tongue out of the laryngeal entrance, but once anaesthesia is deep enough the introduction of a metal airway (Waters's or Connell's) will do much to ensure safety and to lessen the work of the anaesthetist. Hospitals are advised to have a plentiful supply of airways. Other essential equipment includes Mason's gags and tongue forceps. Emergency substitutes for the latter are towel clips or large safety-pins. Since any patient who has to be anaesthetized for an emergency operation may have a full stomach the incidence of vomiting during anaesthesia will be increased. Swab-holders for sponging out the throat should therefore be at hand.

The Shocked Patient

It is essential to recognize that the shocked, exsanguinated, or heavily morphinized patient is already well on the way towards anaesthesia. Such depressed patients *could*, if necessary, be anaesthetized safely by the specialist with any type of anaesthetic—cyclopropane, evipan, ether, nitrous oxide, etc. He recognizes that the required depth of anaesthesia is achieved, in a patient depressed by any means, by a much smaller dose of the anaesthetic drug than would be needed for the same patient in normal health. Here again the occasional anaesthetist is safer with ether. If an overdose of this anaesthetic is given it is probable that removal of the mask and immediate institution of artificial respiration will result in prompt recovery. There is not the same safety margin with any other anaesthetic agent. If a patient has been heavily morphinized little anaesthetic will be needed subsequently, since morphine itself, if given in sufficiently large dosage, will provide full anaesthesia. The fact that major operations such as appendicectomy or hysterectomy have been performed under morphine alone emphasizes the part it plays in diminishing the subsequent amount of anaesthetic needed to produce the desired stage of unconsciousness.

Treatment of Respiratory Failure

Respiratory failure is an emergency which will often have to be faced in war-time anaesthesia. By shock or exsanguination or heavy morphinization the respiratory centre is depressed, and further depression from an overdose of an anaesthetic or deprivation of oxygen will easily result in respiratory failure. If each patient cannot have the undivided attention of a skilled anaesthetist the incidence of this emergency will necessarily be increased. The anaesthetist here must use his hands and not rely on drugs. He must remove the anaesthetic mask, confirm that the airway is clear, and supply oxygen. CO_2 plays no part in the treatment of patients suffering from respiratory failure. The Oxford inflator is the simplest and most effective way of inflating the patient's lungs with oxygen. If this small piece of apparatus is not available some other method of artificial respiration must be instituted without delay.

Chloroform

Although we subscribe to the view that the use of chloroform is rarely justified in peace time we are not satisfied that it will not have a place in war-time surgery. Since it is non-inflammable and portable, and its vapour is comparatively non-irritating, it will inevitably be used by many who would diligently avoid it in hospital practice in peace time. There are four well-recognized causes of death from chloroform.

1. Writers during the last century describe sudden death from psychological causes during induction or early in operation. Half the deaths from chloroform have occurred within fifteen minutes of the start of induction, and these sudden deaths have rightly instilled fear into the anaesthetist. Adrenaline can produce ventricular fibrillation in man and animals. Chloroform sensitizes the organism to adrenaline, so that a smaller dose will produce this result. There is now a strong clinical impression that suppressed fear of anaesthesia or operation leads to liberation of the patient's own adrenaline into his blood stream in quantities sufficient, if the patient is susceptible, to produce ventricular fibrillation in a heart sensitized by chloroform. Deaths from this cause will occur independently of the skill and experience of the anaesthetist. These sudden deaths occur notoriously in the fit nervous patient who is dreading operation. Since it can reasonably be suggested that the patient from the battlefield or air raid who is shocked and exhausted will suffer not from excess but from depletion of adrenaline, it is possible that death from ventricular fibrillation is unlikely to occur during chloroform anaesthesia in war casualties. In this connexion it should be remembered that fear immediately before operation can now be overcome by the use of basal anaesthetics, of which avertin, nembutal, and evipan are familiar examples. Basal anaesthesia should therefore protect the patient against this cause of sudden death.

2. Death may occur from the direct action of strong chloroform vapour (above 4 per cent.) on the cardiac musculature of susceptible patients. The danger from too strong a vapour can be avoided by the use of appropriate apparatus or by taking care not to pour too much chloroform on to the mask.

3. There may be death from paralysis of the respiratory centre by overdosage. This is heralded by increasing depression of respiration, and can be avoided by paying attention to respiratory signs. Should it occur artificial respiration must be instituted at once.

4. Death may also arise from delayed chloroform poisoning. This grave complication is more likely to happen in exhausted patients, in those depleted of tissue fluids, and in those who have been deprived of food for some time. The danger is intensified with increasing debility of the patient and with the amount of chloroform given.

Vinesthene

Vinesthene is becoming increasingly popular as an anaesthetic for the trivial operations of general practice. Although this drug has been found unreliable in producing the deep muscular relaxation often required for abdominal surgery, it has a sphere of usefulness in extra-abdominal surgery which may be of particular value in war casualties. Its advantages include portability, quick induction and recovery, and comparative freedom from after-effects. The excessive salivation which may result from its use can be prevented by atropine.

An invitation from the Queen of Italy has been conveyed to Viscount Dawson of Penn by the British Ambassador in Rome for the visit to Italy of a doctor from Great Britain for the purpose of studying a method of treating encephalitis lethargica which has been discovered by a distinguished Italian scientist, Signor Giuseppe Panegrossi. The method of treatment in question is known to some extent in this country, and is in fact being used at the Northern Hospital (London County Council), where an encephalitis unit is situated. Lord Dawson suggested that Dr. G. A. Borthwick, the medical superintendent of that hospital, should accept the invitation, and the London County Council has given Dr. Borthwick the necessary leave with pay.

RELAPSES AFTER SULPHONAMIDE CURE OF GONORRHOEA

BY

A. J. COKKINIS, M.B., B.S., F.R.C.S.

Surgeon, Emergency Medical Service; Surgeon, Wembley Hospital; Assistant Director, Venereal Disease Department, St. Mary's Hospital

AND

G. L. M. McELLIGOTT, M.A., M.R.C.S., L.R.C.P.

Director, Venereal Disease Department, St. Mary's Hospital

It is now established that three sulphonamide compounds —sulphanilamide, sulphapyridine (M & B 693), and uleron—can produce apparent cure of gonorrhoea in a few days. A year ago we showed that the first of these —sulphanilamide—needs the help of immunity to yield its optimum effects, having noted that better results are obtained when it is started on the eighth to the tenth day of symptoms instead of from the onset, and when it is combined with vaccine. The same policy of waiting has been found to increase the curative value of uleron, although this compound seems to be less effective than sulphanilamide.

After the introduction of sulphapyridine it became obvious that this is a more potent anti-gonococcal sulphonamide than the others, and articles have appeared which claim that it does not need the help of immunity but may be used from the onset of gonorrhoea with almost complete certainty of eliminating the infection. At St. Mary's Hospital we are not convinced that this optimistic claim will be confirmed by experience. While gladly recognizing the great potency of sulphapyridine, we have not yet abandoned its predecessors, and are still exploring ways of combining chemotherapy with immunotherapy in the hope of improving the chances of *permanent cure.* We had intended to publish the final results of our work with all three compounds in the near future, but owing to the present emergency this publication has had to be postponed.

In the present article, the preparatory material for which was collected before the onset of the war, we intend to give prominence to an aspect of chemotherapy which had for some time caused us considerable disquiet and which has an important bearing on the question of permanent cure (as distinct from elimination of symptoms). We refer to the occurrence of *late relapses,* weeks or months after apparently complete cure and after negative tests. The significance of such relapses, if they prove to be frequent, is obvious. Unfortunately they are becoming frequent enough, in our experience, to cause us real anxiety and to check the early enthusiasm with which we hailed the curative properties of these compounds in general and of sulphapyridine in particular.

It is easy to close one's eyes to unpleasant developments in what at first promised to be a perfect outlook, and to dismiss these cases as reinfections, however strenuous the denials of fresh exposure. But when these patients began to return to the clinic in large numbers it became obvious that some of them must be telling the truth and were, in fact, genuine relapses. With further experience we found that these latter cases present a clinical picture usually quite different from that of a reinfection, and we are now able to discriminate between them without having to rely solely on the patient's veracity. Quite recently (July, 1939) we analysed our records of over 1,200 male and 200 female patients treated with sulphonamide compounds long enough ago to provide reliable information on remote results. This analysis reveals an incidence of late relapses sufficient to render unreliable any statistics of results based on a relatively short follow-up.

Significance of Late Post-chemotherapy Relapses

These late relapses have a significance quite distinct from that of the early relapses with which we have all been familiar since the early days of chemotherapy. The early relapse a few days after a sulphonamide course or after the first provocative tests is an immediate warning that infection is still present and that treatment must be continued. But a patient who has passed several tests and remains well for months, only to relapse ultimately, often believes himself cured and may indeed have been discharged. Such a case harbours the gonococcus, which can be transmitted during the quiescent stage, and especially during the early and often inconspicuous stage of the actual relapse. Indeed, the early signs may be so mild that the patient may not reappear until complications are present. Most significant of all is the influence these late relapses must exert on the reliability of tests of cure, on the length of the period of follow-up, and on the final discharge of the patient. Our own experience, as shown in this article, has made us reluctant to give any pronouncement of permanent cure at this stage of the new therapy. The most we feel justified in saying to a patient is that he is probably cured if he has passed exhaustive tests and at least a six-months uneventful follow-up. There are several reasons why this cautious attitude should be rigidly adopted in the conditions which prevail during war time.

LATE RELAPSES IN MALES

Recognition and Clinical Course

In males we employ the term "late relapse" when symptoms return three weeks or more after a successful sulphonamide course and after at least one negative series of tests. This critical period has been adopted because appreciable differences exist in the manifestations of relapses before and after it. The early relapse occurs usually within a week of the end of chemotherapy or of the first test, and resembles the original attack in its acute onset, profuse discharge, cloudy urine, and the rapidity with which pus cells and gonococci crowd the smears. The late relapse is usually quite different. Although it may be provoked by a late test or by alcohol, most of our cases passed several tests quite successfully and then relapsed for no obvious reason weeks or months afterwards. What usually happens is that the patient one morning discovers a slight urethral moisture which in a few days becomes a scanty mucoid discharge. The urine is clear or shows specks or a slight haze, while the smears contain scanty pus cells and either no gonococci or very few groups. The prostatic beads, after being quite negative, may now show pus. Sometimes pus cells and even gonococci appear in the prostatic secretion some days before the clinical relapse; but these "threats" do not always materialize, and the next prostatic test may be quite negative.

This mild urethritis may continue for a week or two and then subside. More often the discharge gradually becomes purulent, the urine more hazy, gonococci more plentiful, and a definite relapse is established after a week or so. Some of our cases, however, developed no discharge, but showed a cloudy urine with prostatitis or basal cystitis; while a few came with other complications, such as periurethritis, epididymitis, or arthritis, but without a coexisting urethral relapse.

The outcome of these relapses has varied. Some cleared up with irrigations and vaccine, while most responded to sulphonamides as readily as the original attack. A number, however, resisted chemotherapy this time, or, after again responding, returned with another relapse. The treatment of these latter cases is a problem we have not as yet solved.

General Incidence of Late Post-chemotherapy Relapses

To discover this incidence an analysis has been made of 1,268 male cases of gonorrhoea the chemotherapy of which was completed more than six months previously. Of this total, 263 either failed to respond to the treatment or defaulted before tests, thus leaving a net total of 1,005 patients who remained well more than three weeks after their last sulphonamide course and who passed one or more series of tests. Of these cases, 118 (12 per cent.) have so far returned with late relapses (112 with one relapse, five with two, and one case with three relapses).

This figure of 12 per cent. cannot be an accurate estimate of the true relapse rate, since a large number of the 1,005 cases defaulted during the follow-up, and some of these must have relapsed subsequently. Another way of computing this incidence is to apportion the relapses into groups according to the time of their occurrence, and then to calculate the relapse rate for each period on the total cases whose follow-up extends into it (Table I).

TABLE I.—*Incidence of Post-chemotherapy Relapses at Various Stages of Follow-up*

Time Group (Period of Follow-up)	Followed-up Cases reaching Each Period	Late Relapses in Each Period	Late Relapse Rate for Each Period
4th week	1,005	20	2%
2nd–3rd month ..	948	48	5.1%
4th–6th „	652	41	6.3%
7th–9th „	173	11	6.4%
Over 9 months ..	68	5	7.3%

The full late relapse incidence, on this computation, is arrived at by adding together the relapse rate of all five groups, and works out at 27 per cent. It may be argued that this estimate is also inaccurate and that it exaggerates the chance of relapse, inasmuch as patients are more likely to return if they develop a relapse than if they remain well. This argument is incontrovertible. The true incidence, therefore, lies somewhere (perhaps halfway) between these two estimates—that is, between 12 and 27 per cent.

Incidence of Reinfections

The above 118 cases are in our opinion all genuine relapses. Another 100 of the 1,005 cases also returned with gonorrhoea in the same period: of these, eighty-seven were definite reinfections, while the other thirteen might have been relapses or reinfections, but for the purposes of this article are included with the latter. The time incidence (between end of chemotherapy and return of symptoms) of both relapses and reinfections is compared in Table II, which reveals another noteworthy difference between them.

TABLE II.—*Comparison of Time Incidence of Late Relapses and Reinfections*

	Under 3 Months	4th–6th Month	7th–9th Month	Over 9 Months
Late relapses (125) ..	68 (54%)	41 (33%)	11 (9%)	5 (4%)
Reinfections (100) ..	23 (23%)	35 (35%)	26 (26%)	16 (16%)

Detailed Analysis of Relapses and Discussion

A special analysis of our material was made to provide answers to the following questions, which are of obvious importance: (1) Does the incidence of late relapses vary with individual sulphonamides? (2) Is this incidence diminished by delaying the chemotherapy? (3) What is the influence of dosage and period of administration? (4) Is the relapse rate diminished by adjuvant treatment—for example, vaccine? (5) Are cases which clear up rapidly less likely to relapse than those which do so slowly or only after multiple courses? (6) Are there periods when relapses are more likely to occur? (7) What proportion of late relapses show gonococci? (8) How do these relapses affect provocative and other tests?

Some of the above questions are answered in Table III, which gives our late relapse figures with sulphanilamide, sulphapyridine, and uleron, begun at various stages of early gonorrhoea. For purposes of comparison the early relapse figures are also included. The late relapse figures (last column) are, as already stated, probably lower than the true incidence, and might be made more accurate by increasing each figure by half its total.

1. In answer to the first question it will be seen that *our male (uncorrected) late relapse rate with sulphapyridine (18.5 per cent.) is nearly two and a half times that with sulphanilamide (7.8 per cent.).* On the other hand, the early relapse rate with sulphapyridine (8.6 per cent.) is less than half that with sulphanilamide (17.7 per cent.). This reversal of the ratio, together with the more rapid and certain immediate curative action of sulphapyridine, provides a negative answer to question No. 5. It may well be that the longer treatment and more frequent need for multiple courses with sulphanilamide explain the lower incidence of *late* relapses after this drug. Our late relapses with uleron show a rate very similar to that with sulphapyridine, but the uleron cases are too few for this resemblance to have any significance.

2. This table gives a positive answer to the second question, as it *shows a fall in both early and late relapses (with all three drugs) when the chemotherapy was delayed until after the first week of symptoms.* This fall is very pronounced in the sulphanilamide group, the figures of which provide justification for the policy of delay with this drug advocated by us a year ago. The increased relapse rate of very chronic cases is associated with chronic lesions—for example, urethral stricture and chronic prostatitis. With sulphapyridine the early relapse rate is again more than halved when chemotherapy is delayed to the second week, but the fall in the late relapse rate is relatively negligible. A very interesting difference is shown in the sulphapyridine cases treated after the second week, depending on whether or not the patient had had previous therapy with another sulphonamide. According to Table III previous (therefore unsuccessful) treatment with other compounds has raised the early relapse rate from 3 per cent. to 11.8 per cent. and the late relapse rate from 15.1 per cent. to 32.3 per cent. These figures suggest that a high proportion of such cases were infected either with a sulphonamide-resistant strain of gonococcus or with one which

Table III.—*Showing Early and Late Relapse Rate after Sulphonamide Therapy*

Compound	State of Gonorrhoea when Compound Begun	Gross Total of Cases*	Net Total†	Early Relapses‡	Early Relapse Rate	Late Relapses‡	Late Relapse Rate§
Sulphanilamide	1st week	216 (all Gc.+)	170	53 (all Gc.+)	31.2%	20 (16 Gc.+)	12%
	2nd week	230 (all Gc.+)	196	27 (23 Gc.+)	13.8%	12 (9 Gc.+)	6.1%
	3rd week to 12th month ..	248 (188 Gc.+)	227	26 (22 Gc.+)	11.5%	10 (5 Gc.+)	4.4%
	After 12th month	66 (25 Gc.+)	57	9 (3 Gc.+)	15.8%	9 (1 Gc.+)	15.8%
Total sulphanilamide cases		760 (659 Gc.+)	650	115 (101 Gc.+)	17.7%	51 (31 Gc.+)	7.8%
Sulphapyridine	1st week	168 (all Gc.+)	128	13 (all Gc.+)	10.2%	24 (17 Gc.+)	18.7%
	2nd week	142 (all Gc.+)	112	5 (all Gc.+)	4.5%	17 (14 Gc.+)	15%
	After 2nd week: Sulphapyridine only ..	47 (39 Gc.+)	33	1 (Gc.+)	3%	5 (3 Gc.+)	15.1%
	Sulphapyridine after other sulphonamides	51 (26 Gc.+)	31	6 (all Gc.+)	11.8%	10 (6 Gc.+)	32.3%
Total sulphapyridine cases		408 (375 Gc.+)	304	25 (all Gc.+)	8.6%	56 (40 Gc.+)	18.5%
Uleron ..	1st and 2nd weeks	46 (all Gc.+)	26	22 (all Gc.+)	84.6%	6 (all Gc.+)	23%
	After 2nd week	54 (34 Gc.+)	34	20 (16 Gc.+)	58.8%	5 (1 Gc.+)	15%
Total uleron cases		100 (80 Gc.+)	60	42 (37 Gc.+)	70%	11 (7 Gc.%)	18%

* All these are cases of proved gonococcal infection, but cases in which gonococci were seen at the start of chemotherapy are given in brackets.

† After deducting early defaulters and failures, and including only cases which passed at least one series of tests and a follow-up of at least three weeks.

‡ Cases which relapsed more than once are counted as only one relapse. Relapsed cases in which gonocccci were actually seen are shown in brackets, but gonococcal infection was suspected and probably present in most of the others.

§ For reasons given in the text these figures are probably considerably below the true relapse rate.

had acquired sulphonamide-fastness through the previous chemotherapy. The high early relapse rate with uleron is a result of treatment with repeated short "stosses" necessitated by its tendency to cause peripheral neuritis if given in longer courses. Both the early and late relapse figures, however, are lower in cases treated after the second week of the disease.

3 and 4. These questions cannot be answered fully in this article. It may be pointed out, however, that only cases treated after the first week of gonorrhoea were given vaccine as a routine, and this may in part be responsible for the lower incidence of relapses in this group. On the other hand, it must be stated that most of the relapsed cases in this group had had some vaccine therapy. Thus far our vaccine dosage has been rather on the small side, and we are now experimenting with much larger doses in the hope of diminishing the relapse rate. With regard to dosage and period of administration of the drugs themselves, an analysis of the late relapses gives the following figures. Of the fifty-one late relapses after sulphanilamide only 18 per cent. had less than what we consider the minimal effective quantity of 56 grammes in fourteen days, while 61 per cent. had over 60 grammes and 18 per cent. over 80 grammes in one course of fourteen to twenty-one days. Of the fifty-six late relapses after sulphapyridine only 20 per cent. had less than a "minimal effective" course of 30 grammes in ten to twelve days; 36 per cent. had over 40 grammes and 9 per cent. over 60 grammes of this powerful sulphonamide in one course of fourteen to twenty-one days. These figures show that inadequate dosage does not account for more than a small proportion of late relapses, and that such relapses can occur after very full courses of both sulphanilamide and sulphapyridine. In other words, a quantity and a period which produce complete clinical cure may not suffice to eradicate the gonococcus, and if there is a quantity and a period which can be relied upon to do this they must be in excess of the very large dosage taken by some of our relapsed cases.

5. As far as can be done at present, the fifth question has been answered (with the first question).

6. Table I suggests that the chance of relapse remains fairly constant through the first year after chemotherapy. In view, however, of the probability that relapsed cases are more likely to return at a late stage of the follow-up than unrelapsed ones, it is likely that in actual fact there is a gradual fall in the chance of relapse with the passage of time.

7. The proportion of relapses in which gonococci were seen is given in Table III, and works out at 81 per cent. of late relapses of cases treated in the first two weeks of gonorrhoea and 36 per cent. of cases treated at a more chronic stage. These figures are based mainly on the results of smear examinations, and it is likely that a greater use of cultures would have shown gonococci in many cases with negative urethral or prostatic smears.

8. The occurrence of so many late relapses throws considerable doubt on the reliability of provocative and other tests of cure in cases treated by chemotherapy. In the period when the cases under review were treated our usual practice was to start the first series of tests one to two weeks after the end of the chemotherapy. The series comprised (*a*) examination of prostatic beads, (*b*) complement-fixation test, (*c*) provocative gonococcal vaccine (400 to 500 millions), (*d*) urethroscopy, (*e*) massage of urethra on metal sound, (*f*) alcohol. Prostatic tests were repeated at intervals of two to four weeks, and larger injections of vaccine (500 to 1,000 millions) given at three-monthly intervals.

Whatever the value of these tests may have been in pre-sulphonamide days, the fact that 118 of our cases relapsed after successfully passing at least one series of tests (seventy-one of them passed two or more) shows that *negative tests are not proofs of cure in cases treated by chemotherapy*. And yet the fact that 20 per cent. of our late relapses were definitely provoked by vaccine, bougie, or alcohol as late as three to six months after apparently complete cure shows that these tests are still of value. In the present state of our knowledge they cannot be dispensed with, but we submit that great caution should be exercised in the interpretation of their results. Particularly we wish to stress the value of repeated examinations (including culture) of the prostatic secretion, as we have reason to believe that many post-sulphonamide relapses are started by gonococci in the prostate which were rendered only temporarily inactive.

A year ago we stated that a positive gonococcal complement fixation does not mean that a patient is uncured. Now we are in a position to add that negative G.C.F. tests do not indicate that a patient is cured. Of seventy-nine late relapses whose G.C.F. test was not vitiated by recent vaccine no fewer than thirty-four relapsed after a completely negative result. It may indeed be of some significance that most of these thirty-four cases never developed a positive fixation at all.

LATE RELAPSES IN FEMALES

In pre-sulphonamide days it was generally admitted that in most cases the female urethral infection was comparatively easy to eradicate, whereas the deep racemose glands of the cervix were apt to harbour gonococci over long periods. Bourne has recently challenged this hypothesis by histological examination of chronically infected cervices, in most of which he found that the inflammatory reaction was superficial. In spite of these findings one cannot rule out the possibility of temporarily inactive gonococci being able to lurk in these glands without provoking an inflammatory reaction.

In most cases of proved female gonorrhoea gonococci are demonstrated only in the urethral discharge in spite of the fact that signs of cervicitis are usually present. When one considers that secondary infection from the vagina of an inflamed endocervix is inevitable, and that these vaginal organisms are able to outgrow the gonococcus, one can appreciate how a gonococcal cervicitis may in many cases be effectively masked. In view of the excellent blood supply of the cervix it is reasonable to suppose that cervical gonococci yield to sulphonamide therapy as readily as do those in the urethra, in spite of the fact that the secondary infection of the cervix with vaginal organisms, most of which are resistant to sulphonamides, appears to be unaffected. For this reason local treatment of the vagina, and in some cases the cervix itself, is nearly always necessary. That persistent cervicitis after chemotherapy is not due to the gonococcus is further suggested by the fact that in such cases no husband has so far been reinfected by his wife.

The difficulty of reliably ascertaining the relapse rate in women is fully appreciated, and the role of the laboratory animal must always be filled by the male. Janet's dictum that the best culture medium for the gonococcus is the uninfected male urethra is to-day as true as ever.

Though we have now treated many hundreds of cases of female gonorrhoea with sulphanilamide and sulphapyridine a large number have been excluded from this analysis on the ground that they did not show gonococci immediately before the beginning of chemotherapy or that they were early defaulters. The almost invariable secondary cervicitis has made it well-nigh impossible to distinguish between failures and early relapses, and we have classed as late relapses only those cases which showed at least two sets of gonococcus-negative smears and cultures and which have again shown gonococci more than one month after chemotherapy. A minimum follow-up of six months has been insisted on where possible, and in no case has provocation been carried out before the end of the third month. The results of an analysis of 210 female cases are given in Table IV; in spite of many obvious "snags," and possibly some concealed ones, the figures are not without interest.

TABLE IV.—*Analysis of 210 Female Gc. + Cases treated with Sulphanilamide or Sulphapyridine*

SULPHANILAMIDE		
Total Gc.+ cases at start of chemotherapy	123	(26 defaulted before 3 months, leaving 97)
Failures and early relapses	18	
Late relapses (Gc.+)	16	(11 relapsed after 3 months)
SULPHAPYRIDINE		
Total Gc.+ cases at start	87	(5 defaulted before 3 months, leaving 82)
Failures and early relapses	5	
Late relapses (Gc.+)	7	(4 relapsed after 3 months)

On the face of it the sulphapyridine figures are more encouraging than the sulphanilamide ones and do not appear to confirm the male findings, but against this it must be remembered that the maximum follow-up period of the female sulphapyridine cases is so far only eight months as against two years in the sulphanilamide cases, so that it is reasonable to expect some further increase in the late relapse figures of the former. Furthermore, it will be appreciated that, as the smaller effective dose of sulphapyridine (2 grammes daily as against 3 grammes of sulphanilamide) was more easily tolerated by women patients, it is more likely that the doses prescribed were actually taken. Experience has taught us the paramount importance of avoiding toxic effects in the treatment of women out-patients.

Summary

This article deals with an important and hitherto neglected aspect of the new chemotherapy of gonorrhoea—namely, the occurrence of late relapses after apparently complete cure by sulphonamide compounds; it also gives the results of an investigation into the incidence, recognition, and causation of these relapses.

An analysis is given of 1,268 male and 210 female cases of gonorrhoea whose chemotherapy was completed from six months to two years previously. This analysis indicates that of cases which have been successfully treated with sulphonamide compounds and which have passed tests of cure about 20 per cent. relapse subsequently.

This figure of 20 per cent. is quite distinct from the incidence of chemotherapy failures and early relapses, and must therefore be added to the latter in any calculation which aims at showing the final results of sulphonamide treatment. In the present article no attempt is made to assess the full incidence of chemotherapy failures or the results obtained with individual compounds.

The analysis gives comparative figures of relapses after sulphanilamide, sulphapyridine, and uleron; it indicates also the effect on the relapse rate of delaying the chemotherapy and of combining it with adjuvant treatment, and provides answers to other pertinent questions.

Special attention is given to the clinical recognition of late post-chemotherapy relapses, and to their differentiation from reinfections and from early relapses. The course and treatment of late relapses are also indicated briefly.

Emphasis is laid on the influence this high relapse rate must exert on the reliability of tests of cure, on the length of a safe follow-up period, and on the responsibility inseparable from the final discharge of the patient.

The fact that half of these late relapses occurred more than three months after apparently complete cure throws doubt on the reliability of certain published statistics of results obtained with sulphapyridine and other sulphonamide compounds.

The first quarterly issue of the new series of reports by the British Association for the Advancement of Science has been received. It is dated October, 1939, and is obtainable at 5s. from the offices of the British Association at Burlington House, Piccadilly, W.1. It contains an introductory account of the history of the British Association, some of the proceedings of the meeting at Dundee, and abstracts of other communications. When that meeting was terminated by the outbreak of war after the first three days of scientific sessions, it was decided that all communications of which the delivery had thus been unavoidably cancelled should be taken as read, and be printed as such in the *Advancement of Science*, as this series of reports is termed. It is intended to supply an index to the four parts in each year, and to print it in the July issue. The papers appearing at length in the October, 1939, issue are the presidential address, "The Western Isles through the Mist of Ages"; the address by Professor W. E. Le Gros Clark, F.R.S., "The Scope and Limitations of Physical Anthropology"; as well as the first instalment of a scientific survey of Dundee and district, and the reports of the research committees of the British Association.

THE MEDICAL RESEARCH COUNCIL BLOOD TRANSFUSION OUTFIT

AS PROVIDED FOR THE SECTORS AND DEPOTS IN LONDON AND THE HOME COUNTIES

BY

JANET M. VAUGHAN, D.M., F.R.C.P.

Director, Emergency Blood Transfusion Depot, Slough, Bucks

Shortly before the outbreak of war the Medical Research Council, acting for the Ministry of Health, established four depots in the Home Counties to collect, store, and distribute blood for civilian air raid casualties in London and the surrounding districts.

These depots and the London sector hospitals were provided with special apparatus for the withdrawal and administration of blood. The apparatus as originally issued was extremely simple, partly owing to difficulty in obtaining certain more elaborate components at short notice. In the light of experience, and as supplies became available, additional equipment is now being issued from the depots. It has also become apparent that the needs of the different hospitals to be supplied are somewhat variable. No attempt has therefore been made to obtain complete uniformity in the apparatus issued. The following practical notes are based on the memorandum of instructions which was issued by the Medical Research Council some weeks ago, but they also include reference to certain modifications which have been adopted since this memorandum was first prepared.

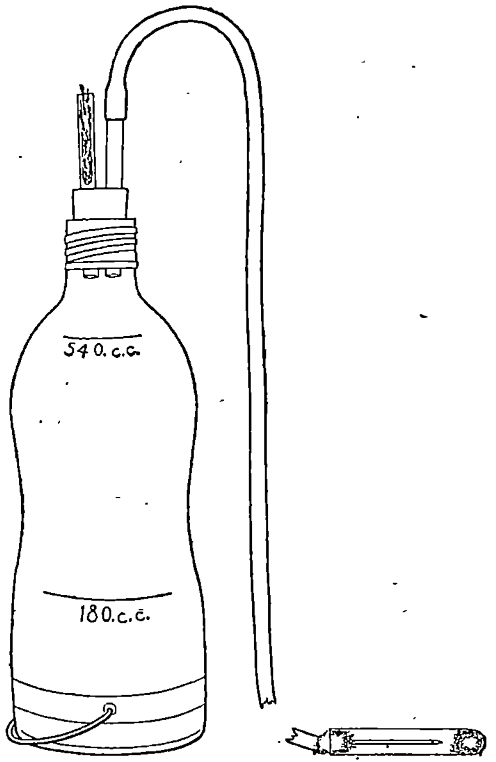

Fig. 1.

The bottle for the taking, storage, and giving of blood is a modified pint milk bottle, slightly waisted to facilitate holding, fitted with an aluminium screw cap lined with a 4 mm. rubber diaphragm, and provided with a metal band and loop at the base for hanging the bottle in the inverted position when it is required to administer blood by gravity. (In Fig. 1 the screw cap has been removed and replaced by a rubber bung.) The bottle is marked at 180 c.cm. and 540 c.cm. for measuring the anticoagulant solution and blood.

Anticoagulant.—The anticoagulant solution used at present is 1.05 per cent. sodium citrate in 0.85 per cent. sodium chloride. Both salts must be of a high grade of purity; the solution must be prepared with freshly distilled water, and should be filtered and autoclaved immediately. One volume of the solution is used for two volumes of blood (180 c.cm. citrate solution to 360 c.cm. blood).

Withdrawal of Blood

The bottle may be used in taking blood either by gravity or by the vacuum method.

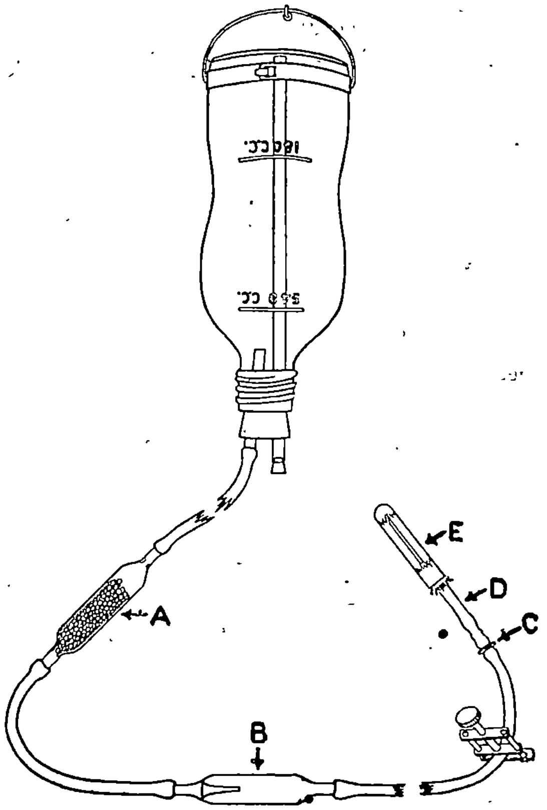

Fig. 2.

Gravity Method.—The screw cap is removed and kept sterile. The bottle is then fitted with a rubber bung pierced by two three-inch glass tubes, one of which is lightly plugged with cotton-wool and acts as an air vent. To the other is attached a length of rubber tubing and a stainless steel needle (Fig. 1), which is protected, after sterilization or during transport, by a small glass test tube. A sphygmomanometer cuff is applied to the upper arm of the donor, the skin over the vein cleaned and anaesthetized, and the needle inserted into the vein. The blood having been withdrawn and the rubber bung removed, the bottle is again sealed by the screw cap. If gravity proves insufficient to maintain a flow of blood, suction may be applied to the air-vent tube by means either of a Higginson's syringe or of a simple suction device. It is essential to mix the blood and anticoagulant by gentle rotation throughout the time of collection.

Vacuum Method.—If the aluminium cap of the bottle is perforated, the rubber diaphragm inside being left intact, the bottle may be used for the vacuum method described by Boland, Craig, and Jacobs (*Lancet*, 1939, **1**, 388). As pointed out by these authors (ibid., 1939, **2**, 905), the outfit provided differs in several important respects from that which they recommended for this technique. Nevertheless it has been found in practice to work satisfactorily when used in this way.

Administration of Blood

Several modifications of the administering equipment have been introduced as the result of experience during the past ten weeks. The glass-wool filter originally proposed is no longer recommended for general use, as it proved very difficult to ensure satisfactory packing of the glass-wool, and this filter was particularly difficult to clean. Three alternative sets of component parts are now available, the main variable being the type of filter used. Two types of drip feed, described subsequently, will shortly be issued from the depots; either can readily be added to the administering outfits.

1. *Closed Glass-bead Filter.*—This equipment (Fig. 2) consists of a rubber bung pierced by two glass tubes, one of which is long enough (9½ in.) to reach almost to the bottom of the bottle and is closed externally by a small cork. The other tube (2½ in.) has attached to its outer end, in sequence, a length of rubber tubing, an elongated glass bulb containing glass beads (Fig. 2. A), a further length of rubber tubing ending with a male metal adapter (C), a female adapter with a Record fitting attached to a short piece (1 to 1½ in.) of rubber tubing (D), and a narrow-bore stainless steel needle protected by a small test tube (E). A screw pressure clip will shortly be available; at present a spring clip is issued; Fig. 2 also shows a simple type of drip feed bulb (B), included between the filter and the rubber tubing attached to the male adapter. To administer the blood by gravity it is necessary to replace the screw cap on the bottle by the rubber bung, invert the bottle, and remove the small cork from the long glass tube, so that the latter acts as an air inlet. The two adapters should be separated, and the needle, attached to the short piece of rubber tubing and the female adapter, is passed into the vein. If the vein is entered blood appears through the end of the female adapter; this can then be joined to the male adapter, from which blood should also be flowing, the filter bulb and delivery tubing having been completely filled with blood by releasing the pressure clip. (If preferred, a Record syringe can be attached to the female adapter before the needle is inserted into the vein, and suction can thus be applied in order to judge whether the venepuncture is successful; alternatively, the needle can be inserted on a Record syringe and afterwards joined directly to the male adapter.) The filter bulb should be kept approximately vertical during the giving of blood, to ensure effective filtration by the beads.

2. *Loose Glass Beads Filter.*—The apparatus is similar to that just described, except that the bulb containing glass beads is omitted. The blood is instead filtered through 25 c.cm. of glass beads, which are separately sterilized in a wool-plugged boiling-tube and poured into the bottle of blood immediately before fitting the delivery bung (Fig. 3). The fish-tail inner end of the outlet tube in the bung prevents obstruction by the beads.

3. *Gas-mantle Filter.*—This third alternative type of filter, devised by Dr. M. Maizels, consists of an open cylindrical stocking of finely knitted cotton, as used in the manufacture of gas mantles. It is three and a half inches long, and is supplied by the makers threaded with a purse string at each end. The filter is supported inside the bottle by a quarter-inch piece of thick pressure tubing, which is pushed on to the long glass tube of the delivery set until it is about two and a half inches from the narrow end of the bung (Fig. 4, A). The stocking is slipped over the bung and the long tube, one end is fastened securely by tying its purse string beyond the pressure tubing, the other is fitted round the inner end of the bung (Fig. 4, B), where it should be fixed by fine copper wire (Fig. 4, D) or by ridging the neck of the bung so that the purse string can be tied tightly. In this way the stocking is pulled into a stretched closed cone over the inner end of the delivery tube.

DRIP FEEDS

As indicated above, two alternative types of drip feed bulb are being provided for the administering outfits. (1) The simpler type is illustrated in Fig. 2 (B). When this is used the screw clip should be placed *below* the drip bulb, near the needle, in order to obtain satisfactory control. (2) The other type is shown in Fig. 3. The screw clip in this case must be placed *above* the drip bulb, which has a glass side-piece with a short piece of rubber tubing attached, controlled by a spring clip. By suitable manipulation the operator can adjust the level of blood in the drip bulb.

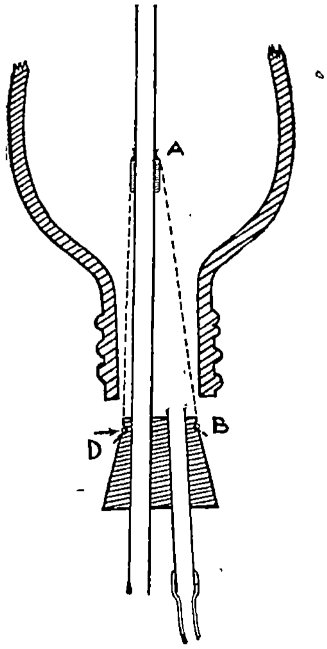

FIG. 4.

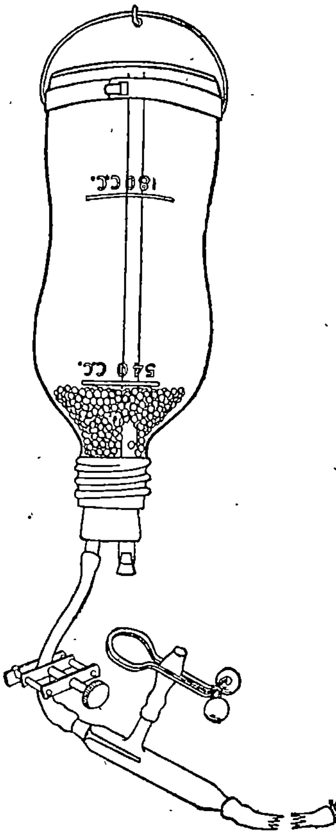

Fig. 3.

The equipment as supplied can also, of course, be readily adapted for use with a simple funnel or with any form of two-way tap or syringe.

Important technical points to be borne in mind in cleaning and preparing the apparatus have been emphasized by the medical officers in charge of the depots (this *Journal*, November 25, p. 1053), and they need not be reviewed here. It is clear from the results reported that the success of a large-scale transfusion service is dependent upon attention to such technical details, and that transfusion with the simple type of apparatus described can be very satisfactory.

THE BARREL BANDAGE FOR FRACTURES OF THE JAW

BY

W. KELSEY FRY, *M.C.*, M.R.C.S., L.D.S.

The treatment for fractures of the jaw is very little referred to in modern surgical textbooks and always appears to be in the " no man's land " of surgery. Simple fractures of the jaw are generally adequately treated by the dental surgeon, but those fractures resulting from gunshot wounds and from injuries caused through air raids will require the very closest co-operation between the plastic and dental surgeons. In order to ensure the successful treatment of these cases the Emergency Medical Service is providing special centres. The emergency treatment, however, will have to be provided at the first-aid posts and casualty clearing hospitals.

The immediate treatment of fractures of the mandible should be directed towards preventing asphyxiation, which is liable to occur through the loss of control of the tongue. The displacement of the tongue may be such that the air passages are obstructed, and in this condition the posture of the patient is important. The stretcher-bearers should be instructed to place the patient on the stretcher with his face downwards and his head hanging over the end of the stretcher. If the patient is able to walk he must be instructed to stoop well forward. The object should always be to keep the tongue well forward.

For the immediate relief of pain and to guard against the backward displacement of the mandibular fragments it is necessary to apply a bandage which will have the maximum pull in an upward and forward direction and must on no account have any tendency to pull backwards. For many years the textbooks have recommended the four-tail bandage, but it became evident in the last war that the backward pull of this type of bandage not only increased the displacement but was in many cases extremely dangerous. It has since been discarded by all surgeons familiar with this type of fracture. The bandage which was found most efficient and easy to apply was the " barrel " bandage. As will be seen from the diagram, this has an upward and slightly forward pull.

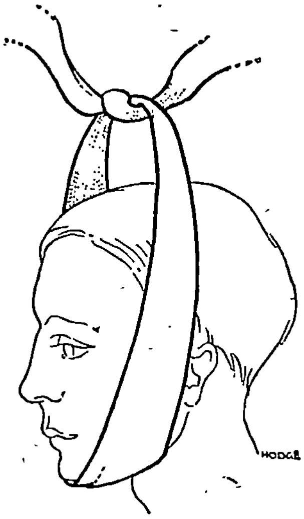

Fig. 1.

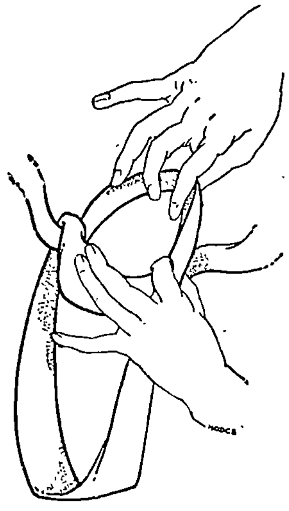

Fig. 2.

To apply this about 6 feet of 2 to 2½ inch bandage—preferably unbleached calico—is required. The middle of the bandage is placed under the jaw, well back just in front of the angle; then a simple knot is tied over the vertex of the skull (Fig. 1). Using both hands, open the knot so that the front loop comes in front of the forehead and the back portion under the occiput (Fig. 2). The two ends are then taken and upward tension is exerted, and by a slight adjustment the two running hitches are made to occupy a position slightly above and in front of the ear. The two ends are then tied in a reef knot on the top of the head (Figs. 3 and 4).

A HAEMOLYTIC STREPTOCOCCAL EPIDEMIC IN A HOSTEL

BY

NESTA H. WELLS, M.B., Ch.B.

Honorary Physician, Duchess of York Hospital for Babies, Manchester ; Woman Police Surgeon, City of Manchester

What has been called the " unitarian " hypothesis with regard to streptococcal epidemiology has often been referred to during the last few years, a particularly interesting account by Bradley appearing in the *Journal* of October 8, 1938 (p. 733), a most opportune moment for me. He stressed the value of typing haemolytic streptococci and showed the varying types found over a number of years in the semi-isolated community of a boarding school. While reading this I was confronted with an epidemic in a somewhat similar community—namely, a university women's hall of residence, numbering with staff and students about 200. The following is an account of it which may be of value to others, for the more we know how to combat streptococcal infections the nearer we are to reducing one of the most crippling as well as most deadly groups of diseases.

Clinical Record

In the summer of 1938 one student, not my patient, was ill, had cervical adenitis and peeled, and was thought to have had an unrecognized scarlet fever. In early June I was asked to see another girl who had a rash like scarlet fever but no rise of temperature, and who later developed enlarged glands. In late June a definite case of scarlet fever occurred, and another in July among the kitchen-maids. On investigation then I found that three others of the domestic staff and two students had been treated by various doctors during the summer term.

The comparatively few students and maids still remaining in Hall were all examined by myself or the assistant M.O.H. for any gross signs of nasopharyngeal infection.

It was hoped that the four-weeks vacation would clear any infection, but within two weeks of returning in September a maid went down with a septic tonsillitis but no rash. The students came back in the early days of October, and on the 8th a series of students and maids started with tonsillitis—one on the 8th, one on the 9th, two on the 10th, seven on the 11th, three on the 12th, one each on the 14th, 15th, and 17th—and four students went home on various dates to be ill there, making a total of twenty-one.

On the 12th it was realized that something drastic must be done to prevent the outbreak spreading, so all persons in Hall were given masks of gauze, which were to be worn for two weeks at all times except when eating, and they were told to avoid close contact with others so far as possible. Gargles were provided for daily use. These steps appeared to stop the epidemic from progressing, and no further cases developed except those which we could explain (see later).

Bacteriological Findings

Having read the above-mentioned paper, I appealed to the Public Health Laboratory to test for haemolytic streptococci Group A, which they agreed to do, though they could not undertake typing. The carry-over from the summer appeared to be somewhere among the domestic staff, so all these were swabbed. Four of them and the assistant in the sanatorium (who was nursing the sick) were found to be positive carriers of Group A, one remaining so for a month. All the sick were swabbed from ten to fourteen days after beginning, and with one exception were still positive. All positives, whether carrier or convalescent, were reswabbed at intervals of ten to fourteen days, and had the throat sprayed or painted twice daily, and were given frequent gargles, until the result was negative. During the acute stage they all had prontosil album, an average of 10.6 tablets (5.3 grammes) each, but mainly between eight and twelve. The highest recorded temperatures of half the cases were 100° to 102° F., with one-quarter higher and one-quarter lower. While the temperature was up, three or four tablets per twenty-four hours were given, and in eight cases this was sufficient to bring it to normal in twenty-four hours; in ten, normal was reached within forty-eight hours, and all were down by four days. Prontosil album was given at first for a day or two after the fall in temperature; but as time passed one or two tablets were administered daily until the throat was clear, a total of fourteen to seventeen being taken by some. The average stay in the sick-room was 6.6 days, and it mainly lay between five and nine days. The patients were then sent home or away for a few days, another swab being taken on their return.

Two patients developed cervical adenitis two to three weeks after the tonsillitis, and two had rheumatism (one so badly that she has been unable to return to college), but most recovered fairly well and had positive swabs long after they were fit. Most took five to six weeks to clear (the usual scarlet fever isolation period), but three were still positive eight weeks after the attack. Two of these had large unhealthy tonsils (which were removed in the vacation) and the other had suffered from nasopharyngeal catarrh for many years, though her tonsils had been removed previously. This case responded to nothing until a paint of glycerin and prontosil was used, a negative swab being obtained within two weeks.

Discussion

The effectiveness of the mask in preventing further trouble was shown early, especially when this precaution was omitted by those with positive swabs. One convalescent did not wear it during the rehearsal of a play, and within three days two members of the cast went down. Another girl thought it foolishness, and did not wear it in her room when others entered, with the result that her friend caught the infection. Two mild cases started in December the source of which was uncertain, but one of these patients had been sitting working in front of an unmasked carrier. By December 22 all cases were negative, except the tonsillectomies, and these patients were all right on their return in January. No further cases developed.

The cause of the sudden outbreak was obscure until it was discovered that during those early days after the September crisis there had been a great trying-on of gas masks, and one of the fitters-on, who was connected with the kitchens, had had some streptococcal infection in the summer vacation. Though this was not known till much later there seems little doubt that she or a maid who remained positive for a month acted as the link between the summer and autumn outbreaks. The summer rashes tended to be Group A of the scarlet fever type, but there were no rashes in the autumn. Both outbreaks were followed in a few cases by a cervical adenitis two to three weeks later. The second outbreak gave rise in five to six weeks to two cases of acute rheumatism, one very severe.

Summary

The history of a haemolytic streptococcal Group A throat infection is given, showing the varying symptoms found.

Droplet contact through the breath is clearly demonstrated.

Group A positive swabs lasted usually five to six weeks, sometimes longer.

The mask is effective in preventing spread, thus reducing time of isolation and period off studies.

The value is shown of throat swab examination for the haemolytic streptococcus as well as diphtheria when dealing with people in a community.

The danger from carriers of Group A is stressed. This is recognized in puerperal cases, but not so well in the case of haemolytic throats in the general community. Persons with positive swabs should be isolated or at least masked until negative.

The severity of the disease declined as time passed.

Prontosil album (or similar drug) taken by mouth or applied locally is of value in dealing with these organisms.

My thanks are due to the staff of the Public Health Laboratory, who reported on the swabs, and also to the nurse at the Hall, whose care prevented further trouble.

Arteriographic Diagnosis of Tumours.—Characteristic displacements of the cerebral vessels and carotid siphon make it possible to determine the situation and extent of frontal lobe tumours. Thus, polar astrocytomas suitable for radical operation may be distinguished from the fronto-medial tumours which are usually glioblastomas of bad prognosis. Laterally situated astrocytomas may also be distinguished.—Arteriographic Diagnosis of Tumours of Frontal Lobe and Basal Ganglia. E. Fischer.—*Zbl. Neurochir.*, April, 1939, **2**, 72.

Clinical Memoranda

A Case of Sturge's Disease

The great rarity of the syndrome known as Sturge's disease, or naevoid amentia, justifies the recording of the following case, which came under my observation recently.

Case Report

The patient, a male aged 18, stated that he had been in good physical health until the age of 16; before that, however, a certain mental ineptitude had been apparent: he always fared badly in school examinations, and his mother stated that he was "rather difficult to get on with." At the age of 16 he began to suffer from fits, and up to the time of examination had had five. In a fit he is suddenly rendered immobile, and he sits and stares straight ahead, being unable to speak or move. This state lasts five minutes or so, after which he notices weakness in the right arm and leg. The fit is usually followed by copious vomiting. The weakness in the right side takes about two weeks to disappear; he then remains perfectly well until the next attack. The last fit was followed by slight weakness in the left leg as well. There had been no headache. He also stated that the vision in his left eye had always been poor, and now he can only read large headlines with that eye.

His father died at the age of 47, the cause being unknown to the patient. His mother was alive and well, as was also a younger brother. The only sister died at the age of 3 months, the cause again being unknown. There was no history of outstanding birthmarks or of epilepsy in the family.

The patient was a well-developed, pleasant-mannered youth, who answered all questions intelligently. The naevus was of the port-wine capillary variety, and of extraordinary extent. It covered the whole of the left side of the face and scalp, including the pinna, and transgressed the mid-line in front. It extended down the left side of the neck, and covered the left pectoral region in front and the left scapular region behind, and the whole surface of the left upper limb to the finger-tips. There was a small isolated patch near the angle of the right scapula. An interesting feature was its encroachment on the buccal mucosa (mainly on the left side) and on the conjunctiva of the left eye. In addition to the naevus there were numerous small varicosities of the superficial veins over the whole surface of the left upper limb, especially pronounced about the wrist and hand. There were also one or two large varicose trunks as thick as the little finger along the posterior axillary fold. This suggested an arteriovenous communication, and, in accordance with this, the left upper limb was found to be considerably hypertrophied, even allowing for the slight degree of atrophy of its fellow.

When seen by me the patient was in the recovery period from the fifth seizure. Signs of a right hemiplegia were present: there was slight atrophy of the muscles of the right arm and leg, and a definite but slight loss of power. The tendon-jerks on both sides were exaggerated, and ankle and patellar clonus could be elicited on the right side. Both plantar reflexes were flexor, and the superficial abdominal reflexes were brisk on both sides. Sensation was unaffected. There were no cerebellar signs.

Examination of the left eye showed a slight degree of heterochromia. It was not unduly prominent, and its tension and movements were normal. The optic disk was cupped. Vision in the eye was poor, only the largest print being readable. The pupils were equal in size and reacted to light. The visual fields were not estimated. The heart and lungs were normal. The blood pressure was 170/135. The skull and spine appeared normal. Examination of the cerebrospinal fluid gave findings within normal limits, and the Wassermann reaction of the blood and cerebrospinal fluid was negative. A skiagram of the skull showed a large mass of calcification in the occipital cortex, with delineation of adjacent sulci and gyri. There was no cranial asymmetry.

The interesting points in this case were the extent of the naevus, its involvement of mucous membranes, and the probability of associated arteriovenous communication.

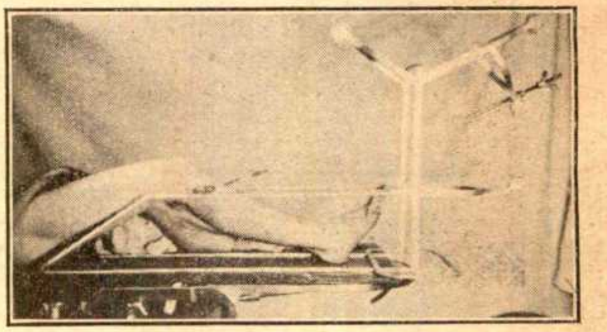
London, W.1 Arthur L. Newson, M.B., F.R.C.S.

Reduction of Fracture of Shaft of Femur

The following method, used to procure axial traction of a fractured femur sufficient to permit of easy reduction and maintain it while a plate was being applied, is described in the hope that it may be found of use in circumstances where assistance is scarce and an orthopaedic table is not available.

Case History

The case was one of transverse fracture at the junction of the middle and lower thirds of the femoral shaft, with overlap of 1½ inches and posterior displacement of the distal fragment, which had been previously manipulated into correct position and alignment with the aid of a Victor portable *x*-ray unit and operating fluoroscope, but which, owing to the interposed muscle (as was discovered at operation), could not be kept reduced, so necessitating open reduction and plating. Previous to operation traction had been applied by means of a Kirschner wire and stirrup, the wire passing through the tubercle of the tibia. This was left *in situ*, and when the patient was on the operating table a modified Braun's frame was slipped into position under the fractured thigh. The screw portion of a Böhler frame for reduction of fractures of the tibia, which had been detached therefrom, was tied on to the Braun's frame. The hook of the screw was linked tightly to the Kirschner stirrup (see illustration). The fracture was exposed by Henry's method (*Exposure of Long Bones and Other Surgical Methods*, 1927), and while an attendant tightened the screw to produce the required tension, the fragments, after removing interposed muscle, were easily manipulated into the correct position. No attention was needed to maintain the correct extension while the plate was being applied. There was no difficulty in fitting the Braun's frame, carrying the injured limb, and the sound limb on the operating table. The method is applicable to fractures of any part of the femoral shaft, and further abduction can easily be secured by placing a wide board (half bed-board) across the distal portion of the table on which the frame can rest and be moved into a position of abduction.



The apparatus illustrated is, I believe, in use in most hospitals and institutions, and easily within the means of cottage hospitals which cannot afford an orthopaedic table. In some cases the question of anchoring patient or Braun's frame, or both, to the table might need consideration, and permits of easy solution.

The portable *x*-ray unit and operating fluoroscope were kindly loaned for test by the Victor *X*-Ray Corporation Ltd.

Reviews

LIFE AS INTELLECTUAL ADVENTURE

Life and Living. By Frederic Wood Jones, D.Sc., F.R.C.S., F.R.S. (Pp. 268. 10s. 6d. net.) London: Kegan Paul, Trench, Trubner and Co. 1939.

It has become a cliché with reviewers of thrillers to assert that they were unable to put the book down until it was finished. Yet this was literally the case with Professor Wood Jones's *Life and Living*, so completely were we fascinated by it. Lord Crawford is reported to have said that he never disbelieved scientists except when they talked philosophy. To this our biologist can retort that he not only appreciates the limitations of his own brain imposed upon it by its ancestry, but also recognizes that these limitations equally apply to the brain of the philosopher even though he himself may not know it! Here we have not the biologist posing as a philosopher but the anatomist turned physiologist. He does not like the obviously inappropriate label *Homo sapiens* for the human race, preferring that of *Homo faber*, for the making of tools was probably man's earliest intellectual manifestation, and tools were the first extension of his personality. To this is due his persistent tendency to mechanistic modes of thought; the physical sciences were far advanced when biology still lacked even a knowledge of the circulation of the blood. By a trick of fate even Harvey's discovery was given a mechanistic interpretation by Descartes, to whom an engineer's universe was a natural conception. For, as Needham says, it is the configuration of our minds that makes us conceive of matter and energy in mechanistic fashion. This concept took possession of medicine; for Morgagni disease was situated in an organ, for Bichat in a tissue, and ultimately for Virchow in the cell; but the individual was lost sight of. The same concept dominated anatomy; the prolonged search for archetypes beloved of Owen crashed and fell with the acceptance of Darwin's explanation of evolution. There was no archetype—it had been a myth and a delusion. Instead of fixity there was change; instead of design, the natural choice of variations. But this teaching had far-reaching implications; if we are just bundles of accumulated structures it might well happen that the whole of our heritage would not be suitable to our present needs. So the search began for unadapted and obsolete structures—and they were found. For Metchnikoff and those who followed him all Nature was an ironic jumble of misfits; a world of creatures
predestined to failure by reason of their inherited di
harmonies; a cruel, unpurposeful struggle against
in the form of useless and harmful relics accum
from our ancestry. But what the pessimists fa
take into account was the astonishing way in
Nature has been at work setting to rights the
monies that have arisen through changing circum
the beauty of readaptations has never had its c

Without going into details we may say that
Wood Jones describes the method of readapta
the label of cytoclesis, the call of cell to cel
to tube; just as men tunnelling from t
mountain tap their call to each other till
does each kidney tubule call to each urete
they join end to end. The optic cup
lying skin to become transparent wh

the cup; with no optic cup in its normal position no translucent cornea is formed. Eyes have been made wherever they are wanted. Similar types of organs have been made over and over again; the only common bond between them all is the function they discharge. So back we come from the rigid tenets of animal morphology and the misleading anatomy based on the formalin-hardened cadaver; back to John Hunter's aphorism "Structure is only the ultimate expression of function," re-echoed by Hora 150 years later as "Evolution is the adaptation of organisms to environment." The optimist can breathe again! The author is no blind optimist, however; he sees how the call of cell to cell may secure the nourishment of the embryo by the invasion of trophoblast into maternal uterine tissue, and yet by perversion of that invasion a deadly form of malignant growth may arise. He sees in sterol metabolism the outstanding problem in the chemical study of life, but notes that these potent and complex substances which produce organization, growth, sexual characters, and all the perfections of the normal body may by a perverse metabolism and when their period of utility is outlived become the agents of death.

If biology has retraced its steps, so has physics. Before modern physics the biologist stands agape, bewildered by it all. He gave up his mysticism out of pure deference to the more exact findings of the physicist, he schooled himself to spell no words with capital letters save perhaps Mechanism, Variation, and Natural Selection. And now the physicist has deserted him, and is moreover doing those very things he taught him to despise. In truth the biologist is very like the little boy who, taught by a slightly older brother to despise girls, subsequently catches him making ardent but immature love to the girl next door!

This we take to be the author's creed running through his pages. It is a creed which enables him to see life as a voyage of intellectual discovery. Physical adventures, brave deeds, and romantic doings are for the young and strong; intellectual adventure waits upon everyone who has the enterprise to embark upon its quest. And yet how few ever undertake it. He rightly maintains that this should be the great aim of a university. In the ideal university the professor should be the leader of an expedition into the most exciting and romantic of all regions —the region of the intellectually unknown. His students should be his eager followers prepared to share
hardships, the excitements
tures. Some such l

DIVERTICULA AND DIVERTICULITIS

Diverticula and Diverticulitis of the Intestine. Their Pathology, Diagnosis, and Treatment. By Harold C. Edwards, M.S., F.R.C.S. With a foreword by Gordon Gordon-Taylor, M.S., F.R.C.S. (Pp. xii + 335; illustrated. 25s. net.) Bristol: John Wright and Sons; London: Simpkin Marshall. 1939.

This work is based upon the essay to which the Jacksonian Prize of the Royal College of Surgeons of England for 1932 was awarded. Mr. Edwards tells us that although the literature on the subject of diverticula, and particularly those arising from the large intestine, is relatively enormous, it is in reality a mushroom growth starting from a few scattered post-mortem observations in the eighteenth century. Meckel in 1822 not only established the aetiology of the diverticulum which bears his name, but recognized that other varieties which he called false diverticula might arise apart altogether from the vitelline duct. This work is divided into four sections, each of several chapters: (1) congenital diverticula, (2) diverticula of the duodenum, (4) diverticula of the jejunum, and (4) diverticula of the large intestine, and a particularly attractive feature is the historical note which introduces each of these sections. Thus we are told of the first case of duodenal diverticula published in 1710 and referred to by Morgagni, and of the first description of jejunal diverticula by Astley Cooper in 1844. The author tells us that the ileum is relatively immune from diverticula and is affected only in severe cases in which diverticulosis has started in the jejunum and spread steadily down the bowel until the ileum is reached and is similarly affected. In the large intestine diverticula of congenital origin are so very rare that section 4, dealing with those occurring in this part of the bowel, is devoted entirely to the condition of multiple diverticula of the colon in which the pouchings are herniations of the mucous membrane through gaps in the muscularis. When uncomplicated the term used for this condition is diverticulosis; when inflammatory changes are present, diverticulitis. The view very generally held that colonic diverticula are commoner in men than in women is not shared by Mr. Edwards, who finds no great difference in the sexual incidence, but that men are far more frequently affected by the complications of the disease than are women.

analysis of available information concerning the technique of transfusion must inevitably therefore, to use a trite expression, fulfil a long-felt want. Two-thirds of the book is an account of his own personal experience, both technical and clinical, of blood transfusion; the remainder attempts to extract the more important material from the extensive literature. All subjects not directly related to blood transfusion have been omitted—for example, the medico-legal and anthropological aspects of blood groups. There is for reasons of space no historical section, which is perhaps unfortunate. In matters of technique, where several alternative methods or patterns of apparatus exist Mr. Riddell has deliberately been dogmatic and has described in detail the procedure he himself prefers. An essential chapter on the methods of obtaining typing sera and its correct titration is included. The recent large-scale enrolment of blood donors, to be used in a national emergency, has shown how little the importance of such high-titre sera is appreciated, and yet it is the keystone of a successful service.

Intravascular haemolysis, on which so much fundamental work has been done in this country during the last few years, is clearly reviewed for the first time in an English textbook. Mr. Riddell draws particular attention to the grave danger of circulatory failure in the transfusion of anaemias of long standing and to the principles governing the rate of introduction and dosage of blood, since he considers altered conceptions in regard to these matters form the two most important advances in blood transfusion in recent years. Possibly the use of stored blood might, by some people, be thought to be of at least equal if not greater theoretical and practical importance. The text is copiously illustrated throughout with diagrams and photographs; even the warming of a tile under the hot-water tap is not left to the imagination. A full bibliography is attached to each chapter, which is closed by a summary of the conclusions reached. Though there may be disagreements with Mr. Riddell on certain points there is no doubt that he has provided us with an important reference book on an important subject.

GALL-BLADDER DYSFUNCTION

Réactions Vésiculaires et Cholécystites. By Étienne Chabrol. (Pp. 184. 40 fr.) Paris: J.-B. Baillière et Fils. 1939.

Disappointed by the number of his patients in whom the operation of cholecystectomy has failed to relieve the pains they suffer from in consequence of disturbed function of the gall-bladder, Professor E. Chabrol has collected his experiences and noted them for the benefit of others, producing a book, the first of a series of monographs on clinical questions of the moment published by Baillière.
uthor finds among patients diagnosed as cases of acute
ystitis, hepatic colic, biliary dyspepsia, and biliary
gradation of reaction, falling into four varieties or
A patient may present little more than a migraine
orary dyspepsia, yet examination shows a rise in

uilibrium of the patient. Such patients secrete
d, more, they discharge it poorly.
painful reaction of the gall-bladder is
iliary passages, which may originate

from inflammation locally, from deposition of calculi, from stasis without stones, from secretory disturbances, and possibly from abnormal nervous reactions. Of the inflammatory causes the author stresses the previous infection of typhoid fever; other bacteria, especially the colon bacillus, may be the source. In the formation of gall-stones metabolic disorder, infection, and stasis may all play their part. In a more difficult group are the cases of simple chronic cholecystitis without gall-stone, a dysfunction of the biliary passages. In all there is the association of right-sided diaphragmatic pain, intermittent reaction often febrile, and some degree of cholaemia. Aids in diagnosis are afforded by laboratory investigations of the blood and (with less success) of the contents of the duodenum recovered by tubage, and by radiological examination of the gall-bladder by special tests and of the surrounding organs, especially the duodenum and appendix.

Treatment medically should not be the immediate hypodermic injection of morphine; local applications of warm compresses and rectal administration of laudanum are preferable; diathermy is recommended. Between attacks a simple diet, especially avoiding fats, eggs, fried foods, and cooked butter; tubage of duodenum with stimulation of biliary drainage on Meltzer-Lyon principles; attempts at disinfection with salicylate of soda and alkalis; and treatment at one of the spas serving alkaline waters are indicated. Surgical intervention is essential for perforation or suppuration of the gall-bladder, and where the gall-bladder fills with fluid secretion so that tumour is felt with rise of temperature. When possible, operation is deferred till the immediate reaction is past, especially in jaundiced patients, but must be carried out for recurrent attacks and for acute attacks that have been controlled by medical measures. The indications are given for operating in other intermediate cases.

The book is well documented, mostly with quotations from French authors, and gives a useful discussion of problems which often present great difficulties in practice.

CARDIOVASCULAR DISORDERS

Cardiovascular Diseases: Their Diagnosis and Treatment. By David Scherf, M.D., and Linn J. Boyd, M.D., F.A.C.P. (Pp. 458; 10 figures. 21s. net.) London: William Heinemann. 1939.

This sets out to be a practical book, avoiding descriptions of complicated methods and apparatus. Emphasis is placed on common disorders and difficulties as suggested by experience with students, and which are often neglected in textbooks—for example, pulmonary embolism. The work is personal; no bibliography is included and citation of authors is reduced to the minimum. Cardiography is almost completely omitted, as it is believed that abbreviated accounts of this only confuse. First paroxysmal cardiac dyspnoea is described, and it is true that this is an important and common disorder of general practice which has been inadequately dealt with in textbooks; but the rather extensive theoretical discussion on the abnormal physiology underlying it is, perhaps, out of tune with the practical aim of the book. Valve lesions are discussed at length, occupying one-sixth of the book—an indication of how attention is returning to this aspect of heart disease. In the following section, dealing with diseases of the myocardium, it is suggested that acute myocarditis is a common condition occurring, apart from acute rheumatic carditis, in infectious diseases and as a result of septic foci, such as, for example, colitis and dental granuloma. The myocardial lesions of these latter conditions are, however, not likely to produce any permanent cardiac disability, and must be treated very differently from the myocarditis of acute rheumatism. There is no need to treat every patient recovering from an acute infection who shows tachycardia or unstable pulse as if he had an active carditis. Cardiac pain and its various causes are clearly described, but perhaps in hardly enough detail considering its frequency and importance. The final section on treatment is full and generally sound, though the statement that the "minimum period which must elapse between the last dose of digitalis and the first dose of strophanthin should amount to three days" considerably underestimates the safe period.

It cannot be said that the style of the text is good, nor has it always the clearness necessary for the type of reader for which the book is designed. As an example of an ambiguous sentence this may be quoted: "If digitalis therapy in a decompensated valvular lesion or myocardial disease is carried to the attainment of an optimal state for the patient concerned, it should not be discontinued until the manifestations of decompensation reappear." However, on the whole a well-balanced account of modern cardiology is presented; in the next edition perhaps the defects will have disappeared.

Notes on Books

The ninth edition of *Thomson and Miles's Manual of Surgery* (in two volumes, 21s. each, Oxford University Press) had not gone far in its preparation, we learn from the preface by Mr. ALEXANDER MILES, when this representative presentation of the teaching of the Edinburgh School of Surgery lost by untimely death the guidance of Sir David Wilkie, one of the greatest teachers of surgery—some say the greatest—of this generation. But with Mr. Miles he had already planned the lines on which this revision should proceed, and had arranged for the co-operation of over a score of his colleagues in the Edinburgh school in that work. The format has been altered decidedly for the better by using a larger page and certain typographical alterations. The first volume deals with general surgery and includes the sections on the surgery of the extremities; the second volume is arranged on a regional basis. There is evidence of thorough revision and rewriting throughout both volumes, and especially in the section devoted to neurological surgery. It is stated that many old illustrations have been discarded, but many still remaining have an old-fashioned air, and the radiographs are hardly up to the standard of most modern textbooks. It might be well for the next edition to contemplate a more drastic and complete revision of the illustrations to make them more worthy of the world-wide fame of this standard textbook of surgery.

First Aid for Everybody, by A. J. B. GOLDSMITH, M.B., B.S., F.R.C.S. (Faber and Faber, Ltd., London, 1939, 2s. 6d.), was first published in 1935, and has now been reissued with a supplement of sixteen pages entitled First Aid in Air Raids. We note that the tannic acid treatment of burns is not mentioned, and that in the section on the treatment of wounds it is stated that "tincture of iodine should be painted on the wound."

Endoscopy by introducing an illuminated speculum into the knee-joint has been suggested as a means of diagnosis, and a small brochure on arthroscopy (*Die Arthroskopie*, Leipzig: Steinkopff) has been prepared by Dr. E. VAUBEL. The author gives instruction in methods, indicating the precautions to be observed, and describes the use of the technique in some selected cases. The findings are illustrated in a series of coloured drawings. Some value may be obtained for scientific medicine by the correlation of the endoscopic appearances with the x-ray findings, but the method is unlikely to be taken into common use.

Preparations and Appliances

A SIMPLE GAS FLOWMETER FOR CLINICAL USE

Dr. JOHN DEVINE, senior resident medical officer, Royal Melbourne Hospital, writes:

There is a definite want of a simple and cheap instrument for measuring the flow of gases for therapeutic purposes. It is still the custom in many hospitals to administer oxygen and carbogen without any measure of the rate of flow. Thus patients are at the mercy of the nurse in regard to her judgment of an adequate flow. Frequently, too, they receive an unnecessary amount of an expensive gas. In most cases measurements are not made because the gauges used, while being very accurate, are expensive and soon wear out with continued use. The apparatus described below was evolved because it was cheap and could therefore be employed for routine use in hospital wards, and because it was so simple to use that any possibility of mistake was eliminated. It can also be used in the construction of a simple and cheap form of gas anaesthetic apparatus.

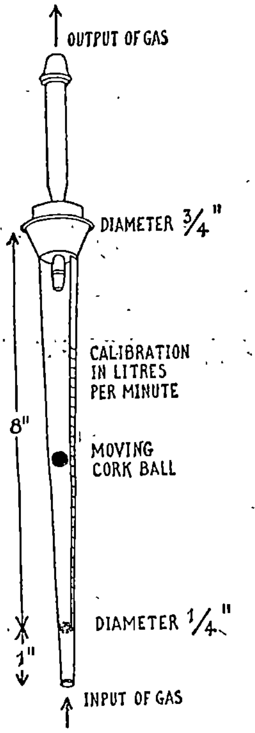

FIG. 1.

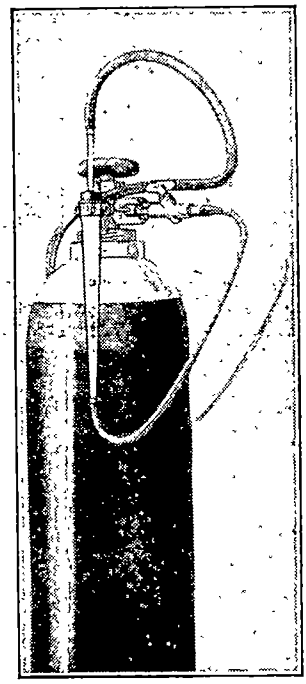

FIG 2.

FIG. 1.—Diagram to show construction of flowmeter.
FIG. 2.—Drawing from a photograph of the flowmeter attached to a cylinder of carbogen by a simple clip.

Principle.—In a tapering tube through which gas is passed the velocity of flow in any part of the tube will depend on the area of cross-section, since the same amount of gas passes through the whole tube. If gas flows in from the narrowest part of the tube in an upward direction, and a small rounded ball of light material such as cork is dropped into the tube, the ball will rise in the tube to such a height that the force of gravity acting downwards on it is equal to the force of the gas acting upwards. Since the tube tapers, the velocity of the gas passing through progressively decreases from the bottom upwards, and the ball finds a position where equilibrium is reached. If the flow of gas entering the tube is altered, the ball will take up a new position of equilibrium. The tube can then be calibrated against a standard flowmeter.

The Flowmeter.—This, as shown in the illustrations, is a glass tube one-quarter of an inch in diameter at the bottom, three-quarters of an inch in diameter at the top, and eight inches long. The ball used is of cork and is one-quarter of an inch in diameter. The meter is calibrated by means of a standard flowmeter to show with very reasonable accuracy flows from one to sixteen litres of gas per minute.

The apparatus has been used in some of the wards of the Royal Melbourne Hospital for the post-operative administration of carbogen and the intranasal administration of oxygen to patients with pneumonia. In testing the flow of oxygen considered by the nursing staff to be adequate for the intranasal administration to patients with pneumonia it was found that in nearly all cases they were giving under one litre per minute of flow, whereas a minimum of four litres per minute is usually considered necessary in such cases.

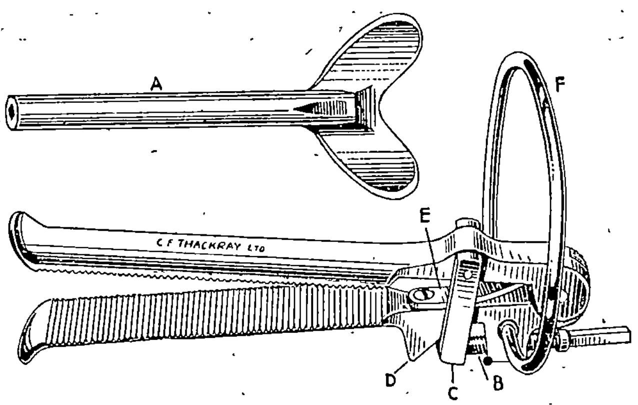
⁂ Carbogen is the term used in America for ready-made mixtures of CO_2 and O_2. In Great Britain the equivalent term is dicarbox.

AN IMPROVEMENT OF THE NON-PROJECTING ENTEROTOME

Mr. MICHAEL C. OLDFIELD, M.Ch., F.R.C.S., honorary assistant surgeon to the General Infirmary at Leeds, writes:

In November, 1937, I described a non-projecting enterotome for crushing a colonic spur. The instrument is used before closing a faecal fistula such as occurs after a Paul-Mikulicz operation or a colostomy. It was devised to obviate the leverage action of the handle which in the older instrument caused great discomfort to the patient. The severity of this discomfort depended directly upon the length of the projecting handle. Whenever the patient moved in bed the handle used to be pressed upon or jarred.

In the non-projecting enterotome the handle has been replaced by a key, which is removed after approximating the blades to the required degree. Each day the key is reapplied to tighten the grip on the spur, and the key is again taken away. The mechanism is simple and strong. By turning the key A the screw B is driven downwards on to the steel collar lever C hinged upon the opposite blade. This collar acts upon the sloping steel shoulder D. As the key is turned the screw and collar are depressed and the blades are gradually approximated. A small flat spring E is inserted between the blades and holds them apart during the application of the instrument to the spur. Maximum separation of the blades has been increased from three-quarters of an inch in the original instrument to one and one-sixteenth inches in the improved model. This has made introduction easier. The face of each blade is transversely serrated and the ends are everted. The width of the serrated jaws has been increased from two and a quarter inches in the original instrument to two and a half inches in the new one. It is found that a better grip of the spur is obtained with the wider blade. A steel ring (F) two inches in diameter has been inserted through a hole in the shaft near the screw B. The ring moves freely and causes no discomfort when the patient moves. It obviates the danger of the instrument slipping inwards into the bowel—an improvement which we have incorporated following the kindly and constructive criticism of Mr. David Lurie of Johannesburg.



I am indebted to Mr. L. R. Braithwaite and Mr. George Blomfield for their advice. The instrument is made by Messrs. Chas. F. Thackray, Ltd., Park Street, Leeds, 1.

ANTIVIVISECTIONIST PROPOSALS IN SWITZERLAND

Experiments on living animals have been an essential condition for the development of physiology, pathology, bacteriology, immunology, pharmacology, biochemistry, and dietetics as experimental sciences, and have played a necessary part in the control of the strength and dosage of the remedies required by the emergence of a scientific therapy. Hitherto this country has stood almost alone in its control by law of such experiments, made for the promotion of knowledge in these departments of science, on which the practice of medicine is founded and built. British research workers in the medical sciences have become accustomed to this control during the period of more than sixty years since it was first established. An Act so old naturally presents historical anomalies, such as that which makes it necessary that every one of the multitude of experiments in which animals are now injected, dosed, or fed—every guinea-pig, rat, mouse, fish, or frog, every tadpole in a basinful, treated with a serum, a drug, a hormone, or a vitamin, to observe or measure its effect—should be returned as an experiment under Certificate A, and accordingly, in spite of repeated official explanations, sedulously misrepresented as a painful "vivisection" without anaesthetics—a kind of experiment for which permission has never, in fact, been given or even sought. The Act, however, has been administered strictly, punctiliously, and with understanding; and though in earlier years, when medical men in general were less accustomed than now to official records, reports, and inspections, there may have been research workers who found these irksome, there cannot be many who now regard the control as a hindrance to legitimate research. They have had reason, on the other hand, to recognize the fulfilment of one of the original objects of the Act—namely, the protection of men engaged in important and essentially humane researches from prosecutions instigated by determined ignorance.

It may seem surprising that other countries, including British Dominions, having standards not obviously different from our own in their care for the interests of animals, have so far not followed our example. They might well have been deterred, however, by observation of our own experience, showing that legal control and official inspection, while they may relieve genuine misapprehension and anxiety, by no means cause any abatement of a reckless and unprincipled agitation. They may even stimulate it by encouraging clamour for further and paralysing restriction, and by supplying official data for distortion. The existence of a strict control is accepted, not as a reassurance, but as evidence of a public sentiment accessible to further appeals.

The position which now threatens research in the medical sciences in Switzerland appears to be in many ways the same as that with which we have long been familiar in Britain. The *Schweizerische Medizinische Wochenschrift*, the well-known medical weekly published in Basle, has issued a special number[1] in which the situation is explained, the necessity for experiments on animals for progress in the medical sciences fully discussed and illustrated, and the nature of the opposition to them examined, in a series of articles by leading Swiss representatives of physiology, pathology, clinical medicine, pharmacology, medical psychology, and veterinary medicine, with some by French and German authorities in certain of these fields. From the article by Professor Hess of Zürich we learn that the Swiss Society for Medicine and Biology, doubtless desiring to allay genuine misunderstanding and disquiet, initiated some years ago the formation of a joint committee of its own members with accredited representatives of the Animal Protection Union of German-speaking Switzerland. The discussions proceeded with mutual confidence and understanding, and to the credit of all concerned a series of resolutions laying down the conditions acceptable to both parties was unanimously adopted, and subsequently ratified in full separate sessions by both the participating societies. The principles thus put forward for embodiment in legislation would have effects closely similar to those of our own Act, though naturally with a more direct reference to modern experience. Vivisection was to be restricted in Switzerland to scientific experiments under fully defined and legally prescribed conditions. These conditions were to provide that experiments on animals would only be made when necessary for a planned research, for diagnosis, or for treatment, and for demonstration only when films could not replace them; that higher mammals, and dogs in particular, would only be used when indispensable; that anaesthesia as full as for a human operation would be used for any operative procedure, the animal being killed while still anaesthetized, or, if its survival was a necessity of the experiment, carefully nursed and cared for, according to its particular needs; that experiments on animals would be confined to institutions under responsible scientific direction and subject to control by a public commission with mixed membership.

Here was an agreed policy which surely should have satisfied anyone genuinely concerned to ensure a proper limitation and control. Our Swiss colleagues were entitled to expect that all in their country who profess concern for the welfare of animals would concentrate their efforts on pressing for the early enactment of such strict and sane provisions. Their experience, alas, has been very similar to our own. An antivivisection organization in the Basle-City Canton has now presented to the cantonal legislature an initiatory petition (*Initiativbegehren*), bearing 10,000 signatures, for a law against vivisection, the terms of which the petition lays down. Some of the clauses of the Act thus demanded have an all too familiar aspect. In Clause 1 propaganda is curiously mixed with legal form by giving, in illustration of what is meant by "vivisection," a list containing horror-provoking descriptions, devised by a lurid imagination or culled, as Professor v. Muralt of Berne suggests, from the publications of many countries over several centuries, and having, in any case, no relation whatever to anything which could now happen in Switzerland; but carefully mixed with these are the normal procedures essential to physiological, pathological, and pharmacological researches. The real purpose of the clause appears in the final phrase, which entirely prohibits the application to dogs and cats of "vivisection," as thus inclusively as well as fantastically defined. Lest it might be supposed that such a prohibition would still allow research workers in the Basle-City Canton to find imperfect substitutes, Clause A would extend the prohibition to other higher mammals, such as horses, monkeys, and ruminants, if the use of these should be found to increase through the effect of Clause 1. Clauses 3 to 6 embody some of the points from the agreed proposals of the joint committee above mentioned, with the difference that demonstrations on the living animal are entirely prohibited, and that veterinary procedures for the treatment or killing of animals, and castration in particular, are not to count as "vivisection" for the purposes of the Act. Anything, therefore, is to be allowed for the benefit of food supply, property, or convenience, and only the search for life-saving and pain-preventing knowledge is to be obstructed; while the antivivisectionist spinsters of Basle are to retain the privilege of coddling their mutilated pets without embarrassment, and with the assurance that such an operation cannot possibly be used for any service to science. Sympathy with colleagues who have to face this sort of thing is tempered by an unworthy sense of relief at the discovery that this nauseous kind of hypocrisy is not, after all, a British monopoly. Clause 7 again fully displays the cloven hoof, making it the right and duty of the police, on receiving a sufficiently well grounded application from the Antivivisection Union or the Animal Protection Union, to visit all places where experiments on animals are conducted—at any time and accompanied by a delegation of the committee of the complainant Union—in order to make an inspection of the premises and to examine the protocols of the experiments.

---

[1] 1939, 69, No. 40.

Small wonder that our Swiss colleagues are concerned to prevent the passing of an Act with such provisions, foreseeing the disastrous impediment which it would produce to the advancement of medicine by experimental research, in which their country takes high rank. The immediate threat is to research in the Basle-City Canton, which is not only a centre of academic research in its important university and medical school, but also the headquarters of the great and progressive pharmaceutical industries of which Switzerland is justly proud. In any case, our colleagues in Switzerland rightly foresee that a success in Basle would encourage immediate agitation for the extension of such cruel prohibitions and inquisitions to the rest of Switzerland. Their own broad-minded initiative has shown their willingness to do everything necessary to reassure genuine humane sentiment in their country. We could have told them, however, from our own experience that such a show of reason would be unlikely to appease their real opponents, but rather to excite them to a wilder frenzy and a more destructive ambition. The special number of our Basle contemporary gives evidence that the members of the medical profession of Switzerland are aware of the danger and are rallying to the defence, with the powerful aid of one of their leading journals.

THE NASOPHARYNGEAL FLORA IN HEALTH

Ten years ago the Ministry of Health published the results of an interesting investigation into the fluctuations in time of the nasopharyngeal bacterial flora of a small sample of the population of Manchester.[1] The inquiry was extended over two years, 1925–7, and the trend of the carrier rates observed during that period suggested that there might be some association between the changes in the bacterial flora of the nasopharynx and the epidemiological events in the city as shown by the prevalence of respiratory diseases. The duration of the inquiry was, however, not long enough to substantiate this association, and Sir George Newman, in his preface to the report, stressed the desirability of obtaining further data. The Ministry accordingly made arrangements for a more extensive study to be carried out in the Department of Bacteriology of the London School of Hygiene and Tropical Medicine, and has now published a full report of the results reached.[2] This inquiry lasted for as long as seven years and included the repeated swabbing of persons on the staff of the London School of Hygiene and of the boarders in a boys' public school in a south-eastern county. Additional observations were made at the Royal Hospital School at Greenwich, at an orphan home near London, and at the Ministry itself, so that data were available for groups of persons of different ages and living in different environments. This plenitude of material, analysed in over thirty tables, gives some very interesting results. Collating it with the previous study in Manchester and other published work, it is concluded that at any swabbing of a large group of adults in normal health and living in an urban community in a temperate zone some 20 to 40 per cent. will be found to be carrying *Strep. pneumoniae* in the nasopharynx and some 5 to 15 per cent. a haemolytic streptococcus; between 40 and 80 per cent. will be harbouring *H. influenzae* and 5 to 20 per cent. *N. meningitidis*. The frequency of isolation from the nose is uniformly very much lower for each organism, though it is interesting to note that in children the nasal and nasopharyngeal rates differ considerably less from one another than is the case with adults. Looked at in another light, the figures obtained at the School of Hygiene suggest that every person in the sample population would, at one time or another within a period of six years, have harboured *H. influenzae* and one or other type of pneumococcus in the nasopharynx, while at least three-quarters would have harboured the meningococcus and a haemolytic streptococcus.

---

[1] *Report on Public Health and Medical Subjects*, No. 58. Ministry of Health, 1930.

[2] A Study of the Nasopharyngeal Bacterial Flora of Different Groups of Persons observed in London and South-East England during the Years 1930 to 1937. By Edith Straker, A. Bradford Hill, and R. Lovell. Together with Some Observations on the Occurrence of *H. influenzae* in the Trachea. By A. B. Rosher and W. T. Cole. Pp. 131. *Report on Public Health and Medical Subjects*. No. 90. Ministry of Health, 1939. H.M. Stationery Office. (2s. 6d.)

Clearly, as Sir Arthur MacNalty points out in his preface to the report, we need not hesitate to accept any epidemiological hypothesis on the grounds that it postulates a widespread distribution of potentially pathogenic bacteria in the absence of overt clinical disease. The pneumococcus tends, it is apparent, to be isolated more frequently in cold, damp weather than during hot, dry periods, while with the haemolytic streptococcus the association is reversed; but in neither instance are the seasonal fluctuations large. Such movements as there are are distinctly more pronounced in the nose than in the nasopharynx, and if the observations for the deeper respiratory passages, reported by A. B. Rosher and W. T. Cole, are included in the picture there are seasonal variations which are of considerable epidemiological interest. The figures then suggest that the cold weather of late winter and early spring is associated with an extension of the mucous surface colonized by the potentially pathogenic bacteria from the nasopharynx forward into the nasal cavities and downwards into the trachea and larger bronchi. There is also evidence that a similar extension tends to occur in association with epidemic influenza or the common cold. On the other hand, the findings give no support to the previous observations at Manchester that epidemics of respiratory disease are preceded by any characteristic change in the bacterial flora which might serve as a warning of the imminence of such an outbreak. Outbreaks of haemolytic streptococcal infection, for instance, seem to be caused, as Dr. F. Griffith has suggested, by the importation into a community of a strain of bacterium possessing an unusual power of spread rather than by a general increase in the frequency of the strains already present. It does not, of course, follow that factors, such as overcrowding, which promote or hinder contact infection are unimportant. They may largely determine the ease with which an epidemic strain may multiply when introduced to a community—a problem of some importance under conditions of evacuation.

Another observation of interest in relation to war-time conditions is the relatively high frequency of meningococci in the nasopharynx. During the last war a carrier rate of 10 to 20 per cent. was regarded as unduly high and a rate of 20 per cent. as a warning of an impending epidemic. Rates of these levels were quite frequently observed in the groups of adults swabbed during this investigation. There is also some evidence that the pneumococcus and the meningococcus tend to be associated in the nasopharynx, so that a person who is harbouring one of these organisms is subject to an increased chance of harbouring the other, and frequent carriers of the former tend to be relatively frequent carriers of the latter. Observations on persons suffering from colds are in conformity with the view that it is a virus infection. At the time that a cold begins there is no pronounced change in the nasopharynx or nasal flora. Swabs taken a week after onset indicate, however, that in the later stages of a cold pneumococci and *H. influenzae* frequently invade the nasal cavities and give rise to a muco-purulent inflammation. With regard to the serological types of pneumococci the report affords the first account based on extensive swabbing of the frequency of such types in the throat and nose of normal persons in this country. At the London School of Hygiene, where differentiation by type was made for over four years, the pneumococcal flora was relatively stable, Type III being consistently the most frequent and no strain showing any outstanding power of spread. Although it is probable that "epidemic" strains of pneumococci might display a power of spread analogous, if not equal, to that displayed by "epidemic" strains of haemolytic streptococci, no such occurrence did in fact arise, although it is likely that repeated interchanges of type took place between one person and another. It is also of interest to note that there was a tendency for each individual to establish a dominant flora containing one or more serological types of pneumococci and persisting over considerable periods of time.

In general, to quote the Chief Medical Officer, this work presents a picture of the normal nasopharyngeal flora, and of the changes it undergoes in response to a variety of external conditions, which is more detailed and extensive than any previously on record.

THE PRESIDENCY OF THE G.M.C.

The session of the General Medical Council—the one hundred and fiftieth in its history—which has been held during the past week has seen the retirement of Sir Norman Walker from the office of President, which he has held for eight years. Sir Norman Walker's " reign " has been exceeded in length by only two of his nine predecessors—the late Sir Henry Acland, who was President for thirteen years, and the late Sir Donald MacAlister, who occupied the chair for the very long period of twenty-seven years. The retiring President had already spent a quarter of a century in the service of the Council before he was chosen as Sir Donald MacAlister's successor, having been elected as one of the direct representatives for Scotland as far back as 1907. For many years he had been at the President's right hand as Chairman of Business, a position hardly less onerous than that of President itself. Among his other noteworthy work for the Council were two visits to all the medical colleges and several of the much more numerous medical schools of India. His report on his return from those visits influenced the Council in dealing with the delicate situation which presently arose with regard to the Indian Universities and their medical degrees. Sir Norman Walker can certainly claim that under his rule the dignity of the chair has been fully maintained and, moreover, that the business of the Council has been distinctly expedited. One of the achievements in which he takes special pride is that during his period of office the Council has sat on the average only for nine days in the year, whereas in the first decade of this century it customarily sat for fourteen. But that, of course, may be due to the fact that delinquent practitioners are not so numerous as formerly as well as to the businesslike methods of the President.

The last act of Sir Norman Walker in the chair was to induct his successor, Mr. Herbert Lightfoot Eason. Mr. Eason has been a member of the Council for fifteen years, having taken his seat as representative of the University of London in 1924. He has served with Sir George Newman as joint treasurer of the General Council and he is a trustee of the English Branch Council. Mr. Eason has had long experience in educational administration in London. He became a representative of the Faculty of Medicine on the Senate of his University in 1911 ; he has also been a representative of the Senate on the University Court, and in 1935–6 he was Vice-Chancellor. He is a member of the Governing Body of the British Postgraduate Medical School, and was a member of the Ministry of Health Postgraduate Medical Education Committee from 1925 until 1930. Another activity in which he is well known is his membership of the General Nursing Council, where he represents the Ministry of Health. But, of course, to Guy's men all over the Empire he is best remembered for his long tenure as Superintendent of that hospital, Dean of the Medical School, and Warden of the College. Those who have watched Mr. Eason on the Council itself and in other bodies are confident that he will prove a wise and able occupant of a position which is always very much in the public eye.

INDUSTRIAL HEALTH IN WAR TIME

The nineteenth annual report of the Industrial Health Research Board appears at an opportune moment,[1] for the work of the Board has a special relation to industrial problems arising in the production of munitions. The Board was, in fact, initiated in 1918 to carry on the work of the Health of Munition Workers Committee, a body which had been appointed in 1915 by Mr. Lloyd George, then Minister of Munitions, to advise on questions of hours of labour and other matters affecting the health and efficiency of munition workers. The health of many of these workers had been gravely affected by excessive hours of labour and poor environmental conditions, and though it is unlikely that the errors of control then committed will be repeated in so serious a form at the present time, it is important that the employers and managers of munition works should be reminded of them, in case they tend to regress. Employers are apt to forget that an increase in working hours does not mean a corresponding increase of output, and that very long hours may so far defeat their object—owing to the over-fatigue induced in the workers—that they result in an actual reduction of output. The investigations made by the Health of Munition Workers Committee were extended by the Board in a number of directions which the committee itself had no opportunity of exploring, and a study of the present report, and of the extensive summary given in last year's report, should be of great assistance to the managers of munition factories, as well as to those engaged in the direction of other industrial concerns.

Some of the work described in the report now published has naturally, from its peace-time character, only an indirect relation to war-time needs ; but the report states that much of this work will remain in abeyance during the war, and the energies of the investigators will be devoted for the time being to problems of immediate interest. Probably the most urgent of these problems relates to the duration of hours of work and the absence of days of rest, for we already hear of munition factories where there is little remission of labour on Saturday afternoons and Sundays. Of the present work of the Board which has a considerable war-time significance that on the effects of mass-production and on " speeding-up " may be mentioned. The physiological and psychological problems posed by the use of conveyers are being studied in the clothing and motor industries, and are found to raise points of considerable importance, both for the employers and the employed. The speeding-up standards set by efficiency engineers are opposed by representatives of labour on the ground that the health and comfort of the workers are being sacrificed to speed of production. The effects of the speeding are being studied objectively in terms of accidents, absenteeism, spoilt work, and output, and subjectively by the collection of personal information from several hundred workers. In addition, a general investigation of the subject of incentives is in progress. The question of accident-proneness arises in almost all industries, including those of munition production, and it is still being vigorously pursued by the Board's investigators. A report on the psychological functions involved in motor accidents has been prepared, but it was thought to be of too complex and technical a nature for the general public. Another report is therefore being written in non-technical language, which summarizes all the work on accident-proneness carried out by the Board.

RACE, KNOWLEDGE, AND EMOTION

"It is no exaggeration to say that racial theories have led to the ruin and death of millions of people in modern times, and they are still potent destructive agencies." The quotation is from a clearly written brochure[1] in which Dr. G. M. Morant, one of the most distinguished members of Professor Karl Pearson's school of statistical anthropologists, sets out the results of modern anthropological investigation of European "races" in Central Europe. Dr. Morant makes clear the futility of the language criterion of race (the sole criterion of many journalists and politicians) and shows further that even the criterion of blood grouping, which, superficially considered, might seem to support a racial differentiation of Germans from others, does not do so. There is indeed a certain geographical orderliness in arrangement, but the "blood group data suggest forcefully that Germany is racially far more heterogeneous than any other country in Europe for which adequate records are available, and this fact is sufficient to demonstrate that the use of a common language by a number of peoples is no evidence of their common descent." The author of *Mein Kampf* at one point of his career would have cordially endorsed Dr. Morant's conclusion on this point; at page 428 he remarked that "nationality (Volkstum), or rather race, is not a matter of language but of blood." But at that time he believed in a mythical Aryan race, identified by his admirers with the Nordics of older anthropologists, and Dr. Morant has no difficulty in showing that the Nordics have virtually disappeared from Germany. "The difficulty now is to find any section of the population of Germany which could properly be called Nordic." Dr. Morant suggests that if knowledge of the scientific facts were universally disseminated "the absurdity of all racial conflicts would then be apparent." This is optimistic, or rather the implication that masses or even individuals will not often do what they know intellectually to be absurd is quite wrong.

> "You'll ask me, why I rather choose to have
> A weight of carrion flesh, than to receive
> Three thousand ducats? I'll not answer that:
> But, say, it is my humour: is it answered?"

Modern medical psychologists know more of the mechanism than did Shakespeare, but the psychological fact was as clear to him as to Freud himself. No more complete proof of the proposition that in a modern large-scale war there are no victors only vanquished could be asked than the events of 1914–39. Yet another war is in progress. But it is certainly true that although knowledge is not a spring of action (as Aristotle pointed out) knowledge does, very gradually and in certain fields of activity, control or deflect action. The practice of our own art is a striking proof of this. It is a more encouraging proof than the obvious illustrations of the physical sciences, because we are concerned with human beings afflicted in mind, body, or estate, and are ourselves human. Many plans of treating mental or bodily disease do stir emotions. Yet the sick in this war will be more rationally treated by us than the sick in the last war; and those sick in 1914–18 were better treated than the sick of 1899–1901. Even over the emotions knowledge has a little power. Dr. Morant's book will do some good even at the emotional level; intellectually it should convince and instruct many.

SYSTEMATIC SCREENING OF THE CHEST

Routine screening has been carried out on all recruits to the French army for several years, and more recently in the navy; it is also employed in the Swiss, German, Belgian, and Czechoslovak armies. It was adopted in Algeria in 1935, and J. Jalet, chief radiologist to the military hospital at Algiers, in a recent paper on this work,[1] states that the percentage of tuberculin-negative recruits is much higher than had hitherto been thought to be the case, particularly among European country people and North African natives. It has been found that during the first six months in barracks no less than 25 per cent. of the men become tuberculin-positive, the change being accompanied in some cases by mild constitutional symptoms of the primary complex or by acute pneumonic or pseudo-influenzal phthisis. These primary syndromes generally develop as a result of contact with unsuspected sputum-positive cases; systematic radiological examination in order to detect such cases should be undertaken not only at the time the recruits enter the army but also at intervals during their training and military career. Screening has been found to be rapid, sufficiently reliable, and compatible with the military authorities' need for recruits. It is not carried out at the time the recruits are admitted, but later in barracks after a large number have been eliminated by the preliminary general medical examinations. Of 19,305 recruits examined since 1934, of whom 13,688 were natives, 890, or 4.6 per cent., were found to have manifest or suspected lesions. After further radiological and clinical investigations 138 persons (0.71 per cent.), including eighty natives, were rejected, ninety-four permanently and forty-four temporarily; all the natives were rejected for good as there is no provision for their temporary rejection. Sixteen recruits, of whom nine were natives, were found to have tubercle bacilli in the sputum, while 318 (1.64 per cent.) were considered "doubtful" and placed under medical supervision. Dr. Jalet states that subsequent periodic screening disclosed further definite cases; these were not necessarily missed at the first examination but were probably the result of endogenous reinfection. In assessing the value of systematic screening, not only must the actual number of cases discovered be taken into account but also the time spent by the men in the military community before they are eliminated. It is of interest that there are fewer eliminations of young native recruits than of recruits from France. This accords with the smaller percentage of natives in whom the tuberculin test is positive, the greater incidence of disease among them later being due to the fact that they are more often the victims of a primary infection. Dr. Jalet has written a paper that merits close study at a time when a similar problem faces us in this country.

LADY NICOTINE

Precise information on the effects of tobacco smoking on the human organism is not easy to obtain, and clinical impressions seem often to be allowed to take their place. As with all impressions, these are rarely formed without much personal bias. Many consider that tobacco is harmful to the cardiovascular system and to digestion, whilst others look upon it as a useful sedative and as a stimulant to digestion—what the psychologists describe as an ambivalent attitude. As with all actions of chemical or physical agents on the body, psychological or conditioned-reflex effects cannot be excluded. The morning cigarette may, for example, be lauded as the ideal laxative by one who has conditioned his colonic evacuation to the post-prandial puff; where there is a wish there is a way, and no pharmacological action need be invoked. It is also a general impression that smoking lessens appetite, and that a cigarette will help one to stave off a meal. Many people in times of stress or strain are inclined to substitute smoking for food. In this connexion it appears that smoking may increase gastric acidity. Dr. Schnedorf and Dr. Ivy[1] in Chicago have reported a number of observations on the effect of tobacco smoking on salivary and gastric secretion in man and in dogs. Both in smokers and non-smokers cigarette smoking increased the flow of saliva; but out of a total of sixty individuals examined gastric secretion was decreased in just over half, unaffected in twenty-five, and slightly increased in only two. These findings are in contrast to those of Gray,[2] made without the same completeness ten years ago. Schnedorf and Ivy also noted little change in the emptying time of the stomach (certainly no increase in rate), but observed a remarkable inhibition of the hunger contractions of the empty stomach. This reflex inhibition, they showed, was due to vagal inhibition and did not occur in dogs given large doses of nicotine subcutaneously. The action of tobacco smoking on the colon was variable, but on the whole there seemed to be slightly increased motility. As these workers emphasize, however, tolerance to tobacco is variable, and with an overdose nausea, vomiting, and increased gastric peristalsis occur. For instance, three patients with gastric ulcers who were tested vomited and fainted after smoking two or three cigarettes on an empty stomach. The conclusion from these studies would seem to be that in patients with peptic ulcer the risk is in their substituting smoking for regular meals, and so prolonging hunger periods, rather than in any direct or indirect effect on gastric secretion or peristalsis. The action of tobacco on the cardiovascular system can be more precisely investigated. Using the electrocardiograph, Segal[3] noted an increase in the heart rate and a lowering of the T wave after smoking either ordinary cigarettes or those of the so-called de-nicotinized brands. Short and Johnson[4] showed the effects to be comparable to those following injection of adrenaline—increase in pulse rate, fall in skin temperature, and slight rise in blood sugar. Alteration in blood pressure varied considerably. Nicotine itself is a powerful vasoconstrictor when injected into cats or dogs, and Helmer and others[5] show that it can be extracted fairly readily from the urine of human beings who smoke. Most investigators have reported some temporary rise in systolic blood pressure after tobacco smoking, others note little appreciable change. Herrell and Cusick[6] have demonstrated on ten subjects an excessive blood-pressure response to cigarette smoking, and they regard this as due to a vasospastic idiosyncrasy. Pressures in some cases rose from 130 mm. Hg systolic to 195, and 70 diastolic to 110; a cold pressor test in these individuals gave similar findings. All these observations show the need for individual judgment in the use of tobacco and its especial danger in those who have, for instance, an excessive vasomotor reaction to cold. The fall in skin temperature from constriction of peripheral arterioles observed in many individuals after smoking must also suggest the need for care in those liable to peripheral vascular disease, among which, of course, endarteritis must be remembered.

Sir Arthur MacNalty's annual report for the year 1938 as Chief Medical Officer of the Ministry of Health is published this week (H.M. Stationery Office, 3s. 6d.), and we hope to give an account of its contents in an early issue. There is a chapter on the emergency hospital organization and medical arrangements, but this was written before the war and before the vast organization came into being.

The Harveian Oration (postponed from St. Luke's Day) will be delivered by Dr. R. A. Young on Friday, December 15, at 2.30 p.m., in the large Library of the Royal College of Physicians of London, Pall Mall East. The Commemoration Dinner will not be held this year.

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation

TREATMENT OF FRACTURES IN THE REGION OF THE KNEE

(EXCLUSIVE OF PATELLA)

BY

GATHORNE R. GIRDLESTONE, F.R.C.S.

Whenever a joint surface is fractured the main object of treatment is the restoration of the form and plane of the articular surface. This is more difficult in the knee than in any other joint because only a small part of the opposed articular surfaces is in contact at any one period. At the same time the restoration of the true plane is rendered more important because the knee is a weight-bearing joint lying between two bones of great length. Here again, although a complete range of movement is very desirable, full extension is of much more consequence than full flexion; furthermore, extension must be strongly controlled by active muscles, for there is no value in full extension if it cannot be fully maintained against gravity. The particular manœuvres directed towards these objects of restoration of form, of movement, and of muscular control are: (*a*) the exact reduction of the fracture; (*b*) the maintenance of traction; (*c*) the institution of early assisted active movements.

One principle is of paramount importance in the treatment of every fracture—namely, the assurance of free circulation in the whole limb.

Lower End of Femur

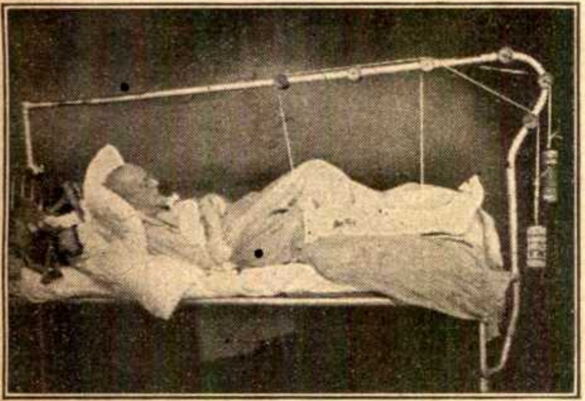

FIG. 1.—Showing the treatment of shattered head of tibia—second stage, with distraction provided and retained by two Steinmann pins, which can be seen in the close-up held in a thigh and leg plaster respectively, with a hinge applied to allow mobility.

Fractures at the lower end of the femur may be supracondylar, intercondylar, T-shaped, unicondylar, or fracture-separation of the epiphysis. Widespread extravasation within and without the joint occurs so quickly that accurate clinical diagnosis is seldom to be expected without radiography. As a first-aid measure immobilization of the lower extremity as it lies is imperative. This is best effected by the application of a Thomas splint. A temporary fixed traction can be used by putting a bandage clove-hitch round the ankle over the boot or shoe (in the latter case the ankle itself should be protected by adequate padding). If no proper splint is available the limbs should be tied together and their movement eliminated so far as possible by improvised splinting. This splintage should not be disturbed until an antero-posterior radiograph has been taken to determine the site and character of the injury; then, after division of the bandages, a cassette can be placed between the limbs and a lateral view be taken from the side without movement of the broken limb.

Supracondylar fracture is typically associated with posterior angulation of the distal fragment, a deformity commonly due to the originating force and maintained by the pull of the gastrocnemius. Reduction can almost always be achieved by a pin or wire inserted through the tibial crest just below the tubercle, the leg being slung in a Thomas splint with a flexing knee-piece at 150 degrees. This allows pull in the long axis of the femur and relaxes the gastrocnemius. Open reduction is rarely required. Prognosis is good, though even after accurate reduction there may be some permanent limitation of flexion, with otherwise good stability and range of movement.

Fracture-separation of Lower Femoral Epiphysis.—This is not very uncommon during the period of school life. Radiographs show that there is separation at the epiphysial plate rather than a true fracture; the distinction is most important, as the prognosis is less certain. Reduction must be exact, but even so premature fusion of the epiphysial line is common and one or two inches of shortening may result by the time the patient is full-grown. On the other hand, full function of the knee is readily restored. Reduction is best carried out by manipulation in flexion with radiographic control. It is often wise to retain about 90 degrees of flexion in plaster (pelvis to foot) for a fortnight or three weeks, then to put the limb in a Thomas splint with a flexion piece arranged as already described.

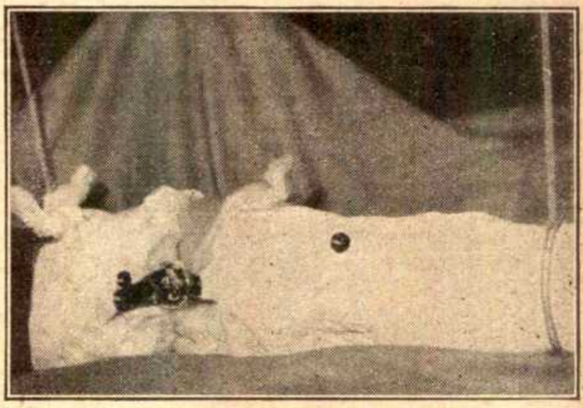

FIG. 2.—Close-up of Fig. 1.

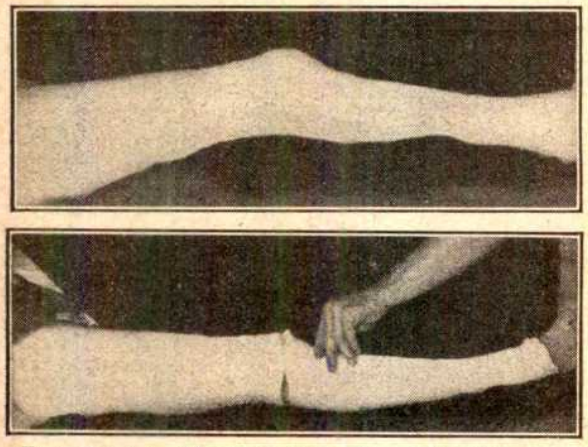
T or Y fractures of the femur or tibia are often the result of direct violence, and then show little displacement. But any broadening of the articulating end of either is to be avoided. A Böhler clamp may be used, or the method, introduced by Kindersley of Bath, of applying, first, traction (of, say, 20 lb.), secondly, an Esmarch bandage (firmly), and, thirdly, a heavy hammer round both sides of the joint with moderation and with purpose in relation to the radiographs. This manœuvre achieves two aims: first, to correct the longitudinal alignment, and, secondly, to reduce the lateral separation; the former by skeletal traction applied through the crest of the tibia, and the latter by circumferential compression and moderate hammering, directed rather towards replacement than to impaction of the fragments. Operative correction followed by screw or bone-peg retention is advisable when radiographs indicate inadequate reduction; this operation can be performed without disturbance of the skeletal traction.

Fracture of one condyle is usually reducible by manipulation in the direction of over-correction of the lateral deformity, perhaps assisted by a few purposeful blows with a mallet over a felt pad. The reduction is always confirmed by radiographs. If accurate reduction has been achieved it can be maintained by a plaster from groin to toes with a good padded hold at the tuber ischii. Then after a fortnight hinges can be added, with the axis of movement very carefully and accurately placed and enough plaster cut away over the knee itself to allow of movement (Fig. 1). The plaster is of course slung and the usual pulley attachment for active movements instituted (Fig. 1). If, however, radiographs show that the position is imperfect, open reduction with fixation by bone peg is indicated. This operation can be done by working through a large window in the plaster. After the operation the hinges can at once be fitted. A technical point helpful towards the exact placing of the hinges is to take a true lateral radiograph with an "R" on the right side of the limb and an "L" on the left, arranged in the position which seems likely to be the right one.

Comminution.—In really difficult cases, especially where there is much comminution, the best method is reduction and retention by Steinmann pin or Kirschner wires, described above.

It was particularly for comminution of the upper end of the tibia that Kindersley's method was designed. In all these fractures of the tibia skeletal traction is even more essential than in those of the femur. Occasionally a detached condylar fragment of femur or tibia may be controlled by a Steinmann pin poked through the skin without open operation. It has already been mentioned that the exact displacement of the articular plates of the tibia is most important, and in cases in which good reduction has not been achieved it is wise to operate. At the operation the joint should be opened in order to control the reduction and to make sure that the menisci are in their right position. As a rule, especially on the outer side, it is better to remove a meniscus which appears to have been damaged or is likely to interfere with function.



FIGS. 3 and 4.—Plaster treatment for a rather late case of traction fracture of tibial spine

Spine of the Tibia.—A traction fracture of the anterior tibial spine is fairly common. It is, of course, pulled off by the anterior cruciate ligament. There is a resultant lack of the normal control of forward movement of the tibia on the femur, but the sign most commonly present is lack of full extension of the knee. This must not be mistaken for a cartilage displacement, which it closely resembles. Accurate antero-posterior and lateral radiographs will distinguish the condition. The treatment is retention for six to eight weeks in full extension. When the case is seen after a week or two full extension cannot be immediately achieved owing to an upward displacement of the spine and infiltration between it and its attachments. In such cases it is wise to put a plaster on in as full a degree of extension as can be readily obtained. Then by cutting and wedging the plaster once or twice at four- or five-day intervals it is possible to obtain full extension by gradually squeezing down the spine into position (Figs. 3 and 4) and so to avoid any stretching of ligaments. It is important that the plaster should get good well-moulded holds behind on the tuber ischii and on the back of the heel; in front, round rather than on the patella.

Complications

Haemarthrosis.—A fracture involving any joint is apt to cause haemarthrosis, but this complication is especially common and troublesome in the knee. Aspiration may be necessary, but it should be delayed or avoided unless the part is very tense and painful. No attempt should be made to get rid of the whole content of blood, for this is both impracticable and undesirable. The earlier and the more complete the relief by aspiration the more likely is the joint to fill again.

The Menisci.—In the knee, too, the presence of the semilunar cartilages adds to the delicacy and complexity of its internal mechanism. The menisci are often troublesome in depressed fractures of the articular plates of the tibia.

Patellar Surface of Femur.—Not long ago I saw a young lady about 21 years of age whose knee was crushed by a car which had been left standing on a hill and had run away. The fore-part of the external condyle of the femur had been crushed inwards across the front of the patellar surface. Such a displacement is not clearly shown in radiographs, and in this case was not recognized. When I saw her the knee was locked in full extension. It was fortunately possible to restore free movement by the removal of the patella and by an extensive plastic operation on the quadriceps and external vastus over a fascia lata transplant.

Ischaemia or Gangrene.—Loss of circulation may be due to an unrelieved popliteal haematoma or even to perforation or thrombosis of the main popliteal vessels following delay in reduction or adequate fixation of supracondylar fractures. Early operation is indicated. The signs and symptoms are pain, cold pulseless foot, and, as a rule, a large extravasation in the popliteal space.

Injuries to Nerves.—These are rare as a direct result of the fracture. I have had one case in which the sciatic nerve was almost divided by the sharp knife-like oblique edge of the lower femoral fragment. But subsequent paralysis of the external popliteal nerve is common and due to pressure on the nerve behind the head of the fibula or as it winds round its neck. Numbness, tingling, and loss of voluntary dorsiflexion of the toes are indications for the immediate relief of pressure at this situation.

Compound Fractures

Compound fractures involving the knee demand immediate operative treatment. After thorough cleansing of the skin by soap and water the edges of the wound are excised and all bruised and avascular tissues accurately cut away. Small detached fragments of bone are removed, and if the patella is extensively fragmented it is better excised. Opinions differ as to the advisability of prolonged lavage of the joint. The wounds need not be sutured, though when the patella has been removed a central suture with fine non-chromicized catgut is best. The suture should not be drawn tight. In cases in which drainage is likely to be required two vertical lateral incisions should be made and fine non-chromicized catgut sutures used to prevent premature closure. Two stitches are applied in each wound, one in front and one behind. By each the skin and perisynovial tissues are gently sewn together; thus granulation is prevented. Following the operation immobilization is essential. It is my practice to carry this out by fixed traction, preferably skeletal, on a Thomas splint with a flexion piece. In my last three cases of this serious type where lateral drainage was necessary I have obtained extraordinarily favourable results by a method learned from Dr. Maurice of Marlborough. In this method the surgeon once a day *very gently* grasps the back and sides of the knee with his two hands, exercising *mild* pressure on the posterior pouches and gently lifting the knee upwards to give it just 5 or 10 degrees of flexion movement. This induces an escape, through the lateral incisions, of fluid from the posterior pouches, which otherwise so insidiously and disastrously spreads into the intermuscular planes above and below the knee.

Acute Septic Arthritis

Whenever this occurs, with illness and high fever, much more radical drainage is necessary. Both lateral ligaments are divided transversely and the incisions are carried back round the posterior pouches with due regard to the popliteal vessels and nerves; the knee is immobilized completely on a Thomas splint with about 20 degrees of flexion in order that ankylosis may take place at a useful angle. If pus spreads into the intramuscular planes amputation is indicated, and should be carried out without delay by a modified guillotine method, followed by skin traction on a short Thomas splint with a terminal ring.

An article on the health of munition workers by Dr. H. M. Vernon, investigator to the Industrial Health Research Board, appears in the November issue of *Industrial Welfare and Personnel Management* (published by the Industrial Welfare Society, 14, Hobart Place, S.W.1, price 1s.). Dr. Vernon, who carried out many investigations for the Health of Munition Workers' Committee appointed by Mr. Lloyd George in 1915, in this article, the first of a series, summarizes the results of the experience of that committee in dealing with the problems of the last war, and indicates their application to the organization of work on the home front in the present struggle. The most important point Dr. Vernon emphasizes is that the experience of the last war showed how foolish it was to work excessively long hours in the hope of securing a larger output. Employers should not be discouraged by the fact that output will fall temporarily after hours are reduced, until the workers get into their stride under the new conditions. Another important conclusion of the Munition Workers' Committee was the need for the appointment of welfare supervisors in munition and other factories.

A FIRST-AID POST IN LONDON

The following article has been written by two medical Students, Mr. Desmond O'Callaghan and Mr. R. A. Shooters of St. Bartholomew's Hospital Medical College, who have been working since the beginning of the war at the first-aid post established at Aldermanbury, in the City of London.

First-aid posts have been instituted to relieve the casualty receiving hospitals from a rush of minor casualties and to act as filters passing on only cases whose injuries necessitate a period of treatment in hospital. Thus "walking" and "sitting" cases will all be directed to first-aid posts, but in addition "stretcher" cases may arrive carried in because they have occurred near to an aid post or because transport direct to hospital is for some reason delayed. By telephoning to the local control centre an ambulance can be summoned to convey "stretcher" cases to hospital, other cases being sent home after treatment. It is obviously an advantage to have first-aid posts situated in a hospital or other medical building, but in the City of London the only hospital, St. Bartholomew's, is a casualty clearing hospital. It has therefore been necessary to establish the five first-aid posts in non-medical buildings.

The post to which we have been attached since the beginning of the war is situated in the basement of a modern steel-framed commercial building five stories high, all the floors being constructed of reinforced concrete. All the windows which look on to areas, and also the pavement lights, have been heavily sandbagged, so that the personnel of the post and any casualties under treatment will be safe against everything but a direct hit from a very large bomb.

Arrangements for Admission

There are three separate entrances into the post. Casualties, male and female, who were not contaminated by blister gas would be admitted through the double doors of the main entrance, and would proceed down a wide flight of stairs, through an air lock, into the male and female first-aid rooms. These have been made quite simply by dividing a large room, formerly a restaurant, into two sections by hessian screens. What was a serving counter is used as an office; folding tables for drugs, dressings, and instruments, and trestle tables for stretcher cases requiring treatment, are provided. Two improvised tables, common to both male and female, support the sterilizer and poison cupboard; and chairs, placed back to back, are provided for sitting cases.

Casualties contaminated by blister gas would enter from the opposite side of the building, where there are separate entrances for men and women. Stencilled placards guide the casualties to their respective cleansing rooms. The male cleansing room is a cloakroom-lavatory which has been converted by the addition of sprays attached to the wash-basin taps; a bar of cement has been laid across the floor to localize waste water, while a hole has been made in the wall to drain away the water to a gully in an area outside. The female cleansing room, the former kitchen, is planned on the same simple lines. These changes have been made at little cost and have involved no structural alterations. "Stretcher" cases which have been contaminated would be admitted by the main entrance, but would be stripped before being taken into the post, where they would first of all be taken into the male or female cleansing room, as the case may be, and then carried into the appropriate first-aid room.

The medical equipment of the post is that prescribed in the Ministry of Health Circular 1789.

Personnel of the Post

The personnel of the post comprises three doctors, who will only attend after an actual air raid on the City

—excepting one who, as medical officer in charge, exercises general supervision over the organization and training; a member of the staff of the Public Health Department who acts as the representative of the medical officer of health in the administration of the post; a trained nurse; four resident medical students; and nineteen whole-time paid first-aiders, who have twenty-four hours on duty followed by twenty-four off. In addition there are some fifty unpaid part-time volunteers, who have undertaken to give assistance at the post in the event of an air raid occurring when they are at work in the City.

If a first-aid post is to discharge its function of dealing with all "walking" and "sitting" casualties, and in addition be capable of giving temporary treatment to such "stretcher" cases as may be carried into the post from a bombed area in the vicinity, its personnel must be trained up to, and if possible beyond, the pre-war first-aid standard. This training should be supplemented with as many and as varied practical exercises as possible.

Interim Practice for the Staff

Though fortunately up to the time of writing London has not been raided, the personnel of the first-aid posts have not been idle. Lectures and demonstrations have been given daily, and combined exercises with "casualties," both wounded and gassed, have been carried out regularly. But in addition it has happened that many cases of injury which have occurred in the streets or in buildings near the post have been brought in for treatment. From a considerable number of cuts, lacerations, burns, and fractures the following two cases will illustrate the application of strictly first-aid principles and also demonstrate the necessity for personnel who have practical experience.

CASE I

A man aged 62 walked into the first-aid post with the assistance of a policeman. Between puffs at his cigarette he complained of pain in the region of the left hip. Ten minutes previously he had fallen down three steps and landed on his left side. He felt no severe pain at the time, and at once could move his left leg slightly.

Examination.—He was not pale or sweating and did not appear to be in any pain. His left leg lay in its normal position, with the pelvis not tilted. There was no "rolling out" of the foot and no local bruising. There was a tender point above the great trochanter. Measurements showed the absence of true shortening. At the hip active flexion was limited to 30 degrees, but extension was full. Passive adduction and abduction caused pain just above the trochanter on approaching their full extent. Passive flexion over 30 degrees caused pain. Diagnosis of fractured neck of the femur was made.

Treatment.—(1) A stretcher was prepared by the R.A.M.C. method, using two blankets folded to give two thicknesses above and four below. The patient was placed on a stretcher. (2) The patient's feet were tied together with a triangular bandage. (3) A long Liston splint, padded by wrapping with a blanket, was applied to the left side, extending from axilla to beyond the heel, and was held in place by seven triangular bandages tied by the St. John method. (4) The patient was given a cup of hot sweet tea and sent, with a hot-water bottle, to C.C.H. (St. Bartholomew's Hospital) in an ambulance. (The time from entry of patient to arrival at hospital was fifteen minutes.)

Radiographs confirmed the diagnosis.

CASE II

A cook aged 30 slipped and fell on her left shoulder while at work. She walked to the first-aid post with her employer, complaining that her left arm was useless and her left shoulder was painful.

Examination.—She was a tearful, extremely obese woman. Her left forearm was supported by her right hand. No obvious shortening or asymmetry was observed. No bony points were visible, and local examination was difficult on account of the patient's fatness. There was no palpable tenderness along the shaft of the humerus and no crepitus. Examination to elicit the position of the humeral head was not persisted with on account of difficulty. Active movement was not present, and all passive movements were prevented by pain at the shoulder. No abnormality was detected in the clavicle. A provisional diagnosis of fracture of the neck of the humerus was made.

Treatment.—(1) The patient was given tea and was wrapped in a warm blanket. (2) The arm was placed in a large Red Cross arm sling. In view of the adequate support provided by the size of the patient's chest it was considered unnecessary to bind the arm to the side. (3) The patient was sent as a "sitting" case to the C.C.H.

Radiographs confirmed the diagnosis.

Discussion

These two cases illustrate three principles for first-aid posts: (1) not to try to accomplish too much at the patient's expense; (2) the inadvisability of a too thorough search for a fracture; (3) treatment of injuries is not stereotyped, and circumstances alter cases.

In the event of an air raid these might have been "walking" cases. In spite of the severe injuries present there would have been little to show in the way of physical signs, and they would have presented considerable difficulty to a first-aider lacking in practical experience. As can well be imagined, one of the main factors in arriving at the diagnosis in Case I was the fact that a similar case had been seen in the past. This again stresses the necessity for a large variety of practical exercises. The most instructive and at the same time the most interesting is one in which a dummy casualty is placed in some part of the first-aid post. This provides useful practice both in transport and treatment of the patient.

The patient in Case I walked in, and left on a stretcher —a thing that can be expected to occur often. As all stretchers are of a standard type the patient can remain on the same stretcher from the first-aid post to, if necessary, the base hospital. Time is not lost and the return of stretchers to depots is facilitated.

The first-aid post personnel should have training in the proper method both of placing patients on stretchers and of carrying stretchers. The post should also be laid out with an eye to providing adequate room for circulation of stretchers. The R.A.M.C. plan for advanced dressing stations does this admirably.

As a last point it is important that the labelling system be adequately understood. If it is not the records for the Ministry of Health will be incomplete, and if in particular the spaces for time, morphine, A.T.S., and tourniquet are not filled in on the Label M.P.C. 46 or written in blue pencil on the patient's forehead the patient will suffer. Simplicity should be the ideal, and this is fulfilled by Label M.P.C. 46.

Summary

An account is given of the purpose and organization of a City of London first-aid post.

Two cases are taken to illustrate first-aid casualties and the routine casualty treatment at a first-aid post.

They also show the necessity for a high standard of first-aid training, and that this training should be predominantly practical.

The type of training being carried out is shown.

We are indebted to Dr. Charles F. White, medical officer of health to the City of London, for permission to describe this first-aid post and our experience therein.

SECONDARY HAEMORRHAGE IN 1582

A Royal Case History

The attempted assassination of the Prince of Orange, also known as William the Silent, is fully recounted in Motley's *Rise of the Dutch Republic,* and its detailed description of the circumstances affords considerable medical interest. The account is fully documented, so that there is every reason to suppose that it is an accurate one, and indeed it rings true. The relevant extracts of the history are as follows:

> On Sunday, the 18th of March, 1582 . . . the Stranger suddenly drew a pistol and discharged it at the head of the Prince. The ball entered the neck under the right ear, passed through the roof of the mouth, and came out under the left jaw-bone, carrying with it two teeth. The pistol had been held so near that the hair and beard of the Prince were set on fire by the discharge. He remained standing, but blinded, stunned, and for a moment entirely ignorant of what had occurred. As he afterwards observed, he thought that perhaps a part of the house had suddenly fallen. Finding very soon that his hair and beard were burning, he comprehended what had occurred, and called out quickly, "Do not kill him—I forgive him my death!". . .
>
> The Prince, supported by his friends, walked to his chamber, where he was put to bed, while the surgeons examined and bandaged the wound. It was most dangerous in appearance, but a very strange circumstance gave more hope than could otherwise have been entertained. The flame from the pistol had been so close that it had actually cauterized the wound inflicted by the ball. But for this it was supposed that the flow of blood from the veins which had been shot through would have proved fatal before the wound could be dressed. The Prince, after the first shock, had recovered full possession of his senses. . . .
>
> The surgeons implored his silence, as speaking might cause the wound to prove immediately fatal. He complied, but wrote incessantly. . . . For eighteen days he lay in a most precarious state. . . . But the hopes [for his recovery] which had gradually been growing stronger were on the 5th of April exchanged for the deepest apprehensions. Upon that day the cicatrix by which the flow of blood from the neck had been prevented, almost from the first infliction of the wound, fell off. The veins poured forth a vast quantity of blood; it seemed impossible to check the haemorrhage, and all hope appeared to vanish. The Prince resigned himself to his fate, and bade his children "good-night for ever," saying calmly, "It is now all over with me."
>
> It was difficult, without suffocating the patient, to fasten a bandage tightly enough to staunch the wound, but Leonardo Botalli of Asti, body physician of Anjou, was nevertheless fortunate enough to devise a simple mechanical expedient which proved successful. By his advice, a succession of attendants, relieving each other day and night, prevented the flow of blood by keeping the orifice of the wound slightly but firmly compressed with the thumb. After a period of anxious expectation, the wound again closed, and by the end of the month the Prince was convalescent. On the 2nd of May he went to offer thanksgiving in the Great Cathedral, amid the joyful sobs of a vast and most earnest throng.

Surgical Commentary

The wound was a remarkable one in passing close to so many important structures without proving immediately fatal. It seems doubtful whether any big vessel can have been damaged in the first instance, as the flame of the pistol discharge could scarcely have prevented severe primary arterial haemorrhage. But the flame did perhaps disinfect the wound. The subsequent infection which caused the secondary haemorrhage might have occurred either by reinfection from outside (antiseptic wound dressing being then practically unknown), or else from the mouth. Against the latter view, however, is the fact that the haemorrhage did not take place into the mouth, but through the original wound (though whether of ingress or egress we are not told).

The treatment was masterly in its simplicity and effectiveness. It resembles the method described in the older textbooks as a treatment of aneurysm, and also the first-aid treatment of haemorrhage from the common femoral artery.

In conclusion one may add that the Prince made a perfect recovery, but only to be again the victim of an assassin's pistol. Two years later he was shot through the heart and died within a few minutes. So ended the career of a noble man, and, as Motley has it, the guiding star of a brave nation.

ROBERT C. TAYLOR, F.R.C.S.

AMERICAN NOSOGRAPHY

Dr. David Riesman delivered the Shattuck Lecture at Boston on May 31, 1938.[1] He took as his subject "American Contributions to Nosography." He reviewed the discoveries and early descriptions of disease by American writers, gave some biographical details, and in several instances a transcript of their observations. The lecture, therefore, is useful as a source of information because he appends references, and is readable, for he has the gift of a ready pen. Almost the earliest writer to draw attention to new factors in disease was Benjamin Rush, "the Father of American Medicine," who in 1801 described the case of a lady whose rheumatism ceased after the extraction of a decayed tooth. Focal infections as factors in chronic affections engaged the attention of many physicians and surgeons, but it was not until 1912 that they were studied in detail by Frank Billings of Chicago. Hezekiah Beardsley drew attention about 1784 to the condition now known as congenital hypertrophic stenosis of the pylorus and gives details of a case occurring in a boy who died at the age of 5. John C. Otto, too, who lived from 1774 to 1844, recognized that haemophilia was transmitted solely through the mother, and records the family history of a case which had been under his care. W. W. Gerhard (1809–72) distinguished typhoid from typhus clinically before the two diseases had been recognized in Europe.

Some Eponyms

George Sumner Huntington described "Huntington's chorea" in 1872, when the disease was devastating Long Island. John M. Riggs gave his name to "Riggs's disease" before it was known as pyorrhoea alveolaris, and the names of Weir Mitchell and G. M. Beard are inseparably connected with neurasthenia and the rest cure. "Milroy's disease," now called angioneurotic oedema, was described in 1892 by W. F. Milroy, professor of clinical medicine at Omaha. Sir William Osler's name, says Dr. Riesman, is more especially connected with erythema exudativum *or* nodosum, which might well be called "Osler's disease," for he drew attention to the visceral manifestations.

The American contributions to dermatology are considered. Duhring, Schamberg, Fordyce, Dercum are mentioned, and there is an excellent account of the American discovery of tularaemia in 1904. Attention was first drawn to it by Ancil Martin, an ophthalmic surgeon of Phoenix, Arizona, but it was not until 1912 that McCoy and Chapin isolated the microbe and called it *Bacterium tularense,* after Tulare County, California. Still later Edward Francis of the United States Public Health Service demonstrated in his own person that its micro-organism, carried by the deer-fly, could penetrate the unbroken skin.

STANDARDIZATION FOR STRETCHERS

The standardization of stretchers and ambulance equipment generally has been under discussion for some time. Five years ago attention was drawn to the unsatisfactory position of stretchers and stretcher gear. The question arose again later when a large hospital in the south-west of England was installing new equipment and endeavoured to standardize its gear to take the stretchers which arrived at its doors. The enormous development of blocks of flats, with lifts seldom constructed large enough to take existing patterns of stretchers, also brought home the difficulty. In mines, again, the need for standardization was apparent; we are told that when an injured miner is placed on an ordinary stretcher in the ambulance room, not infrequently the stretcher will not go into the ambulance that is sent to fetch him to hospital.

The matter was eventually considered by the Hospitals Committee of the British Medical Association, and, through the Council, was referred to the British Standards Institution, a body which, with its innumerable committees, has effected standardization in many directions in industry. The Ministry of Health endorsed the request to the Institution, and accordingly a technical committee was set up with representatives, amongst others, of Government Departments interested (including the three fighting services), the British Red Cross Society and St. John Ambulance Association, the Mining Association of Great Britain, and the British Medical Association, whose representative, Dr. Lockhart, was elected chairman.

A draft specification has now been issued under the authorization of the council of the Institution and has been sent to all interested parties for their comments and suggestions. Very large numbers of stretchers are being manufactured at the present time, and it is considered essential that a British standard should be produced and approved without delay. For the present, therefore, the proposed standard will be limited to dimensions, and the questions of materials for stretchers may be taken up at a later date.

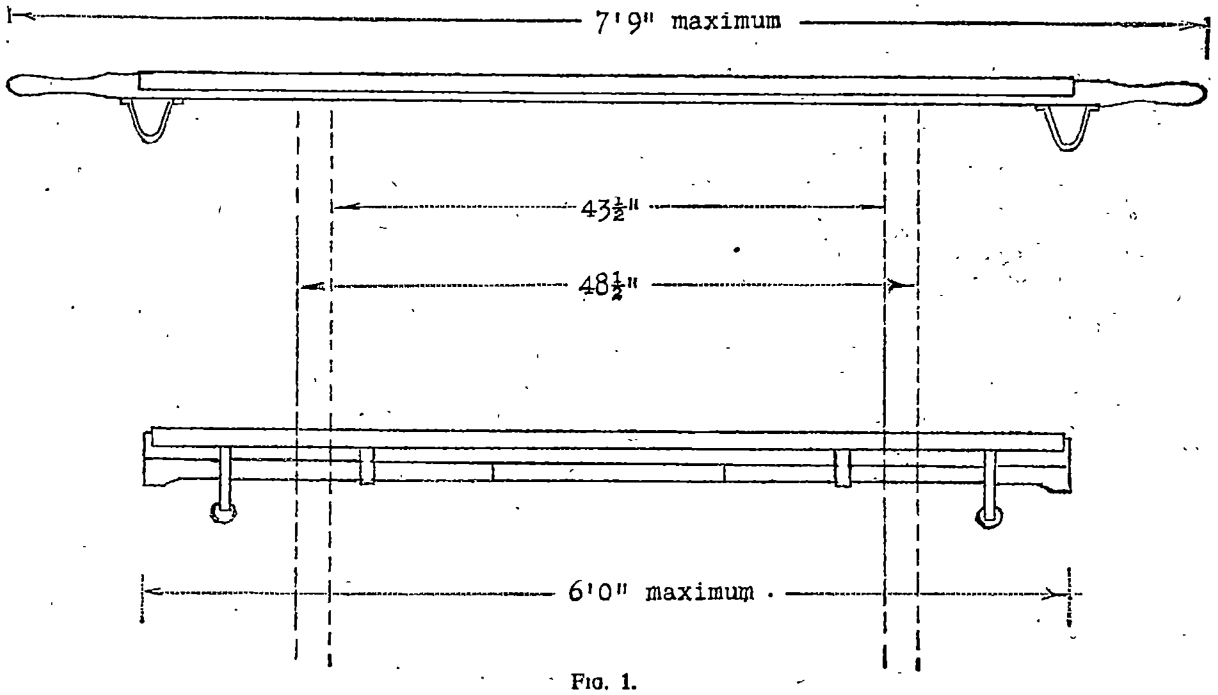

FIG. 1.

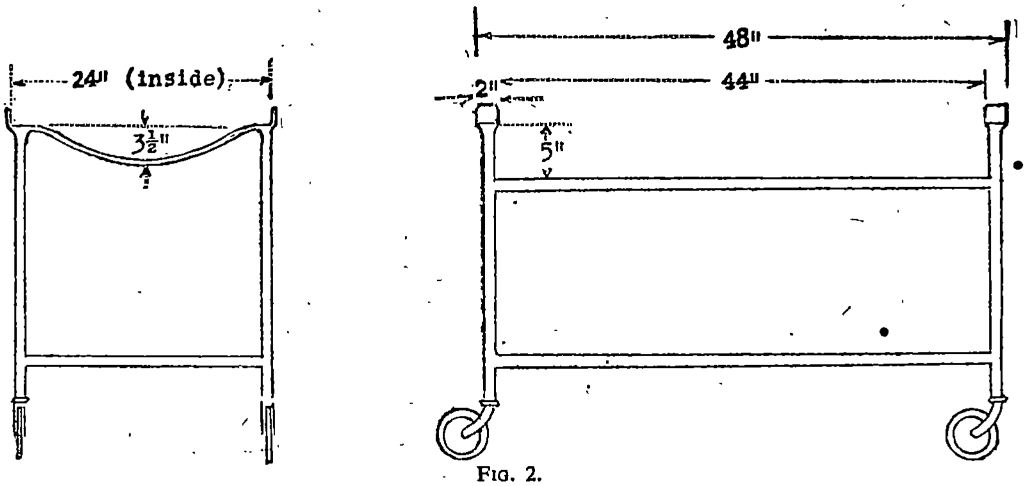

FIG. 2.

Sizes of Stretchers

It is recommended that the overall length of the stretcher with fixed handles should not exceed 7 ft. 9 in. when the handles are projecting, and that 6 ft. should be the standard length for the stretcher with sliding handles when these are pushed in underneath. This length has been used by the fighting forces since the last war, and for many years by the L.C.C. ambulance department. A very strong recommendation is that all ambulances in future should be built to accommodate the 7 ft. 9 in. stretcher, and that in large buildings, factories, and flats the lifts, staircases, and corridors should be constructed in such a manner that the 7 ft. 9 in. stretcher may be reasonably manipulated and turned. The 6 ft. stretcher can be readily fitted into the smaller ambulances or vans converted for the purpose.

A further recommendation is that the length between any portion of the wheels or runners should be either more than 48½ in. or less than 43 in. so that such wheels or runners may be clear of the hospital trolley supports (see Fig. 1). For the same reason the overall width of any portion of the wheels or runners, for a vertical distance of 2 in. measured from their lowest point, should not exceed 22½ in., nor should their overall width at their lowest point be less than 22 in.

The locking devices in ambulance bracket supports and on hospital trolleys—that is to say, the locks or stops on the rails against which the wheels of the stretcher rest while it is in the ambulance—are of divers patterns, and fail to act except with a limited range of stretchers.

In place of these mechanical locking devices it is strongly recommended that straps with buckles should be riveted to the angle runners used for holding the stretcher in position, thereby ensuring the complete firmness of the stretcher while in transit. In other words, the lock should be disregarded, and the strap fixed to the ambulance runner, being wrapped round the stretcher handles and joined up. This forms an effective hold irrespective of size of stretcher or runners, and is a simple device universally applicable.

Three sizes are suggested for the steel angles serving as stretcher carriers in ambulances, but the size favoured is the largest of the three: 2 in. in depth and 2½ in. in horizontal projection. A smaller size is more easily obtainable, but does not seem sufficient to obviate the risk of upset on a sudden lurch of the ambulance.

With regard to hospital trolleys to accommodate stretchers it is considered that the manner of support should be by angle brackets attached to the uprights, the width of the brackets (in the longitudinal direction of the trolley) to be 2 in., and their distances apart to be, internally, 44 in. and, externally, 48 in. The width between the inner vertical faces in the transverse direction should be 24 in. and each bracket project horizontally inwards for a distance of at least 2 in. The internal vertical height of each bracket should be not less than 1½ in. or more than 2 in. The top of the longitudinal connecting rails of the trolley should be at least 5 in. below the horizontal face of the bracket which supports the stretcher, and the transverse connecting rails are to form a curve between the brackets, the centre of which is 3½ in. below the horizontal face. A glance at the two drawings in Fig. 2 will make this clear.

In view of the national emergency it is felt to be very important that this equipment should be standardized as soon as possible, and the dimensions given above for stretchers, carriers, and trolleys are those most generally in use. It must be repeated that this is only a draft specification, and the British Standards Institution, whose address is 28, Victoria Street, S.W.1, would be grateful for comments.

A course of six lecture-demonstrations on the first-aid treatment of air raid casualties will be given by members of the honorary medical staff of the Manchester Royal Infirmary in the clinical lecture theatre there, each beginning at 3.30 p.m. on Tuesdays and Fridays, as follows: December 5, Professor H. Platt, fractures of limb bones, and injuries to joints, simple and compound. December 8, Mr. W. R. Douglas, (*a*) shock and resuscitation of shocked patient; (*b*) general first-aid treatment of wounds, burns, etc. December 12, Professor G. Jefferson, head and spinal injuries; Mr. E. Matthews, jaw injuries. December 15, Professor J. Morley, abdominal injuries; Mr. A. Graham Bryce, chest injuries. December 19, Dr. F. R. Ferguson, air raid neuroses and their treatment. December 22, poisoning by mustard gas and other poison gases, with special reference to the treatment of lesions of (*a*) eyes—Dr. J. Wharton; (*b*) skin—Dr. P. B. Mumford.

OUT-PATIENT FACILITIES AT THE LONDON VOLUNTARY HOSPITALS

As some confusion still exists among the general public as to the availability of out-patient facilities at the London hospitals, the King's Fund wishes it to be known that the great majority of the departments are now functioning.

On the outbreak of war it was necessary in many cases to curtail out-patient department activities owing to the movement of part of the medical and nursing staff to hospitals on the outskirts of London. It was, however, possible to keep them open sufficiently to deal with urgent new cases, and since then strenuous efforts have been made to re-establish them on the full pre-war scale. Among the more important hospitals where the majority of the clinics are functioning regularly are the following, comprising thirteen teaching hospitals. thirty general hospitals, and thirty-four special hospitals:

Teaching Hospitals

Charing Cross Hospital; Guy's Hospital; King's College Hospital; London Hospital; Middlesex Hospital; Royal Free Hospital; St. Bartholomew's Hospital; St. George's Hospital; St Mary's Hospital; St. Thomas's Hospital; University College Hospital; Westminster Hospital; West London Hospital.

General Hospitals

West: Acton Hospital; King Edward Memorial Hospital, Ealing.

West Central: London Homoeopathic Hospital.

North-West: Hampstead General Hospital; National Temperance Hospital; St. Andrew's Hospital, Dollis Hill; Willesden General Hospital.

South-West: Battersea General Hospital; Bolingbroke Hospital; Nelson Hospital; Princess Beatrice Hospital; Putney Hospital; Weir Hospital.

South-East: Croydon General Hospital; Dreadnought Hospital; Miller General Hospital; St. John's Hospital, Lewisham; Woolwich War Memorial Hospital.

East: Connaught Hospital; East Ham Memorial Hospital; German Hospital; King George Hospital, Ilford; London Jewish Hospital; Metropolitan Hospital; Mildmay Mission Hospital; Poplar Hospital; Queen Mary's Hospital for the East End; St. Mary's Hospital, Plaistow.

North: Prince of Wales's General Hospital; Royal Northern Hospital.

Special Hospitals

Children: Belgrave Hospital for Children ; Evelina Hospital for Sick Children; Hospital for Sick Children; Invalid and Crippled Children's Hospital ; Princess Elizabeth of York Hospital for Children ; Princess Louise Kensington Hospital for Children ; Queen's Hospital for Children ; Victoria Hospital for Children.

Women: Grosvenor Hospital for Women ; South London Hospital for Women and Children.

Maternity: City of London Maternity Hospital; Mothers' Hospital of the Salvation Army ; Queen Charlotte's Maternity Hospital.

Chest: Hospital for Consumption, Brompton ; London Chest Hospital ; Royal Chest Hospital (branch of Royal Northern Hospital).

Ophthalmic: Central London Ophthalmic Hospital; Royal London Ophthalmic Hospital, Moorfields ; Royal Westminster Ophthalmic Hospital ; Western Ophthalmic Hospital.

Ear, Nose, and Throat: Central London Throat, Nose, and Ear Hospital ; Golden Square Throat, Nose, and Ear Hospital.

Nervous: Maida Vale Hospital for Nervous Diseases ; National Hospital, Queen Square ; West End Hospital for Nervous Diseases.

Other Special Hospitals: All Saints' Hospital ; Hospital for Tropical Diseases (branch of the Dreadnought Hospital) ; Mount Vernon Hospital and Radium Institute ; Royal Cancer Hospital ; Royal National Orthopaedic Hospital ; St. John's Hospital for Diseases of the Skin ; St. Mark's Hospital ; St. Paul's Hospital ; St. Peter's Hospital for Stone.

King Edward's Hospital Fund (10, Old Jewry, E.C.2) is shortly to issue a new edition of its Out-patient Time-table giving the latest information on when clinics are open. This will be sent to all the 8,000 doctors within the King's Fund area (eleven miles from St. Paul's). Pending the receipt of this time-table, any doctor who cares to telephone the Emergency Bed Service will be given the information he requires.

STANDARDS FOR PROLACTIN AND FOR THE GONADOTROPHIC SUBSTANCE OF PREGNANT MARES' SERUM

It was stated in our issue of May 13, 1939, that the third International Conference on the Standardization of Hormones, held at Geneva in 1938, had decided that international standards should be established for certain hormones of the anterior lobe of the pituitary gland and analogous substances found in urine and serum, and that international units should be defined in terms of a weight of each such standard. It was further decided that the final preparation of these standards, their dispensing in a form suitable for the use of the laboratory worker, their storage, preservation, and subsequent distribution should be undertaken by the National Institute for Medical Research, Hampstead, London. The first of these new standards, as announced earlier in the year—namely, that for the gonadotrophic substance of human urine of pregnancy (chorionic gonadotrophin)—was established in May of this year.

We are now asked to announce that the preparation of two additional international standards has been completed—namely, for the gonadotrophic substance of pregnant mares' serum and for the lactogenic (crop-gland stimulating) substance of the anterior lobe of the pituitary gland. The former standard has been prepared from substantial amounts of material generously provided by five manufacturing firms in four different countries, and the latter from material supplied by seven manufacturing firms and two research institutes in five countries. In the case of each standard the individual samples were examined by members of the conference and a suitable mixture was then made to serve as the respective international standard, and finally dispensed in the form of tablets which have been packed in sealed tubes. In the case of each standard each tablet contains approximately 100 international units.

Dispensing and Distribution

The international standard for the gonadotrophic substance of pregnant mares' serum is dispensed in the form of 25-milligramme tablets, each sealed tube containing ten of the tablets, and the international unit has been defined as the specific gonadotrophic activity contained in 0.25 milligramme of the standard preparation. The international standard for prolactin is dispensed in the form of 10-milligramme tablets, each sealed tube containing ten of the tablets, and the international unit has been defined as the specific activity contained in 0.1 milligramme of the standard preparation.

As in the case of the international standards for other hormones, drugs, and vitamins, the above international standards are held, on behalf of the Health Organization of the League of Nations, at the National Institute for Medical Research, Hampstead, and are distributed therefrom to national control centres established in other countries for local distribution to laboratories, institutes, and research workers; and to workers in other countries in which the establishment of national control centres has not yet been completed.

With regard to the supply of these new standards to those requiring them in the United Kingdom, applications should be made to the Department of Biological Standards, the National Institute for Medical Research, Hampstead, N.W.3.

Reports of Societies

TREATMENT OF WAR FRACTURES BY THE CLOSED METHOD

At a meeting of the Section of Surgery of the Royal Society of Medicine on November 22, Mr. V. Zachary Cope presiding, Dr. J. Trueta of Barcelona read a paper on the treatment of war fractures by the closed method. The paper is printed in this week's issue of the *Journal* at page 1073.

In calling for discussion on the paper the President described Dr. Trueta's contribution as a momentous one, bidding fair to revolutionize one of the most difficult problems that faced surgery, especially during war. One of Dr. Trueta's remarks linked itself in his mind with a finding by Lord Lister. Dr. Trueta had said that the limit of time which might be allowed to elapse between the production of the wound and the operation if infection of the wound was to be avoided was from four to eight hours. In Lister's original paper on the treatment of compound open wounds and fractures he stated that if after six hours the antiseptic treatment were applied it was not uniformly successful in its effect; if applied before that time its effect was more certain.

Dr. A. D. Wall, who had recently returned from China, said that in the war which enveloped Shanghai in 1937 he tried out the plaster immobilization method which Dr. Trueta had used in Spain, and obtained exactly the same quality of results. He could confirm everything that Dr. Trueta had said about that method. With regard to the contention that it might not work on the soil of France in view of the greater possibility of gas gangrene, there was no more heavily manured soil than that of the Yangtze delta on which Shanghai stood. Although not much gas gangrene had been experienced in the hostilities around Shanghai, there had been cases, especially in what he described as the gunshot wounds of civil practice—that is, conflicts between police and gangsters.

Dr. Leonard Colebrook said that in considering Dr. Trueta's most interesting work he could not help wondering whether one of the essential pieces of evidence had not been omitted. At all events he had been disappointed not to learn whether in actual fact haemolytic streptococci were present in the wounds which were encased in plaster. A great deal had been said about gas gangrene, but in the great war the haemolytic streptococcus was a far more important enemy than the gas-gangrene organism. He thought it was true to say, although it was not generally recognized, that 80 or 90 per cent. of all open wounds in the British base hospitals in the last war were infected by haemolytic streptococci, and an enormous number of deaths were due to such infection. It would therefore be of interest to learn whether these organisms were present in the Spanish cases which had been treated under plaster. He thought it was the experience of the last war that if the haemolytic streptococcus was not present the wounds could take care of themselves, whether sutured or not sutured. If, on the other hand, the haemolytic streptococcus was present many troubles occurred, such as cellulitis and septicaemia, and not infrequently death resulted. (Dr. Trueta interposed to say that in the 1,073 cases referred to in his paper there had been six deaths from septicaemia.) Dr. Colebrook added that he had gathered from Dr. Trueta's book that when failures occurred they were due to deficient drainage. He wondered whether these were actually cases in which there were haemolytic streptococci. But apparently little pathological investigation had been done in Spain.

Dr. Trueta replied that in the cases at his clinic all types of the streptococcus and all types of the staphylococcus had been found. He believed that it was only the character of the treatment carried out which prevented complications. It had been noticed that when the plaster was changed a slight rise of temperature, some pain and local infection occurred, lasting for one or two days. The immobilization of the soft tissues together with the antiseptic treatment was the reason why the complications were so few.

Dr. C. A. R. SCHULENBERG referred to the disagreeable smell caused by the saturation of the plaster with the discharges of the wound. This might seem a small disadvantage, but it had to be remembered that, whereas the doctor saw the patient only for a few moments, his fellow patients and the nursing staff were continually in his proximity, and, having to endure the smell day and night, became rebellious, so that the plaster had to be changed prematurely. He wondered whether Dr. Trueta had tried any local measures of combating the smell, and if so with what result.

Dr. TRUETA said that in a certain number of cases yeast obtained from breweries was employed locally on the wound, and when this was done the smell was not so pronounced. A certain smell did remain, but it was less disagreeable, the local fermentation of the yeast requiring the products of disintegration of the tissues, so that a cleaner wound resulted. The technique did not interfere with the excellence of the result in other respects. It had been employed in only a few cases, however, because the problem in the latter part of the Spanish war was to obtain the yeast.

Mr. G. GORDON-TAYLOR paid a tribute to Dr. Trueta's paper, which was novel and might almost be said to be iconoclastic. But methods of surgery changed, and what had been brought forward that day was eloquent proof of the methods which Professor Trueta had championed. It might be that in the days to come these methods of excision and immobilization in plaster would prove to have been the methods of election in the war which began in 1939.

Mr. W. C. GISSANE said that he had followed this treatment in dealing with civilian injuries. On changing the plaster in those patients who had sustained gross muscular and bone injury it was extremely difficult to hold the original reduction of the fracture. If it was held by traction he found that the fragments became distracted. Had any method of overcoming that difficulty been found?

Dr. TRUETA said that the necessity for changing the plaster generally depended on the bad smell, and if there were means of ameliorating the smell it should be possible to retain the first plaster to the end. In the absence of any clinical necessity for a change the first plaster was retained longer than subsequent ones, generally for six weeks. But sometimes it was desirable to change the plaster after ten or twelve days in order to obtain a better reduction than had been possible, owing to the danger of severe infection, in the first instance. This reduction should always take place under *x*-ray control.

Finally, in reply to a question by Lieutenant-Colonel D. C. MONRO, who asked whether any idea could be given as to the weight of the plaster used by a surgical team in the average day, Dr. TRUETA said that the difficulty was to give an average day in the Spanish war. On March 17, 1936, for example, at his own hospital 200 plaster cases were dealt with in the twenty-four hours. Perhaps on a busy day as much as 600 lb. or 700 lb. of plaster might be used.

FOOTGEAR AND COMMON SENSE

In his presidential address to the Section of Physical Medicine of the Royal Society of Medicine on November 17 Dr. JAMES MENNELL took the subject of footgear, dealing only with the normal foot. He announced that the subject of foot hygiene is to be a general theme of the Section meetings during the year, and that foot abnormalities will be considered on the next occasion. His demonstration was assisted by a lady model and accompanied by an assemblage of an extraordinary number of types of shoes.

Dr. Mennell began by referring to the very general ignorance on this subject. On one occasion he was present at a meeting of medical men when footgear was discussed, and yet although those attending were accustomed to prescribe for the feet, a question revealed the fact that they did not know what was meant by "size" as the term was specifically used by shoemakers. Dr. Mennell was informed that the problem of clothing the feet in the case of the evacuated children was proving to be far more difficult than that of clothing their bodies, and this was not remarkable because as a last resort one could wrap their bodies in newspaper with something underneath, but no material as amenable as paper had yet been discovered for the feet.

Scientifically the human foot with its marvels of design did not include one pattern for men and another for women. Indeed, the only bone in the foot which could be distinguished anatomically as belonging to a male or to a female was the astragalus, and even there a micrometer screw was necessary to detect the difference. There should in practice be no difference between shoes for the two sexes; if there was a difference it was because we were the slaves of fashion and of the shoemaker. Yet in the ladies' department of a boot shop would be found relatively high heels and pointed toes, and in the gentlemen's relatively low heels and square toes. For children there was a reversion to the low-heeled, square-toed build of shoe, but of a somewhat different type.

The Sole of the Shoe

Dealing first with the sole of the shoe, Dr. Mennell said that there would be few to deny that the general contour of any shoe, to be accurate, should be roughly triangular as seen from above, the angle of the heel being somewhat rounded. The variation in shape in manufactured shoes could easily be tested by placing a straight line from the centre of the heel to the toe of the shoe, running along the middle of the waist. In the normal foot this line usually passed through the space between the second and the middle toes, but in many shoes the design was such that this line passed much too obliquely on the one side or the other, which meant that there must be a forcible strain on the joints of the fore part of the foot, tending to swing it away from the side which had the pressure. He illustrated from commercial examples how very varied was the line on which shoes were built. Another point often forgotten was that the measurement of the foot standing as well as sitting was essential in estimating the length of shoe required. The laws of physics applied to the fitting of a shoe as much as to other matters. When the sole was lifted from the ground it assumed a curve, and to accommodate the foot for standing and for walking it was necessary to allow two shoe "sizes" beyond the limit of the actual foot measurement. What happened to the front of the shoe once this essential space had been safeguarded was a matter of indifference. It was immaterial to what degree the further pointing of the toe took place. Any shape was permissible provided always that the inner side of the shoe did not begin to slope towards the point until the front of the big toe was reached. There should be no quarrel between the human foot and the pointed toe if that condition was fulfilled. The important thing was where the sloping towards the point began. Shoemakers often sloped away too early, with the result that on one side there was compression of the hallux while on the other there was no room for the little toe to slide forward.

High Heels

Turning to the vexed problem of the high heel, Dr. Mennell said that there was but one consideration on which the solution of this problem depended. The point in question was the elasticity of the calf muscles. When the head of the first metatarsal was separated from the internal malleolus and the distance between them increased, strain was caused on the flexor longus hallucis, and the victim had hallux rigidus. It was the tension here which probably set off the train of impulses that led to the increase of the formation of the arc on standing when propulsive effort was required. The high heel—certainly up to 2¼ in.—was not of necessity to be condemned, whereas the low heel of 1/2 to 3/4 in. on the men's side might be as baneful for some men as a heel of 3 in. or more for some women. There were many men who would never walk in comfort with less than a 2¼-in. heel, and many women who would never walk in comfort—at least without some very special form of footgear—unless they had only a half-inch heel or no heel at all, particularly those who suffered from hallux rigidus. The low heel might be most pernicious even for a man. Pseudo-intermittent claudication arose from one cause only—the wearing of too low a heel. He did not want to be taken as an advocate of the extravagantly high heel, and he could not honestly say that any human foot, unless extraordinarily abnormal, required a heel of more than 3 in. in height. The sufficiency of the tendo Achillis alone should control this problem, and on this depended that of the flexor longus hallucis. He demonstrated the technique of the wedging of a heel, and added that the wedging of a sole was fallacious unless all hope of restoring mobility was abandoned. A final word on this subject was with regard to the set of the heel, and here he criticized the custom of being measured for a fitting while seated in a shop chair. The fact was ignored that when weight came on the foot the foot would shoot forward for at least one "size," perhaps for one and a half "sizes." This slip forward was overlooked, and no allowance was made for the two shoe "sizes" beyond the actual foot measurement, with consequent cramping.

The "Upper"

With regard to the "upper," he said that reliance should not be placed on the length measurement given on the boxes in the ladies' department. If a "5" shoe was requested it was as likely as not to be found on measurement to be a "7." In men's shoes there was less disparity in this respect. The shape of the upper varied greatly according to different lasts. He emphasized the importance of depth under the toe-cap and over the outside. It was customary to slope the front part of the shoe down gradually over a considerable distance, but if this were done it must reduce the amount of room available in the fore part, over the big toe. It was necessary to have something to keep the heel back in the heel of the shoe. This position must be properly controlled by straps, laces, or other contrivances. Two straps, preferably buckles, were the minimum; one strap would not serve. In children especially it was necessary to have a definite grip to prevent the foot from slipping forward into the front of the shoe, which was just as bad as wearing a shoe that was too short. The placing of a pad of felt underneath the tongue of the shoe should reduce materially the whole instep measurement and so enable walking to take place with freedom without the foot running forward into the front part of the shoe. Inequality of length of the two feet was another problem, and it was often difficult to persuade boot shops to sell a pair of shoes having different sizes for the right and the left.

Dr. Mennell concluded by saying that, save in the case of the victims of some congenital abnormality or gross disease or injury, a painless or perfect foot should be regarded as the human heritage. Of this heritage we had been deprived by our footgear and nothing else, and that was a reflection on the lack of co-operation between shoe manufacturers and the medical profession. The extent of the evil could be gauged by the thriving businesses of the chiropodists, much of whose work should not be necessary if people were properly shod. Our foolishness in subjecting the marvellous mechanism of the human foot to the tyranny of fashion caused intense suffering, was fatal to the maintenance of correct posture, and was a fruitful source of irritability and bad temper.

At the October meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland Professor L. ABRAHAMSON read his presidential address on "Pericarditis." He dealt with a series of twenty-four cases, treated in the Richmond and Whitworth Hospitals. Thirteen of the cases were clearly and ten were probably of rheumatic origin. Four were tuberculous, one septic; one, associated with anaemia, enlargement of the liver and spleen, remained obscure in spite of necropsy. In ten cases the condition followed pregnancy in patients with antecedent rheumatic heart disease and was probably due to hydropericardium rather than to a fresh attack of rheumatic infection. In the remaining case there was a congestive hydropericardium. Post-mortem examination had been carried out in seven cases, and in each was confirmatory.

Local News

SOUTH AFRICA

Medical Research in South Africa

The report of the South African Institute for Medical Research, Johannesburg, for the year to December 31, 1938, was prepared by the late Sir Spencer Lister, who was Director of the Institute from 1926 until his sudden death in the library there last September. It contains a further account of the investigation into the aetiology and therapeutics of pulmonary diseases in South Africa, including a note on the benefits resulting from prophylactic inoculation against pneumonia in cases which are later treated with 2-(*p*-amino-benzene-sulphonamido)-pyridine, confirming the work of Fleming in London. An unduly high disease incidence and death rate in one district variously ascribed to pneumonia and heat stroke proved on investigation to be due to African relapsing fever. The outbreak was terminated by anti-tick and disinfection measures in the compound housing native labourers, and no fresh cases occurred subsequently. This was the first recorded instance of an extensive outbreak of this infection in South Africa, only occasional sporadic cases having been reported previously. Research was continued into the anti-scorbutic value of kaffir beer, which ought to be regarded, the report states, as a food rather than as an alcoholic drink, since it contains appreciable quantities of anti-scorbutic and other vitamins which are absent from the native diet. It is urged that until present customs have altered, the standard of agriculture has been improved, and other protective foodstuffs have been made available and popularized, kaffir beer should be accepted as, on the whole, a beneficial form of food for the rural population. No one special factor has been detected to explain the frequent occurrence of primary liver cancer in natives of the South African Union and the Portuguese Colonies. Some reason was found for the assumption that in the majority of cases of spontaneous human cancer malignancy was preceded by a definite pre-cancer stage, the diagnosis of which might be difficult, the worst cases being those in which such a stage was absent. The pre-cancer stage was thought to indicate an attempt to combat the cancer-producing factor, and it seemed that with a greater tissue liability to cancer or a more powerful cancerogenic influence went a shorter and less pronounced pre-cancerous period. In the majority of "industrial cancers" there was a longer pre-cancerous period, especially when there was no constitutional or hereditary factor. Work was continued at the Institute on the entomology of malaria, and it was indicated that the half-mile drainage control area was inadequate in South Africa. A survey was started of plague-bearing fleas, and it is pointed out that too little interest has been previously taken in insects of medical significance in South Africa—a country in which the major diseases are insect-borne.

AUSTRALIA

Rural Hospital Management in Victoria

The 28th annual report of the Victorian Bush Nursing Association reveals the great variety of medical institutional work which was carried on successfully in 1938–9 in the State of Victoria, comprising local as well as district nursing relief, and including work in hospitals as well as among isolated communities in the bush regions. The Bush Nursing Association is essentially a co-operative concern, each centre managing its own affairs; in the case of the bush nursing hospitals the visiting medical practitioners are *ex officio* members of the committee of management, the function of the central council being limited to providing the staff and to calling the attention of the local committee to any circumstances which seem to require investigation. The Bush Nursing Association does not ask any district to adopt its system nor does it publish any propaganda, but gives its support when a wish to form a centre is expressed by the local residents and medical practitioners, all such centres being independent and self-supporting. There are in existence fifty-one hospitals, while three more are being built and organized. There are nineteen bush nursing centres also. The central council remarks that few city dwellers realize the desire of people of independent mind to provide in their own districts modern and well-equipped hospitals, owned and managed by themselves, staffed by their own doctors and by the best nurses in the State, and provided at very low rates. Hospital extensions are often found necessary after their first building by reason of the enthusiasm which results; some have had some financial difficulties in carrying on, but in most cases they are all paying their way without help from outside. Had the co-operative system of nursing in the bush not been developed originally, it is doubtful whether the system could have been transferred later to the rural hospital centres. The local inhabitants regard their subscriptions as a form of insurance; one hospital closed its doors five years ago to non-subscribers and is thoroughly satisfied with the result, so much so that a second hospital has followed this example. A few hospitals have been forced to close by shortage of medical practitioners; if more practitioners were available the number of hospitals could be much increased. Bush nursing hospitals may not be established within twenty miles of the nearest city. A fundamental feature of these hospitals is that they take cognizance of persons before they become definitely ill. The rate charged for care in hospital depends on the number of subscribers; if there are 100 to 150 subscribers the charge can be lowered to about £2 a week, and if there are enough subscribers it falls to 10s. a week. Non-subscribers are charged full business rates of £5 5s. or more. The council's report adds that the association is not to be considered as a charity but as a co-operative movement, the public hospitals remaining available for those in necessitous circumstances, but it is open for anyone to secure the admission of such cases to a bush nursing hospital by paying for them.

ENGLAND AND WALES

Bristol's New Red Cross Centre

On November 18 Queen Mary paid a surprise visit to Bristol to open the British Red Cross Society's new Bristol headquarters and Regional Hospital Supply Depot in Lewin's Mead. During a tour of inspection her Majesty showed keen interest in the various branches of the work of the depot and spent a considerable time in the workshop and in the hospital library. Among those who received Queen Mary at the entrance to the centre were Professor J. A. Nixon and Dr. L. E. Claremont; and Dr. R. H. Parry, medical officer of health for Bristol, with other leading workers, was presented to her by the Lord Mayor, who in a speech of welcome referred to her Majesty's interest in the work of the British Red Cross Society. An explanation of the activities being carried out at the centre was given by the County Director, Alderman F. Sheppard. Working parties, he said, had been formed throughout the five neighbouring counties, where ladies gave their services. "Another branch of the service which is doing a very fine work indeed is the V.A.D. and the Red Cross detachments. The total personnel in Bristol is ninety-four men and 382 women. Work in this connexion has been carried on in peace times, and therefore a large number of fully trained personnel is available to undertake duties with the Forces or for home service. The Red Cross, too, is working in connexion with the authorities in training men and women for casualty and anti-gas duties. An A.R.P. Reserve of 370 men and 900 women has already been trained, and more volunteers are still required. Over 2,000 volunteers, in addition, have been trained for the casualty services." The Regional Supply Officer (Lady Wraxall) said that the Bristol Centre was formed primarily to co-ordinate the work of the British Red Cross Society, the Order of St. John of Jerusalem, and the women's voluntary services. At the opening ceremony her Majesty named the centre "Queen Mary House."

Cost of Croydon Typhoid Epidemic

The Croydon Borough Council is applying to the Ministry of Health for sanction to borrow £92,169 for the purpose of meeting expenses in connexion with the typhoid outbreak of 1937. The number of claims settled up to the present is 260, of which 28 are in respect of fatal cases. The loan is intended to include the sum of £4,768, being damages and plaintiff's taxed costs in the case of Read *v.* Croydon Corporation. In this case, which was taken as a test, Mr. Alfred Read of South Croydon brought a claim on behalf of his daughter, who became ill during the epidemic. After a nine-days hearing the child was awarded £100 damages and the father was awarded agreed out-of-pocket expenses. Mr. Justice Stable held that the duty of the Corporation was statutory and that there was not a contract between them and the ratepayer; further, that the obligation to provide pure water to the occupant of a dwelling-house was not absolute but was an obligation to exercise all reasonable care and skill to secure its purity, and this duty the Corporation had not performed. The damages and costs paid in other cases amount to £87,401, and this will be covered, together with the Read damages, by the sum it is proposed to borrow. From a statement issued by the Finance Committee of the Corporation it appears that the costs of the public inquiry, which was held in December, 1937, and January, 1938, amounted to £7,728. This sum, together with the Corporation's costs in the lawsuit, amounting to £5,055, other legal costs to the amount of £1,096, and costs for convalescent treatment and sundry expenses amounting to £460, have been charged to the general rate and the waterworks revenue accounts. Recently it was proposed by the Metropolitan Water Board to seek power to acquire the Croydon water undertaking, but now, in view of the altered conditions brought about by the war, the Board has decided that the negotiations for the transfer shall be suspended *sine die.*

Low Death Rates in Sheffield

The health of Sheffield, as shown in the annual report of its medical officer, Dr. John Rennie, is improving rapidly. The general death rate and the infant and maternal mortality rates were all lower in 1938 than for England and Wales as a whole. Up to the end of the last war the mortality rates of Sheffield were always above the national average; since 1921 the position has been reversed. The mortality from infectious diseases, apart from diphtheria, was low, and even for diphtheria the rate was lower than for England and Wales. Deaths from infantile diarrhoea and enteritis were only 1.96 per 1,000 births, as compared with a national rate of 5.5, the mortality being lower in Sheffield than in any other of the large towns except Bristol and Plymouth. Influenza, too, took a relatively small toll in Sheffield last year, only four of the large towns of England having a better record, and even cancer mortality over a series of years has been almost consistently lower in Sheffield than the national figures. The mortality from tuberculosis in 1938 was the lowest ever recorded in the city. The death rate of 581 per million is not much more than half what it was ten years ago; only one other among the eighteen large towns has a lower figure—namely, Croydon, and Croydon is hardly to be ranked with the great industrial centres. Tuberculosis mortality among grinders and cutlers, who at the last census numbered some 8,000, is, however, several times higher than among the general population. Sheffield is proud of its low infant mortality—50 per 1,000 births, as compared with 53 for the whole country. Only fifteen years ago this rate was 90 in Sheffield, as compared with a national rate of 69. The two outstanding problems in Sheffield are slum clearance and smoke abatement. A large part of the report deals with the considerable work of the city council on slum clearance and the rehousing of the people. But the pall of smoke remains as thick as ever over the city; at one collecting station the amount of solid matter deposited during 1938 was equal to 369 tons per square mile.

Correspondence

Treatment of Gas Gangrene

Sir,—Dr. Ivens-Knowles ends her valuable letter (November 25, p. 1058) on gas gangrene with (1) a "strong protest" against Dr. Trueta's plaster-of-Paris treatment and (2) a brief crack at the Thomas bed splint. Her criticisms should be directed not to the method or the splint but to their faulty use! Indeed, it cannot be too widely recognized and clearly understood that neither Trueta's method nor Thomas's splint is fool-proof. Advocacy of a special technique only too often means that it is widely applied but imperfectly understood. It will be disastrous if Tom, Dick, and Harry apply closed plaster to war wounds, but not in Trueta's way! So, too, have many patients suffered miseries from the ring of a Thomas splint improperly used. Yet Thomas devised his splint *in order to avoid* any constriction, and Trueta is equally insistent on the fundamental principle of ensuring unrestricted circulation in the part. Trueta's plaster supplies to the naked deep tissues of the saucerized wound that support which is ordinarily given by deep fascia and intermuscular fascial planes—a polite and gentle pressure, nothing more.

The proof of the physiological character of this degree of circumferential support is provided by the restoration of the natural colour, activity, and comfort of the hand or foot, with the disappearance of any pre-existing oedema. The patient soon shows in his expression that he appreciates this restful and comfortable support of his wounded soft tissues. The ensurance of free circulation to the enclosed part is the paradox of the true Trueta method—*you shut it up to set it free!*—I am, etc.,

Headington, Oxford, Nov. 26. G. R. Girdlestone.

Psychological Casualties in War

Sir,—In your issue of November 4 (p. 925) you kindly inserted a letter from me calling attention to the fact that men were being enlisted who were likely to have a nervous breakdown early in their military career. There have been four letters published—two in your contemporary's and two in your own *Journal*. I have received twenty letters, and I have had several conversations with doctors in a position to know the facts. I have also heard of some old patients of my own whose laboriously acquired stability has been broken down by a few weeks of service. I think therefore that there is a problem. A chairman of a board wrote to the *Lancet* to ask if I could tell him how to recognize these patients in a few minutes. I do not think that anyone could tell him how to do that. He says that examiner No. 1 has six and a half minutes to test the vision, to examine the nervous system, and to take a complete medical history. As there were still eighteen and a half minutes left distributed among other members of the board for the rest of the body I feel that No. 1 has a grievance.

It is not always easy to get a good psychiatric history in a single interview no matter how long it is. Your genuine neurotic is not always a person who is expansive at the first interview. He is not always a person who will buttonhole all and sundry about his health. There are such, but there are also many who are ashamed of their neurosis, who will try to conceal it, who will not own up till they really get to know the doctor. This kind will certainly not tell their troubles to a board. The difficulty should, however, be got over without much trouble. Every person in this country has a doctor. It would be very easy to arrange that every recruit should bring a short note from him. This would say that the person was never ill, or that he was always falling ill, or something in between. The doctor who has had someone on his list for years might surely be trusted in this matter. He is the one person who really knows the history. Unfortunately the patient whose case stimulated me to begin this correspondence brought such a report from his doctor, but it was ignored; and I have been told of others. The admission of unsuitable persons is not, however, merely a question of the neuroses. In a hospital which I visited lately there are patients returned from France with grave organic diseases such as general paralysis and disseminated sclerosis, in addition to several cases of severe neuroses and even psychoses. It is true that these were reservists who had been called up, and therefore the responsibility does not rest with the boards. It would seem that the investigation into these cases also had not been searching enough.

As a practical attempt to meet these difficulties I would make three proposals. (1) Real histories could be got without difficulty. (2) It might be a good thing if hospital physicians were chairmen of the boards. There are many of these in cold storage. From their long experience in out-patients they have acquired special facility in spotting quickly the people who are likely to have something wrong, the people who should be set aside for further consideration. (3) For some of these a specialist assessor should be available—psychiatrist, aurist, neurologist.

I should like to call special attention to Dr. Culpin's letter, which shows conclusively what a large proportion of patients who broke down might have been spotted beforehand had a psychiatric specialist been available. I think that the same would hold good for early physical cases.—I am, etc.,

London, S.W.1, Nov. 27. T. A. Ross.

Psychological Treatment Centres

Sir,—The polemics of your correspondent Dr. Allan Macdougall, in your issue of November 18 (p. 1020), resemble Hitlerian propaganda. The assertions made are so roundly extravagant as to stupefy opposition; the more so as they contain sometimes an ingredient of fact. In my previous letter I refrained from setting forth the principal arguments for believing that mental illness in general was probably less during the last war than in peace time, as to do so would have meant exceeding the permissible limits of a letter; but the Nestor of English psychiatry, Dr. Weatherly, in your columns of November 18, has stated some of the reasons very succinctly from his own observation; and these will do as an example.

There is little evidence for Dr. Macdougall's contention that "a very large proportion of the psychic [*sic*] casualties of the last war, both civilian and Service, did not become notifiable until some years after the war." Had this been true there should have been as part of the evidence a notable advance in the annual rate of increase in admissions to mental hospitals in the years following the last war, but there was no such advance. Moreover, those who examined Service patients remaining in mental hospitals after the war usually concluded that they would sooner or later have been admitted there even without a war. Nor is it "axiomatic" that any period of great national stress produces more psychoses and neuroses. There is a well-known observation of Bonhoeffer's on 6,000 Serbian prisoners in the last war, who had been subjected to greater and more prolonged privation and hardship than almost any other body of people in those years, that while physical debility and deterioration were very pronounced mental disease was almost unknown among them. As for any considerable post-war increase in psychoneuroses, the only figures available of a general kind are those of Dr. J. L. Halliday (published in your columns). They do not refer to the immediate post-war period, and their significance depends on peace-time factors. I am happy, however, to find myself in agreement on one point—namely, that the change from war to peace may be more devastating to some individuals than a change in the reverse direction; for peace presents problems often more complicated and to some natures more distasteful than those of war. But it is not war itself that produces such conditions. They are not the consequences but, at most, the sequels of war.

I repeat that a wide advertising of the supposed inevitability of increase in mental and nervous breakdown from war conditions among the civilian population does more harm than good. On the precedent of the last war it does not correspond to the facts, although we must never forget that the civilian population is likely to be subjected to dangers far exceeding those of 1914–18. It is not the great dangers of life, shared in common, that mainly produce mental illness. It is far more often the private and sometimes petty distresses that are effective in this way, and then it is the psychoneurotic rather than the psychotic type that is engendered. Nevertheless, few people are neurotic in the face of inevitable death; many become so from disappointments in their careers or in unhappy marriages. No psychiatrist will agree that "any of us is capable of being psychotic." Predisposition, not necessarily inherited, is of fundamental importance in most cases. Dr. Macdougall exhorts us to "think of confinement in a mediaeval dungeon." I am not sure why, but may I quote a clinical observation of Oliver Goldsmith's in this connexion:

"I remember to have once seen a slave in a fortification in Flanders who appeared no way touched with his situation. He was maimed, deformed, and chained; obliged to toil from the appearance of day till nightfall, and condemned to this for life; yet, with all these circumstances of apparent wretchedness, he sang, would have danced but that he wanted a leg, and appeared the merriest, happiest man of all the garrison. What a practical philosopher was here! A happy constitution supplied philosophy, and though seemingly destitute of wisdom, he was really wise."—I am, etc.,

Nov. 24. R. D. GILLESPIE.

SIR,—Sir Farquhar Buzzard, at the special clinical and scientific meeting of the British Medical Association (April, 1919), reviewing the medical experience of the last war, called attention to the fact that

> "the large numbers of victims of functional nervous disorders resulting from the war . . . *had stimulated an intelligent interest in the question not only in the medical but in the public mind* [my italics], and it had forced a Government Department to take cognizance of its existence and to make provision for adequate treatment. . . . The war had taught us that when recognized in their earliest stages these disorders were easily cured—but not by tonics. The fatigue factor must be met by rest, the anxiety factor by psychotherapy. . . . There was no adequate provision for the treatment of patients suffering from these disorders who had limited means. They haunted our hospitals and our consulting rooms crying for help which we were powerless to give. . . . Sooner or later the provision of treatment for such persons must be undertaken by the voluntary hospitals or the Ministry of Health. . . . The Ministry would have two duties in relation to this problem—preventive and remedial."

Such conclusive testimony amply supports my plea (*Journal*, October 7, p. 743) and the axiom of Dr. Allan A. Macdougall (November 18, p. 1020); it should also resolve the doubts of Dr. R. D. Gillespie (November 4, p. 926), who had never heard of any data which purported to show a rise in psychoneurotic and minor psychotic illness during the years 1914–18, and feared a national hypochondriasis from the public becoming too interested in their mental health.

Hypochondria cannot be created here or now because already, as our philosopher Berkeley observed as far back as the seventeenth century, "hypochondria *is* the melancholy complexion of us islanders." Sir Farquhar Buzzard warned us in 1919, and Sir Walter Langdon-Brown, another Regius Professor, in 1939 (October 14, p. 783). Are we to wait another twenty years for "psychological treatment centres"?—I am, etc.,

London, E.17, Nov. 17. A. C. D. TELFER.

Anaesthesia in War Time

SIR,—At the risk of being thought reactionary may I put in a plea for the use of chloroform as the anaesthetic of choice for emergencies. It requires no elaborate apparatus and can be used in any kind of climate and for patients of any age. Induction is easy and not unpleasant to the patient, and is not followed by so much nausea and sickness as ether; moreover it does not have an irritating effect on the lungs.

As regards toxicity, are the number of fatalities from anaesthetics less than they used to be when the present complicated apparatuses were undreamt of? In my humble opinion too much reliance is now placed on the various mechanical aids to anaesthesia. Is the student taught to rely on the patient's colour, state of the pupil, lid and conjunctival reflexes, respiration, and pulse? If he does so then there is no more danger in chloroform than in any other anaesthetic.

I was brought up on A.C.E. and ether, and when a resident was fond of giving ether with a Clover. On going to India I found that chloroform given with a Junker was the universal anaesthetic. Ether is unsuitable in the Punjab in the hot weather owing to its rapid volatilization; also rubber articles perish very rapidly in the dry heat. I may say that during twenty-five years' service and many thousands of operations I have seen only two deaths from chloroform. One was delayed chloroform poisoning in a young girl who had been under anaesthesia for three hours and died the next day; the other was sudden heart failure in a young boy before the operation had started. I am quite sure that other I.M.S. officers will bear out my statement that chloroform is both an efficient and a safe anaesthetic.

During the last war in a field ambulance, a hospital ship, and in base hospitals, in which I was surgical specialist, we used nothing but chloroform. In the hospital ship and the base hospitals the Vernon Harcourt apparatus was employed, but in the field the Junker apparatus was used. It is so simple and takes up so little room that I do not see why it should not be generally employed. If any stimulation seems to be required, a little ether on a mask can always be given.

The only cases in my civil hospitals which were not anaesthetized with chloroform were those of rectal trouble, piles, fistulae, and so forth, in which spinal anaesthesia was used so as to obtain full relaxation of the sphincter ani.—I am, etc.,

H. C. KEATES,
Lieutenant-Colonel I.M.S. (ret.).

Streatham Park, S.W.16, Nov. 26.

SIR,—In reply to Dr. W. Hamilton's letter (November 25, p. 1058) with regard to statistics of deaths under anaesthetics, we do not yet appear to have arrived at any method of recording mortality figures that is not fallacious, chiefly because the figures are small and the recording is made with varying degrees of accuracy. The skill and experience of the anaesthetist, the methods of administration that were employed, the condition of the patient, the nature of the operation, and how long the anaesthesia lasted are only a few of the details required that are often not mentioned but which are necessary if we are to discover the actual cause of death and be able to classify it. The patient's state of health and the technique employed are most important in drawing conclusions on the actual part played by this or that anaesthetic before attributing a death to its employment. A study of books on anaesthesia reveals much repetition of statements and opinions, and both chloroform and ether, especially the former, have been too much condemned on insufficient premises.—I am, etc.,

Edinburgh, Nov. 25. G. D. G.

X-ray Examination of Militiamen

SIR,—The letters of Dr. A. Robinson Thomas (November 4, p. 928) and of Dr. L. Banszky (November 18, p. 1020) call for a reply, since they give a misleading view of the argument I intended to bring forward in my letter in the *Journal* of October 7 (p. 745). Let me therefore state emphatically that I believe radiological examination of the chest of militiamen to be indispensable. Our allies, the French, have practised routine radiological examination in the Army for several years, and it has been adopted in Belgium, Switzerland, and Germany. The world literature on the findings of routine radiological examinations of the apparently healthy (including students, nurses, industrial employees, and whole communities in America, Scandinavia, Holland, etc.) is now extensive. But both the personnel and the technique (including apparatus) must be such that we obtain the most benefit from the procedure—detection of unsuspected cases of active phthisis—and also avoid harm from it by labelling healthy recruits as tuberculous.

Everyone will agree that a radiograph obtained with a first-class apparatus is the best technique available. Whether screening is as satisfactory (apart from the fact that it does not provide a permanent record) will depend on the type of apparatus, the experience of the examiner, his adequate adaptation to darkness, the time at his disposal, the type of material (for example, thin women or very muscular men), and the duration of each screening session. (Holm in Denmark, in a reliable comparative study undertaken several years ago, found that the occasional case missed by screening and detected by means of a radiograph was always a student screened towards the end of a session when the examiner was getting tired.) Screening has the advantage in that the interpreter faces the patient and can if necessary put questions that may help in a doubtful case. Miniature screen photography enables a very small photograph of the screened image to be obtained which can be examined at leisure with a magnifying lens or be thrown on a screen. Much time is saved at the moment of *x*-raying, but it is difficult to see how the negative can improve on the actual screened image; indeed, the help obtained from studying the movements of the diaphragm and the relative lighting up of the apices on inspiration is lost.

Granted that routine radiography, with further investigation of suspicious cases, is the most reliable method available, the cost per person, including film, personnel, etc., works out, I believe, at a little over 5s., but no doubt in dealing with very large numbers the cost could be reduced.

As regards who should interpret the films or do the screening, I still maintain that the best person is a tuberculosis physician with the necessary radiological experience or a radiologist with special experience in chest radiology.

The large numbers of patients who have been and are still being sent to sanatoria because of misinterpretation of apical shadows, normal hilar shadows, heavy lung markings, healed primary complexes, often in radiographs of very poor quality, give ample support to the view that availability, choice, or training (if necessary) of personnel is a matter that should at any rate be considered before we insist that the military authorities adopt a method that may result in our being hoisted by our own petard.—I am, etc.,

Staines, Nov. 19. G. Gregory Kayne.

Sir,—I should like to join in your discussion about the *x*-ray examination of militiamen.

First let me tell a story. A short while ago a child of 15 months died in Redhill County Hospital of miliary tuberculosis, and last week the other members of its household were brought by one of my health visitors to the clinic for examination. They were all screened, and one was found to have an azygos vein lobe, and another, a young man of 21, was found to have two large cavities in the left lung with commencing infiltration in the right lung. These observations were confirmed by *x*-ray film. The young man had recently been before an Army medical board, having passed Grade 1, fit for military service anywhere. Whether he had the physical signs of disease I do not know, but it is certain that his condition was overlooked, and should he have at length joined the Army he would have infected many of his fellow soldiers, some of whom would have died of the disease and some become pensioners.

The moral of the story is that ordinary examination failed to demonstrate what was obvious on the screen at a glance, and it seems to me very wrong that the Army doctors are not allowed the facilities of this method of examination. It may be that if only screening is used a few lightly infected cases will slip by unobserved, though, for myself, I think one gains more information by screening than by filming, the only disadvantage being that one has no permanent record; at all events the heavily infected and infectious cases, such as that described above, will be found. And the method is so practical; twenty-five men can be readily screened in an hour, and should any abnormality be detected a film is soon taken. It is the method adopted by the military authorities in French Colonial Africa, who, using a mobile *x*-ray set, screen all the recruits and film the doubtful ones.

No great expense need be involved: the medical board would have to move from its present rooms to the local hospital, and that is about all.—I am, etc.,

A. Stephen Hall,
Tuberculosis Officer.

Redhill County Hospital, Edgware,
Nov. 21.

The Treatment of Peptic Ulceration

Sir,—For the past twenty years I have not hesitated to express the opinion that the essential principle in the "medical" treatment of peptic ulcer is complete uncompromising confinement to bed for three to four weeks, and that severe dietetic restriction or drug therapy plays an insignificant or negligible part. Whether confinement to bed contributed to healing through physical inactivity (or even posture) or on the nervous side through seclusion from responsibilities and other psychical disturbances, or through both factors, was not perhaps a necessary decision. But I entertained a suspicion that the success of several forms of dietetic treatment, though widely differing, might be due to one factor they had in common—the protracted rest, a state often inevitable through the elaborateness of the details which must in addition have a high suggestive value.

It must be admitted—and the weakness will be condoned—that a physician to a teaching hospital is in duty bound to represent to his students that this is not the orthodox practice and to indicate to them the views held in general by eminent colleagues regarding the role of acidity in the genesis and aggravation of a peptic ulcer and the necessity to administer alkalis for its possible continuous neutralization. But control observations of patients treated solely by rest and a relatively bland diet have persuaded me that the results were at least as satisfactory as in those submitted to the orthodox elaborate regime—results judged by the complete amelioration of symptoms and subsequent radiographic examination.

It is naturally a considerable satisfaction to me to learn from the article by Dr. James Ronald in the *Journal* of November 25 (p. 1033) that he has found it impossible to correlate the variations in acid level with the symptoms and signs of ulcer; that improvement occurred whether the acidity was diminished, unaltered, or increased; that no distinction could be drawn on clinical grounds between cases in which hyperchlorhydria was or was not altered during treatment; and that, in fact, healing could take place although the hyperchlorhydria actually increased. We are entitled, therefore, to deduce from his investigations support for the belief that there is no justification for indicting acidity as the villain in the piece, and to assume that there are other factors concerned in the production of peptic ulceration, with the encouragement to divert our interest from the local lesion, upon which attention has necessarily been fixed through the exhortations to deal with the acid as the essential factor. It may be that the orthodox ground so long established will not be abandoned without a struggle, but there can be no doubt that there has for some time been a growing tendency among experienced practitioners of an inquiring and sceptical turn of mind towards this revision of treatment. And I for one cannot refrain from endorsing on purely clinical lines the conclusions derived from Dr. Ronald's more scientific investigations.—I am, etc.,

London, W.1, Nov. 25. Adolphe Abrahams.

Sources of Vitamins A and D

Sir,—In May this year Miss Anne Wilbraham and I published under the title *The Englishman's Food* a historical survey of the changes in the character of the English diet during five centuries and of the influence which these had on the health of the people. In discussing rickets we had to deal with the important part played by vitamin D, and we naturally made reference to the remarkable developments which had been brought about by the discovery of the high-potency oils, such as halibut-liver oil, and by the production of concentrated preparations. Exception has been taken to some of the statements we made in this section of the book by Mr. K. MacLennan, general manager of British

Cod Liver Oil Producers (Hull) Ltd., and as some of the points raised in correspondence between us were also mentioned in a letter from him which appeared in your issue of July 29 (p. 264) it seems appropriate that a reply should appear in the same place.

On one point his objection was certainly well founded. We stated on page 180 that "halibut-liver oil has almost displaced cod-liver oil as a means of giving vitamins A and D." At the time this was written it was my belief that such was the case. I had been led to form that opinion by consideration of the remarkable rise in the consumption of halibut-liver oil in this and other countries—a production hardly existed six years ago, yet last year something like 4,500 gallons were consumed in this country alone—by an equally impressive rise in the use of concentrates of A and D, many of them prepared from high-potency oils of the type of halibut-liver oil, by evidence that ever-increasing quantities of high-grade cod-liver oil produced in this country were used for poultry and animal feeding either here or in the U.S.A., and by the strong impression I had formed from conversations with medical men and chemists that the popularity of substitutes for cod-liver oil was growing rapidly.

What I did not then know was that a volume of oil of medicinal quality estimated by various experts at from 1,000 to 2,000 tons a year in Great Britain is still employed for human use. It would, therefore, have been more correct to have stated that halibut-liver oil and other high-potency materials have raised a serious challenge to cod-liver oil during the last few years. How serious the challenge is can be appreciated from the fact that the annual consumption of halibut-liver oil alone—leaving out of account entirely the large production of proprietary preparations rich in A and D—represents between one-half and one-third of the vitamin A and between one-quarter and one-sixth of the vitamin D contained in the annual consumption of cod-liver oil.

Exception was also taken to our giving the range of potencies of cod- and halibut-liver oils as 50–200 I.U. and 1,000–4,000 I.U. of vitamin D respectively, on the grounds that these figures understated the case for cod-liver oil and overstated that for halibut-liver oil. I have had a wide experience of testing liver oils for vitamin D potency, and I stand by those figures. I do not deny that exceptional oils are encountered from time to time, and that by selection of fish—coal fish is an example—or by judicious blending or fortification liver oils of higher D potency than the figures I have given may be obtained. What I maintain is that for authentic liver oils of the two species the figures I have given are representative.

I have also been called to task for expressing the view that a small volume of halibut-liver oil—or, for that matter, any other high-potency A and D material—will provide all that a much larger dose of cod-liver oil will supply. The statement was made in the discussion of human rickets in our book, but I am prepared to defend it in a much wider connexion.

The calories supplied by the fat in the doses of fish-liver oil taken medicinally are of no significance under conditions such as prevail to-day in Great Britain. It is another matter when starvation is rife. For this reason I had no hesitation in recommending the International Relief Commission which operated in Spain during the recent civil war to purchase cod-liver oil in preference to concentrates of A and D. At such times every calorie counts.

There was at one time a theory that the fatty acids of cod-liver oil have some peculiar nutritive virtues. It was thought that their highly unsaturated character made them more readily absorbed and assimilated than the fatty acids of the commoner edible oils and fats. This theory never had substantial foundation, and it is now entirely discredited. Even before controlled investigations had shown that the common saturated fatty acids are absorbed and oxidized in the tissues as readily as the unsaturated ones, the supporters of the "fatty acid" theory of the efficacy of cod-liver oil had been routed by the disastrous results which followed an attempt to replace cod-liver oil by the highly unsaturated linseed oil in infant feeding. Curiously enough, the fish-liver oils are actually deficient in the recognized "essential fatty acids." In only one respect do the fatty acids of cod-liver oil show peculiar properties, and that is that under certain conditions they appear to exert a curious toxic action leading to forms of muscular degeneration. There is a considerable and growing literature on this interesting subject, but it is not easy at the moment to get all the evidence into perspective.

Finally, I am of opinion that little or no importance can be attached, in discussing the nutritive value of the fish-liver oils, to the small amounts of iodine which all of them seem to contain. Many years ago an "iodine" theory of the physiological action of cod-liver oil was popular, but it, like the "fatty acid" theory, died of inanition.—I am, etc.,

J. C. Drummond.

Virtues of Brown Bread

Sir,—I was particularly interested in the letter in the *Journal* of November 18 (p. 1022) from my old school-fellow and colleague Dr. Geoffrey Taylor regarding the virtues of brown bread. It contains more than a "germ" of wisdom that those responsible for national health might well encourage, and contrasts strongly with a dispatch from France that appeared in the lay press telling of troops clamouring for white bread and of the pathetic efforts to obtain "fine quality white flour." What misplaced energy to obtain an artificial and anaemic product denuded of its natural vitamin by excessive milling! Even without great military activity, the present war has already demonstrated the great nervous tension to which the community is likely to be subjected, and it would be a wise provision to encourage the production and consumption of flour in which the health-giving properties of the natural vitamin B had been retained.

In view of the campaign for national fitness and the recent work on nutrition, would it not be possible for the B.M.A. to take a lead in this matter and persuade His Majesty's Government of the importance of preserving intact the essential factors in wheat flour instead of allowing persistent wastage through excessive milling and whitening?—I am, etc.,

London, W.2, Nov. 20. R. Cove-Smith, M.B.

Sir,—Professor Geoffrey Taylor (*Journal*, November 18, p. 1022) once again champions the virtues of brown bread over white bread on the ground of the vitamin B content of the former and its absence from the latter. Professor Taylor, however, overlooks the psychological factor that to modern taste modern white bread is far more palatable, and usually more digestible, than the brown bread as purveyed by modern bakeries.

There is the recognition among all engaged in the bakery trade that the conditions required for making very attractive brown bread differ greatly from those in use for making white bread. They are, therefore, not prepared to arrange for incurring extra expense for a portion of the community who are not prepared to pay a higher price for their loaf of brown bread. It is better to eat good white bread and obtain the vitamin B from other sources than to eat a brown bread which is unpalatable or less digestible. I would point out two excellent methods of obtaining vitamin B and at the same time preventing the curse of habitual constipation. The first is to take frumenty as a porridge two or three times a week. The second is to give your baker a few pounds of freshly crushed white wheat and instruct him to incorporate a quarter of a pound into the dough when making up each 3-lb. loaf. I should be happy to send a specimen of this attractive bread to any doctor who would like to test it.—I am, etc.,

London, W.1, Nov. 21. Josiah Oldfield.

Sir,—Dr. Geoffrey Taylor is quite right about the "virtues of brown bread," and if the Government would put a tax on white flour and let the wholemeal flour go free of tax we should not have so many anaemic and constipated children, nor have to go to the chemist to buy wheat-germ to cure complaints they ought never to have had. The bread is more nourishing and sweeter.—I am, etc.,

Bassingham, Lincoln, Nov. 24. OSBORNE JOHNSON.

Radium Treatment of Cancer

SIR,—It is reported that Sir Leonard Hill, in a paper which he read at the Royal Society of Arts on November 23, severely criticized the use of radium in the treatment of cancer, and this reminds me that in a pamphlet which was published in 1936 by Messrs. H. K. Lewis I wrote in reference to "cancer treatment by irradiations":

> "It is now established that many toxic effects may result from the use of these rays, that morbid changes may ensue, and that the lymphoid tissues and endocrine glands may be seriously affected."
>
> "It is obvious that irradiations will destroy an easily accessible growth, and so would many other physical and chemical agents, and, of course, simple surgical measures could not possibly produce any direct constitutional ill results."
>
> "As regards deeply seated growths, the use of radium or x rays, whatever the technique employed, seems to be not only useless but dangerous."
>
> "If we concede that radiations have a selective influence upon cancer cells, and if we further allow that they can be used so as not to injure overlying or surrounding parts, can we even then conceive that they will destroy not only the centrally situated cancer cells, but those spreading in all directions from the main mass? And, furthermore, can we conceive that their toxic constitutional effects will not occur or even that the peripheral cells may not be stimulated to more rapid growth?"
>
> "I have seen radium inserted into an inoperable cancerous growth . . . but the outlying parts have seemed to grow more rapidly. . . ."
>
> "I believe that this x-ray and radium treatment is unsound, unscientific, and dangerous, and that it will be totally abandoned within a few years."

—I am, etc.,

Cardiff, Nov. 24. W. MITCHELL STEVENS.

Viruses and Cancer

SIR,—In the leading article on the above subject in your issue of November 11 (p. 959) relative to Dr. C. H. Andrewes's presidential address it is stated that "any doubts of the specificity of some of the immune reactions observed would seriously imperil the conclusions which have been drawn from existing facts." Elsewhere (*Journal*, March 26, 1938, p. 698) I have expressed very considerable doubts in this regard; but it is with another aspect of the same subject which has been raised in Dr. Andrewes's address that I propose to deal here.

If the results of the immunity reactions, the carrying out of which has been undertaken by the virus-advocates in the attempt to demonstrate the existence of a causative virus in tumours, have any logical meaning, they must mean that, so far as the virus-upholders are concerned, for each and every individual case of the hundreds of possible types of tumour there exists a separate specific causative virus. What this implies in terms of Dr. Andrewes's hypothesis I refrain from discussing, largely because of a lack of desire to treat as serious the bewildering, ever-increasing tangle of makeshifts that has been and is being piled up to support a theory—that of virus causation—which has long since been shown to be quite inadequate.—I am, etc.,

Aberdeen, Nov. 18. J. P. McGOWAN.

Melted Wax in Therapeutics

SIR,—I endorse the opinions of Dr. E. Scott in your issue of October 28 (p. 885). It is a most efficient method of applying heat. It is eminently suited to general practice work for treatment of arms and legs, as one can have a large bucket of it kept handy. But it is useful for more than treating inflammation. I have used it very much for many of the aches and pains that won't label themselves. For sprains of ankles or hands it is very good to have a bucket full of the wax. I have always heated mine on the ordinary gas stove. When the wax is at the right temperature (my wax melts at 60° C., and I use it at about 65° C.) the hand or foot is quickly plunged in and taken out; when the wax on that has set, but not cooled, it is plunged in again and so on until a thick layer is obtained. Each additional layer adds heat and prevents rapid cooling. So far as heat is concerned, I fail to see the use of leaving it on for more than an hour or so; but it would probably have an effect like elastoplast if left on longer. Knees and elbows can be treated by holding over the bucket and pouring wax over the joints, using a small saucepan. When one layer has set, more is poured over it until a thick layer is obtained. Hips can be treated; so can the whole body. For this I use a sheet of lead placed on a table and folded up at the edges. The patient, with a towel round the buttocks, lies on the sheet of lead; several buckets of wax must be ready at the right temperature; then it is poured on from saucepans until the patient is enclosed in a thick layer. The temperature rises to about 101° F. or so and there is profuse sweating. The wax is always removed very easily, as it does not stick to the skin. All wax removed is used again. For hands and ankles the process is simplicity itself. The one thing is to plunge the hand or foot in and not let it move about in the wax, for that reheats the wax which has set on the part, and then the heat is severely felt. I have never had a burn. Melted wax is also excellent for cosmetic work, for it produces a very nice skin. I have used it for the face, putting an airway in the mouth. Wax combs out of the hair without trouble.

I hope that others will follow Dr. Scott's suggestion. Would it be too absurd to suggest that it ought to be a good method to use at the front?—I am, etc.,

Kingston Hill, Surrey, Nov. 15. W. F. COOPER.

Personal Hygiene in Syllabuses of Training Colleges

SIR,—May I comment on the letter of Dr. Octavia Lewin in the *Journal* of October 14 (p. 785). In connexion with certain problems of evacuation and the need for education in matters of cleanliness she states: "It is well known that personal hygiene is not on the syllabus of the training colleges." May I say that Dr. Lewin is misinformed to this extent, that hygiene has been a compulsory subject for training college students for many years! It seems to me to follow that matters of personal hygiene must of necessity be discussed with all students in the training colleges, if by personal hygiene Dr. Lewin and myself understand the same thing. I mean by the term the personal habits which maintain and preserve the health of the individual and therefore of the community. In the hygiene courses of the training colleges are discussed the fundamental necessities of health—namely, nutrition, activity, sleep, warmth, cleanliness, and light—and I submit that it is impossible to study these without including and embracing personal hygiene. I state emphatically that personal hygiene, in the sense I give to the term, is studied with seriousness in all training colleges, with enthusiasm in many, and that it is studied realistically and practically.

May I ask Dr. Lewin what prompted her remark? I should like to lay bare the source of the inaccuracy.—I am, etc.,

F. C. CONSITT,
Chairman, Training College Association.
London, W.C.1, Nov. 16.

Bronchography

SIR,—It is not a little surprising that in his paper on bronchography in your issue of November 11 (p. 950) Mr. Glass should have omitted reference to the most popular method of introducing radio-opaque oil into the bronchi—namely, by means of syringe and needle, using the crico-thyroid route. Apart from its being less unpleasant to the patient, this method presents certain definite advantages over his: (*a*) the technique is less difficult of accomplishment; (*b*) it is more applicable to children, who object less to the needle than to throat manipulations; and (*c*) the preliminary anaesthetization requires only about one-tenth of the time. This last consideration is of importance when it is necessary to perform several bronchographies in one session.

While I am in complete agreement with Mr. Glass in his summary dismissal of the bronchoscopic introduction of iodized oil, I do not agree that bronchoscopy should in most cases precede bronchography. Careful bronchography sometimes renders bronchoscopy unnecessary; hence bronchography, the lesser procedure, should always be performed first.

The positions described by Mr. Glass as suitable for filling the various lobes leave rather more to chance than is desirable. Posturing based on gravity and the anatomical distribution of the bronchi, as described in the *Lancet* (1936, **1**, 1236), facilitates the filling of individual lobes and eliminates the necessity for fluoroscopic control, which must in any case be a matter of great difficulty in some of the positions advocated by Mr. Glass.

In conclusion I would point out that oleum iodisatum is now a pharmacopoeial preparation in Great Britain, containing 40 per cent. of iodine in poppy-seed oil.—I am, etc.,

The Liverpool Sanatorium, Frodsham, Nov. 21. G. S. ERWIN.

Spasmodic Flat-foot

SIR,—In his article in the *Journal* of September 16 (p. 602) Mr. Alan H. Todd described spasmodic flat-foot as a distinct clinical entity, though he acknowledges it has not a pathology all its own. Why not, then, let it be classed as one of the accompaniments of flat-foot, early or late?—in my experience, more often the latter. Perhaps our adolescents in Australia are sturdier and do not go to arduous work so early in life as in London.

I quite agree with him that division or exsection of the peroneus longus is useless; I would say criminal. I have never seen a case that did not clear up with rest and care, in severe old cases with wrenching as well. The peroneus longus is one of the most useful muscles of the foot, and the French school of orthopaedics considered it the most important. On two points I would venture to disagree with Mr. Todd. From time to time I am a martyr to cramp in my feet and can only obtain ease by stretching the affected muscles. The second point is the use of inner wedged heel and sole. I know it is a very common practice, but none the less it is absolutely wrong mechanically. The foot is so constructed that the weight should be borne by the talus, calcaneus, navicular, and cuneiforms, most of it being transmitted to the first digit. As Humphrey the anatomist wrote many years ago, "Man stands in the animal kingdom literally on his big toe." All through that wonderful monograph *The Human Foot*, by T. S. Ellis, the same theme is delightfully maintained. This I also endeavoured to show by sections through the tarsal bones (*Deformities of the Foot*, Walsham and Kent Hughes, Chapter I). The lateral portion of the cuboid is purely cancellous and the medial portion contains but few longitudinal striae, whereas they are more numerous and stronger as we pass from the third to the first cuneiform. Any treatment, then, which tends to throw the weight of the body on to the lateral border of the foot is bad tactics. It is much better to raise the waist of the sole by a leather arch beneath the insole, its thickness and height being adjusted to the case in point. I have used this for nearly fifty years.

As regards the causation of the spasm, we are on an uncharted sea. We have disturbances in the mechanism of the foot, the earliest of which is often a slight but definite flattening of the dorsum lateral to the head of the talus and a dropping of the heads of the metatarsal bones. The peroneus brevis is generally involved with the peroneus longus. Could this flattening pull on the sheath common to both peronei, or can the irritation arise from pressure on the calcaneo-cuboid joint and thus cause the spasm? Spasm is as a rule the result of irritation from inflammation, and it might be suggested that by walking with the foot everted the distal insertion of the peroneus longus would be subjected to irritation. This would not apply to the peroneus brevis and does not occur in the tibialis posticus, the insertion of which into the talo-navicular ligament is certainly often subjected to much more irritation.

Mr. Todd in his article mentions the weak foot. What is it that makes some feet liable to flat-foot? In my opinion it is mainly due to diminution of dorsal flexion, which occurs in about 20 per cent. of people, leaving out the wearers of high heels. Ever since Schaefer wrote his article on non-deforming club-foot I have been keenly interested in the occurrence of a short tendo calcaneus, and was amazed to discover its frequency. We seldom see a very severe flat-foot without a shortened tendo calcaneus, and I find it almost universally present in people who sprain their ankles and knees. It is seldom noted before 7 years of age, when an awkward gait or swollen ankle draws somebody's attention and advice is sought. It is easily removed by stretching exercises up to 15 years of age and even later. While on the subject of a contracted tendo calcaneus, if an operation of lengthening be required might I suggest that this is best obtained by cutting away the insertion from the bone. I have never seen a weak tendon or wasting of muscle follow this procedure during the last twenty years.

As regards priority of mention of spasmodic flat-foot, may I quote from the book I wrote with Mr. Walsham in 1895 (p. 424): "The peronei are in advanced cases tense, either from spasm or from adaptive shortening. The tendo Achillis is in some instances shortened, as are also the dorsal flexor muscles." On pages 438-9, under the heading of "Spastic or Spasmodic Flat-foot," a fairly accurate description is given of early adolescent and advanced cases. My late collaborator ascribed it as due to spastic paraplegia, and stated at the end of the paragraph that he had not met with a severe rigid case in adults. I wrote the article on pathological anatomy of acquired flat-foot, but I was not responsible either for the statement as to spastic paraplegia or for the "we" in the last sentence. Collaboration is always difficult, and especially so when, as in this case, the two authors were 13,000 miles apart for the last two years.—I am, etc.,

Melbourne, Nov. 6. W. KENT HUGHES.

Streptococci of Scarlet Fever

SIR,—I notice in your annotation of November 11 (p. 960) on the streptococci of scarlet fever you refer to the fact that scarlet fever follows the invasion not of one strain only but of several groups of haemolytic streptococci. You ask if it would not be logical to group all forms of streptococcal invasion under a comprehensive title. I should like to know whether there is any experimental proof that mutation of the various strains of haemolytic streptococci does take place.

For some years I have been resident in Kunming, a city in South-West China, and have been interested in epidemiological matters. A survey undertaken by the Research Council of the Chinese Medical Association, of which I was a member, during 1933 and 1934 amassed a great deal of information about the incidence of disease in China. *Inter alia* it was shown that scarlet fever was endemic in most of the provinces (Gear, H. S., *Chinese med. J.*, 1937, **51**, 203). Curiously enough, during the two-year period of the survey no special epidemic of the disease was encountered. Thus in 1933 the total number of cases in sixteen areas where scarlet fever occurred was 208 out of 181,800 patients seen, and in 1934 it was 121 out of 218,000 patients seen. From 1926 to 1938 in Kunming the number of cases seen has been small compared to the total registered out-patients—twenty to twenty-five out of 16,000 to 18,000 per annum.

This year the city was grossly overcrowded owing to the effects of the war, and there occurred the first real epidemic of scarlet fever I have known there. It began in March and reached its peak in May. It was estimated that there were over 5,000 cases. In former years cases had been mild in type, somewhat like present-day scarlet fever in England, but now the disease was of the septic type with a somewhat high mortality. During the course of the epidemic there was a sharp rise in the number of cases of erysipelas. Normally these would average about one a month, but in April and May

I myself diagnosed about fifteen cases, and there were others. Two were of infants, and were associated with streptococcal infection of the mothers; the remainder were in adults over the age of 40. In no instance was a second case found in the same household, but it was evident that the disease was epidemic. To complete the picture of a general invasion of a population by haemolytic streptococci, there was a coincidental epidemic of streptococcal sore throat with a number of cases of quinsy. One sufferer from the latter complaint, himself a bacteriologist, went down with a typical and severe scarlet fever three weeks later.

I merely record the occurrence of epidemics of three different groups of haemolytic streptococci concurrently. The reaction to treatment by sulphonamide preparations was specific to each group. All cases of erysipelas recovered, including two patients who when first seen were desperately ill. Not only was a favourable response to adequate dosage prompter than in the other two groups, but the length of time of treatment was the shortest. Ordinary streptococcal epidemic sore throat responded well to treatment, though in some cases it was three or four days before there was marked improvement. Response to sulphonamide treatment in scarlet fever cases was less dramatic, and there was considerable variation. It rarely shortened the duration of the disease, but patients seemed easier with it. On the other hand, several untreated patients seen in the second week of the disease who were almost comatose showed dramatic improvement. This varying response to chemotherapy merely corroborates the known specificity of each strain of haemolytic streptococcus, but the problem of the genesis of each remains for solution.—I am, etc.,

London, E.2, Nov. 24. ALEXANDER J. WATSON, M.D.

Cancer and Pernicious Anaemia

SIR,—It was refreshing to read Dr. E. F. Hunt's letter in the *Journal* of November 25 (p. 1062) advancing the plea that investigation of the cancer problem should be directed along the lines of deficiency disease instead of prolonging the sterile search for some unknown virus or organism.

It is many years since Richard Cabot drew attention to the fact that both cancer and pernicious anaemia tended to occur in people of the same age period, and in a letter in the *Journal* I suggested as a corollary to this that cancer might indeed be also a deficiency disease. Acting on this theory I have given to many cancer cases, mostly of the inoperable and apparently hopeless type, liver both by mouth and intramuscularly, but unfortunately without any success. It would have been surprising if this therapy had been successful and in a way accidental, but I still think that it is on such lines that success will ultimately come; only it will not come without research, and that is why one would support Dr. Hunt's plea for an intensive inquiry.—I am, etc.,

W. LEES TEMPLETON.

London, N.6, Nov. 26.

Black-out and Ventilation

SIR,—I had visions of making a small fortune by patenting my solution of the combined problem of ventilation and eye-strain, but I don't know how to proceed, so, lest the war is over before others can benefit, let me present it to the profession.

The urgency of bedroom ventilation, with freedom to use my bed-light, was the original stimulus, and the "Thomson ventilating light-trap" evolved and simplified itself till it became three bits of wood, the actual blind or curtain being a matter of choice or of material available.

The trap I like best is in my sitting-room with a high bow-window; it has been passed by the authorities with three unscreened 100-watt lamps ablaze in the room, while I have free ventilation through the window open to two and a half feet from the top. Actually I used five pieces of wood in this trap. The amount of free ventilation depends on the size, and the size depends on the two end-pieces, which are rectangular, slotted diagonally from one corner to centre, and fixed by hinges to the sash (Fig. 1). Into the grooves fits a piece of ply-wood (Fig. 2) as wide as the distance between the end-pieces and as deep as half their diameter. Laths, slightly longer than the total width, secure the free corners of the end-pieces and hold the ends of the ply-wood firmly in the grooves (Fig. 3). All the wood, except outside the end-pieces, is painted matt black.

The cheapest way of covering this trap is to mount the blind belonging to the window at A, along the upper lath, have a cord across the window to pull the blind close to sash at B (Fig. 4), and cover the lower part of window, where blind now falls short, with paper or cloth or wood. Or the curtain or blind may be made long enough to fall below the bottom of the window. To avoid a haze of light passing the trap, especially on misty nights, care must be taken that the patch of ceiling immediately above is not directly illuminated.—I am, etc.,

Grimsby, Oct. 16. E. J. THOMSON, M.B., Ch.B.

Administration of A.R.P. Casualty Services

SIR,—With reference to Dr. H. Mainwaring Holt's interesting and informative letter on the administration of A.R.P. casualty services (*Journal*, November 18, p. 1021), it may be of interest to your readers to know that the Halifax A.R.P. casualty services schemes provide for the attendance of doctors at the scene or scenes of disaster. It may be objected that such a provision is not sanctioned in any of the numerous official circulars. Nevertheless I am sure it is well worth the attention of A.R.P. casualty services administrators.—I am, etc.,

GEORGE C. F. ROE,
Medical Officer of Health.

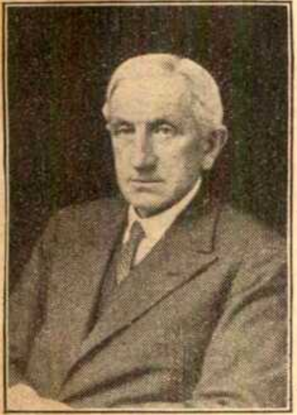
Halifax, Nov. 22.

The E.M.S.

Two letters commending to the profession the plan for reorganizing the Emergency Medical Service, which was announced in our last issue, will be found on the first page of the *Supplement* this week. They are signed by Sir Robert Hutchison, President of the Royal College of Physicians of London, Mr. Hugh Lett, President of the Royal College of Surgeons of England, and Professor W. Fletcher Shaw, President of the Royal College of Obstetricians and Gynaecologists; and by Mr. H. S. Souttar, Chairman of the Central Medical War Committee and of the Council of the British Medical Association.

Obituary

WILFRED TROTTER, M.S., F.R.S., LL.D., M.D., D.Sc., F.R.C.S.



The death of Mr. Wilfred Trotter on November 25 has taken from us an intellect of brilliance outshone in our century by none in medicine, science, and philosophy. Among the losses that we have sustained in medicine in the last decades have been many great men whom we could not afford to lose nor could we truly replace. All had their hosts of admirers, but we believe that neither among these illustrious men nor in the number of their followers may there be found any affronted by the statement or disputing that Trotter had no equal. Our time has given us surgeons, physicians, experimentalists, whose magnificent achievements gave light and leading to those that cared to follow, yet a surgeon who attained the highest in his intensely practical art and who at the same time graduated through medicine to philosophy is among them unique. Philosophy—the love of wisdom and of the knowledge that concerns the most general causes and principles—is commonly approached through early years of more constricted studies, yet the power so attained to contemplate the abstract and mentally to encompass it may discard the earlier preoccupation with the practical aspects of science. Some philosophers there have been, however, whose early pursuits and whose intellectual progress have instead advanced together, so that the abstract has shared with the concrete the objects of their thought. Such a one was Trotter, and while we confidently assert his claim to the highest seat in surgery, at the same time with diffidence we suggest that the daily contact with the practical, involved in the pursuit of his profession, gave his philosophy also a force and distinction that it might have lacked had he approached it through another education. Who can doubt that had Trotter's delicate youth been followed by a life passed in the contemplative retreat of an ancient university, had his occupation offered no hard problems urgently needing practical solution, not only would surgical advance have been by so much the less, but his philosophy itself would have lacked something of its vigour, its nip of common sense?

The writer has no knowledge of Wilfred Batten Lewis Trotter's birthplace or of his parentage, and little of his later home life. As a boy he had a spinal malady that kept him, so he said, on his back until the age of 16, and after that he was for a short time at University College School. He entered University College in 1891, and passed his M.B. with distinction in medicine in 1896. Later he gained a gold medal and scholarship in the B.S., and of course the higher qualifications and degrees. In the Medical Faculty of University College in those days were a number of luminous intellects, among which, if we are to judge by Trotter's conversation, for him the most powerful influences were those of Victor Horsley and of John Rose Bradford. In such an atmosphere of intellectual clarity he learned his medicine; but we should not forget that in surgery it was of a man of far different type, his chief Arthur Barker, that he ever after spoke in terms of the greatest respect. Horsley was the physiologist, the experimenter, who worked surgical miracles in the cranial cavity, but Barker was the Master. He was the predecessor of the expert technicians of the present day whose pleasure it is to incorporate in their work at the first possible moment the latest advances in theory and procedure, who have at their fingers' ends the surgical progress of the rest of the world and in their minds its literature. Though Trotter never assigned to technique anything but a secondary importance, his fingers were skilful partly because he had learned his art from Barker, who during Trotter's youth brought from abroad so many things now standardized in surgery.

Trotter's own influence on his contemporaries was now growing, and on his immediate juniors was so great as to be formative and exclusive. There are indeed at this present time many men, educated at University College in the first decade of the century, whose minds were formed and polished by Trotter, and in whose conversation his habits of speech may still be heard. Some even may be recognized by their curiously softened and lazy-sounding sibilants.

Nevertheless his progress to the honorary staff of University College Hospital was retarded by the fact that always in front of him was the flashing brilliance of Rupert Bucknall, to whom in those early days he had to give place. He was appointed surgical registrar in 1901, and it is thus true that the century and Trotter's influence dawned together. It is a tradition, which the writer is sorry to say that he has never confirmed or clarified, that at this period Trotter removed a carcinoma of the cervical oesophagus with success. He then demonstrated anatomy for a few years, until in 1906 Horsley's premature resignation permitted his election to the honorary staff as assistant surgeon. He had already been elected to the staff of the East London Hospital for Children, where his new associates proved themselves impressionable, as had been those of his own school, where he made many devoted friends.

Delay in the occurrence of a vacancy in the staff of U.C.H. had probably an important bearing on the future, because then, for the first and maybe for the only time in his life, he had the unfatigued leisure that was necessary for the working of his mind. It was then that he wrote what is perhaps his greatest claim to academic distinction, his two papers published in the *Sociological Review* in 1908 and 1909, on "The Instincts of the Herd," written thus at about the age of 34, when nearly all other aspirants to surgical staffs would be straining to become known by contributions to professional literature.

Now firmly established in his chosen career he began to hold that sway as leader and teacher that he retained with effortless right until his retirement thirty-two years later. Almost at once he betrayed his interest in difficult surgical problems, the same ones mostly that beset the surgeons of to-day, and began to have a reputation for carrying through the removal of malignant growths that had daunted others to inaction. The mouth and pharynx provided some of the unsolved problems of those days, yet in a few years, and with what the chief of a modern Continental clinic would regard as an insignificant number of cases, he established the surgery of malignant disease of the pharynx on a firm basis. His Hunterian Lectures of 1913 are models of clarity in clinical description, and the greater part of his operative recommendations were subsequently proved to be sound. Trotter was nevertheless the last man to belittle any kind of progress, and contemplated with a detached interest the temporary sweeping away of all his oral and pharyngeal work by the various forms of radiotherapy, accepting fully the proposition that if radiotherapy could apparently cure for the time being the far too numerous inoperable cases, might it not do the same for the operable ones? And might not the failures of radium disappear with increasing experience and knowledge? He made no further comment on his own work than to remark that owing to the introduction of radium it had never had a chance. His operations had not become established practice because few people other than his own assistants had ever learnt their underlying principles or their anatomical bases. Time has passed, and who would say to-day with confidence that radiotherapy has anything better to offer to a woman suffering from carcinoma of the hypopharynx than has a lateral pharyngotomy?

From Horsley he caught an interest in the thyroid gland and in thyrotoxicosis, and from his election to the staff until his retirement he operated frequently on cases of Graves's disease. Horsley and he were probably the pioneers in this country of this now popular operation.

He became greatly absorbed in head injuries, and applied his original mind to the elucidation of their pathology. His work on concussion, though not at the present time accepted as a completely satisfactory explanation, has a closer correspondence to the symptomatology than any other supposition so far expressed, and forms part of a larger conception of the mode of production of symptoms in the central nervous system. It was elaborated in a way that was characteristic of Trotter's thought, for he did not begin by making observations on damaged brains himself. He assembled the known main facts, and then from physical laws reconstructed in his mind what *must* happen to the brain in certain circumstances. He then compared the known clinical and pathological consequences with his deductions, and found a close correspondence. These views he expressed in an important article on the scalp, skull, and brain that appeared in Choyce's *System of Surgery*. Since then he has made a number of contributions to the subject of cerebral and spinal injury, both major and minor, among which his paper on subdural haematoma in the *British Journal of Surgery* in 1914 established clearly the nature of the lesion.

Neurological surgery presented another field whence success could sometimes be snatched from a morass of difficulty and confusion, and about this time he carried out with his assistant, Mr. Morriston Davies, and on their own limbs some work on the clinical evidences of peripheral nerve regeneration that has also stood the test of time and is now recognized at its true value in the simplicity and clarity of its conclusions.

So passed the time until the outbreak of war, prior to which, in March, 1914, he had succeeded to the senior staff on the resignation of Mr. Bilton Pollard. It was early in the year 1914 that the present writer began to know him well, having the fortune to become his house-surgeon. As dressers we had regarded him with awe, though we admired with true reverence the perfection of his work. We agreed that he never made a mess of anything, big or small, and that when he was defeated, as he often was, it was because, as he frequently demonstrated, what in fact proved to constitute inoperability was not yet clear to him. It was thus with the patients presenting the syndrome of the malignant nasopharyngeal tumour, described by him and Dr. Wilfred Harris, in which disease he finally came to the conclusion that the existence of his syndrome in a case was an indication of its inoperability, though a far more formidable-looking tumour of the upper jaw or ethmoid might possibly be removed at operation with anatomical perfection.

His teaching of general surgery at this time was a delight to hear; always concerned with principles, he would patiently talk to us and in questions try to get from us response to his stimulus. A flash of his famous lambent wit would usually show that he had failed, but he would then begin again and perhaps again, and he would not leave his subject until a light had dawned in our thick heads that we were being led patiently to some useful and practical conclusion. A thoughtful consideration with a practical deduction was his usual method, and never the one without the other when a patient's welfare was in question. There was no kind of patient whose trust and affection he did not immediately impound, and he would listen to long and irrelevant stories of their often trivial complaints with simple and sympathetic courtesy. It was true that the play of every kind of mind was his favourite study, and though we would sometimes draw the conclusion that from his point of vantage the differences between the clever and the stupid, the malevolent and the helpless, were relatively slight, this was not in fact the whole explanation of his attitude, in which an important factor was his own exquisite sensibility that made him unable to be outwardly discourteous to anyone. Fortunately he had no scruples when the object of his study was out of hearing, and his estimate of this particular example of the human mind was usually forthcoming, delivered with a quiet but impish and by no means strait-laced humour.

During the war he did much important work in London for wounds of the head and spine, and also in response to official pressure found time to republish in book form his two articles on the herd instinct with further newly written chapters dealing partly with the applications of his theorem to the state of war. Some there were who, in the easier comprehension of the newer part, thought it was not the equal of the earlier, but his studies of the herd habits of wolves and his comparison with those of the German nation have an unpleasant truth for us to-day. It is no idle hope that his views on the disruption of the wolf herd as an offensive body when an enemy herd is stronger may once more indicate the essentials of the present situation in Europe. Trotter was rarely wrong.

It was not until 1920 that return to London permitted the present writer to renew his acquaintance. Five years had made a great change. In 1914 he had been the pride of the small circle of our hospital, hardly known elsewhere except in certain professional and intellectual groups. In 1920 he was famous. He was the acknowledged authority on the subjects of malignant disease of the upper respiratory passages, of neurological surgery, and of the thyroid gland. He was the consultant that others would turn to when in doubt and his opinion was widely sought in difficulties of all kinds; he was skimming the cream of London practice, and in U.C.H. he was as near a god as man can be in that candid and critical institution. From now on his pre-eminence was assured in the world of surgery, but it was not his published writings that gave him place—though these were important and unique—it was just himself; and it is probable that many doctors who trusted him implicitly had heard neither of the instincts of the herd nor of lateral pharyngotomy.

Honours came. The Council of the Royal College of Surgeons in 1924; the Royal Society in 1931—a signal honour for a surgeon; Honorary Surgeon to His Majesty the King in 1932 and Serjeant Surgeon thereafter; President of the Association of Surgeons in 1932; the Gold Medal of the Royal Society of Medicine in 1938, and numerous honorary degrees. It is no secret that the Royal Society and the Royal College, of each of which he was vice-president, paid especial heed to his counsel; but unfortunately about this time his health began alarmingly to fail, and one may say that for the rest of his life he preferred to perform only those public functions that he knew were the duty of one of his exceptional gifts. In 1932 he delivered the Hunterian Oration, taking as his subject "The Commemoration of Great Men." In this remarkable lecture he chose the theme that it would be better to help great men during their lives than to commemorate their deaths, and for the rest of his life, and indeed for many years before this, he devoted much of his energies to helping younger men to succeed. The oration was in the best style of his maturity, its penetrating criticisms, its crystal wit, and the polished art of its wording affording his hearers a wondering momentary entry into the working of his mind and the originality and range of his thought. His choice of language on all such occasions, as in private conversation, was appropriate to the keenness of the matter, and, often modelled on the Scriptures, its Biblical simplicity gave him epicurean pleasure.

About this time he took the characteristic step of retiring from his private practice while retaining his appointment at U.C.H. Having toyed with the idea for years, one day he said he would wait no longer, and from then on gave his whole time to his official duties, to his hospital and school. On the retirement of Professor Choyce in 1935 he took over the professorship of surgery and the directorship of the Surgical Unit at U.C.H. In the two years left to him he set himself to train a number of fortunate young men as he would have them trained. He spent his days stimulating their brains and teaching them from his experience, passing hours and hours in the theatre watching them operate and giving counsel. No one was ever more acutely bored by the trivial in surgery, as in everything else, and it was the mark of a great man that Wilfred Trotter should spend his now failing health over what he knew was trivial neither to his patients nor to his assistants.

At the end of 1928 he had with Sir Hugh Rigby earned the national gratitude for his surgical care in bringing his late Majesty King George V through his desperate illness, and though his Royal patient pressed him personally to accept an honour, he characteristically declined this mark of gratitude, preferring to remain one singled out from others by his attainments only.

In this sketch of his professional life claims to a remarkable pre-eminence have been made, and it would not be fitting if no short indication were given of how he did his work. There have been many great surgeons who have each placed themselves at the head of a group of assistants and who have achieved their important results by elaborating technique and by governing the smooth working of what in these days are called their teams. Such men have often stressed their technique as the cause, and the statistical estimations of their results as the justification, of their success. Not so Trotter, who saw in the post-war elaboration of technique the danger that the essentials might be forgotten in devotion to the smooth working of the machine, and in the modern passion for "statistical research" the obliteration of the individual, the neglect of consideration of the extent to which each several sufferer might be benefited by treatment, inestimable in his opinion by any percentage figures.

His method was to do his own personal very best for a few patients, and in his private practice the real care of patients was where the responsibility was, even to the doing of dressings and the removal of stitches, which services he performed himself knowing that no gentler hands were ever given to a surgeon. In operating there was no elaboration of material and hardly a special instrument, so that some have been known to conclude that his technique was poor. In fact nothing was further from the truth. His effortless skill was perfection and needed no apparatus to show it off, his temperature charts the despairing envy of his juniors. A pharyngeal growth would present itself to him in the middle of his wound apparently of its own volition as would a spinal tumour. In his early days he would plate fractures with restoration to an anatomical and functional perfect normal so that we thought then that finality had been reached in fracture management. His secret was that to every case he applied his brains anew, and later, if necessary, a skill so gentle and so great that it sometimes escaped attention.

Reference has been made to Trotter's health, which, never robust, had since 1925 caused anxiety to many in his own circle, more especially as his attitude regarding his personal concerns was one of the closest reserve. It is now breaking no confidence to say that during the closing years of his greatest professional activity and ever after he suffered pain and unending discomfort with an unbroken fortitude that was true to type. Yet as recently as this last summer he kept an engagement to address the students of St. Mary's Hospital, in words that might have been intended for the Royal Society.

In attempting a memoir of a figure of his international, philosophical, and surgical importance the writer feels his inadequacy, but has taken courage from Trotter's own Hunterian Oration—"The commemoration of great men is of less importance than their living recognition." If our time has produced no Bossuet for Trotter, it did not fail to appraise him during his life, for the worth of few men has been more justly estimated during life. So we will end with the thought, not that we have justified the claim of our opening paragraph that he was the greatest surgeon of the century, but that since surgical, philosophical, and intellectual worlds have long recognized its justice, we have our great man's own authority for believing that these hasty sentences are a matter of little importance.

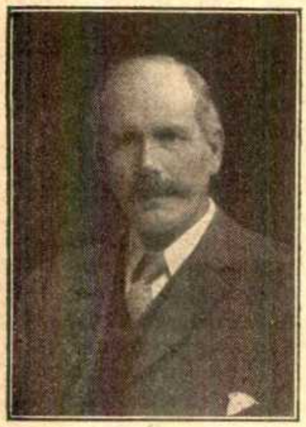
J. T.

[The photograph reproduced is by Russell, London.]

Dr. DAVID EIDDON PARRY died on October 3 after four months of illness at the early age of 28. He received his education at Brecon College and St. Mary's Hospital. In 1936 he obtained the diplomas M.R.C.S., L.R.C.P., and graduated M.B., B.S. He was a fine rugby and cricket player; he was captain of the Brecon College Rugby XV and vice-captain of the cricket team. He was captain of the St. Mary's Rugby XV during its cup-winning season 1936–7. After qualifying he held the post of resident medical officer at the Brighton Fever Hospital and Sanatorium, and last February took up the appointment of assistant medical officer of health for Carmarthenshire, having obtained the D.P.H. in 1938. His sadly premature death is deeply regretted by many professional and athletic colleagues and friends. Dr. Parry was a member of the British Medical Association, and jointly reported on a case of sulphanilamide poisoning which was published in the *British Medical Journal* on September 9, 1939.

C. J. BOND, C.M.G., F.R.C.S.

Consulting Surgeon, Leicester Royal Infirmary



We regret to announce the death on November 23 at his home in Leicester of Mr. Charles John Bond. Born on October 27, 1856, the son of George Bond of Bittesby, Leicestershire, he was educated at Repton School. After a year or so in agriculture he entered as a pupil at the Leicester Royal Infirmary early in 1875, and in October of that year became a medical student at University College, London, where later he served as assistant demonstrator of anatomy and won gold medals in physiology and anatomy and silver medals in surgery, midwifery, and medical jurisprudence. Having qualified in 1879, he went to the Bedford General Infirmary as house-surgeon. He obtained the F.R.C.S.Eng. in 1882, and returned to the Leicester Royal Infirmary as resident house-surgeon; in 1886 he was appointed honorary surgeon. On retiring from the active staff in 1912 he was elected consulting surgeon and a vice-president of the hospital; in the following year he served as vice-chairman of the board of governors, and from 1925 to 1932 as chairman of the drug and medical stores committee. For two years he presided over the Literary and Philosophical Society of Leicester, which made him a life vice-president. He served on the Leicester City Council for two years, and for seven years on the Leicester Health Insurance Committee, and in 1925 received the Freedom of the City. He opened the new operating theatres at the Royal Infirmary in 1929, and to a large audience related experiences of the days before antiseptic surgery. It was he who, with Sir Charles Marriott, had introduced aseptic methods at the hospital. Other offices held by Mr. Bond were those of vice-president of the Leicestershire and Rutland University College, president of the Leicester Medical Society, and vice-chairman of the Medical Consultative Council of the Ministry of Health. He had been a member of the Departmental Committees on the Cause and Prevention of Blindness and on Cancer, and chairman of the Industrial Fatigue Research Council. He was also a member of Lord Trevethin's Committee on the Prevention of Venereal Disease, a past-president of the Society for the Study of Inebriety, and an original member of the Sociological Society and the Eugenics Society. The British Association honoured him with life membership, and he was elected a Fellow of University College, London, in 1924. During the last war he represented the Medical Research Council on the Inter-Allied Commission on the Treatment of War Wounds, which met in Paris; he was consulting surgeon to the Northern Command with the rank of honorary colonel A.M.S., was twice mentioned in dispatches, and created C.M.G. in 1917.

Mr. Bond joined the British Medical Association in 1881, and at the Annual Meeting of 1905 gave the Address in Surgery on "Septic Peritonitis." In 1924 he was vice-president of the Section of Medical Sociology, and president in 1926. He gave the William Withering Lecture before the University of Birmingham in 1932, taking as his subject "Human Biology."

Dr. Astley V. Clarke writes:

The passing of Mr. C. J. Bond at the ripe age of 83 removes from Leicester probably the best known and the most respected citizen of the last half-century. Probably, also, his was the best-known Leicester name of his time in England and beyond its shores.

His life can be regarded in three parts: the beginning as a farmer; the professional life as a medical practitioner and surgeon; and the full scientific life after he retired from active work on the Leicester Royal Infirmary honorary staff. The farmer stage was before my time, as also, of course, the period of his student days, during which he formed a great and lasting friendship with Victor Horsley, but I do remember him being house-surgeon at the Leicester Infirmary in 1882. These were the days of the sudden expansion of the fields of surgery, and Mr. Bond became known as a pioneer of the new aseptic technique. Not only did he become well known for his surgical skill, but in his personal manner towards his patients he endeared himself to everybody. In those days before telephones and motor cars he had many years of intensely hard work; driving and by train, trying to get somehow to the many and distant calls on his professional services, for he covered a large area. In these days, too, the spirit of research in him kept him always investigating and investigating into scientific phenomena.

When the British Medical Association met in Leicester in 1905 he was president of the surgical section and established for himself a fame in surgery far and wide by his presidential address on a subject which he had been able to investigate in connexion with his surgical operations. He always intended to retire from his active practice so that he could have more time to devote to research, and so in 1912 he gave up private practice, continuing only his hospital work for a year or two longer. Then he went to Australia in 1914 and returned to find that England was at war. He offered his services as consulting surgeon and devoted himself immediately to operating on recruits at the Royal Infirmary who had hernia or other recoverable conditions which prevented them from being accepted for service. During the great war he made several visits to France in a consultative surgical capacity, and by his knowledge so acquired he assisted those in Leicester who were doing the military surgery and inspired them in the use of new techniques. He was invited to serve on Lord Dawson's committee which was set up to consider hospital conditions in England and to make suggestions for a model scheme for hospitals and auxiliary hospitals. This brought him in contact with all branches of the profession.

Mr. Bond took a keen and active part in the starting of the University College immediately after the war was over. He was a generous benefactor, but his advice and encouragement to that scheme were of supreme value to it. As a member of the College Council he has continued assiduously in his attendances and has given much time to seeing into the details of the work also. As a city councillor for three years—as an Independent—he gave valuable help in the reforming of the isolation hospital when Alderman Wilford was chairman of the Health Committee; as a scientist of national repute his work in eugenics and heredity has been his chief hobby, and he enhanced his fame by his rearing of cocks and hens to study breeding phenomena. This attracted many scientists to visit him and his breeding houses in his garden in Leicester. In every intellectual sphere in Leicester he was deeply interested and helpful. He played a prominent part when the British Association met here recently. Leicester honoured him and itself when he was made an Honorary Freeman. His kindly disposition endeared him to all, and Leicester mourns his end, for he has been a wise counsellor and a great inspirer for the generations which have only been too ready to learn from him. His full and varied life and accomplishments will for long be a treasured memory, not only by the medical profession but also by the many activities for social betterment of the citizens to which he has been a trusted friend.

Dr. C. Killick Millard writes:

By the death of C. J. Bond the city of Leicester has lost its most distinguished and most beloved citizen. I enjoyed the great privilege of his friendship for very many years. I was associated with him for some years on the Leicester branch of the National Council for Combating Venereal Disease, of which he was chairman and I honorary secretary. We were also associated in a similar relationship on the Leicester Cancer Committee; and for the last five years of his long and useful life we were still more closely associated in connexion with the Voluntary Euthanasia Legalization Society, which we founded together, he being chairman of the executive committee from the outset.

Others will testify to his work as a brilliant operating surgeon, and to his many and important contributions to science; also to his great and practical interest in many forms of public and social work; so in this brief note I will confine myself to a reference to his personal character. Few men can have been more loved and respected by his friends. Utterly unselfish in all that he did, scrupulously conscientious in everything he undertook, he was the very essence of courtesy, kindliness, and consideration for others. The dominant guiding principle of his life was love of his fellow men—how best he could serve humanity—and he devoted himself unsparingly to this object. He possessed true nobility of character to a quite exceptional degree. He carried modesty regarding his own achievements almost to an extreme, and but for this he could doubtless, had he wished it, have occupied an even more prominent position in the scientific world than he did. In spite of his advanced years his mind was keen and alert almost to the very end, and he maintained his interest in the many and varied lines of work in which he had been engaged. But in the later years of his life I think it may be said that one of his chief interests was voluntary euthanasia, and he had the satisfaction of seeing the movement for its legalization, which he had done so much to promote, thoroughly established and meeting with steadily increasing support.

NAUGHTON DUNN, M.A., M.B., LL.D.

Honorary Surgeon, Royal Cripples' Hospital, Birmingham; Surgical Director, Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry; Lecturer in Orthopaedics, University of Birmingham

We regret to announce the death on November 19 at Dolgelly of Mr. Naughton Dunn of Birmingham, one of the most distinguished exponents of orthopaedic surgery in this country and at the time of his death president of the British Orthopaedic Association. Mr. Dunn was a member of the Orthopaedic Group Committee of the British Medical Association, and he had acted as vice-president of the Section of Orthopaedics at the Annual Meeting of the Association in 1925.

Naughton Dunn was born in Aberdeen in 1884 and was educated in the grammar school and university of that city, graduating in medicine in 1909. In 1910 he went to Liverpool to take up the post of house-surgeon to Robert Jones at the Royal Southern Hospital, and soon found that orthopaedics was his true vocation. From the Southern Hospital he went to that famous home of orthopaedics—11, Nelson Street—as one of Robert Jones's private assistants, and during that time acted as assistant demonstrator of anatomy in Liverpool University. In 1913 an opportunity of establishing himself as an orthopaedic surgeon in Birmingham was brought to his notice. On the recommendation of his chief he was appointed surgeon to the Birmingham Cripples' Union, and he left Liverpool well versed in the principles and practice of the school of orthopaedics founded by Hugh Owen Thomas and Robert Jones. The new venture was soon to be interrupted by the war of 1914–18, and for the first two years Naughton Dunn served in the R.A.M.C. in the Eastern Mediterranean. He returned home after a severe attack of dysentery, to find Robert Jones at the head of the Military Orthopaedic Department of the War Office and engaged in establishing an orthopaedic centre at the Shepherd's Bush Hospital, London. Dunn became one of the original members of the staff of this great hospital, and later was transferred to Birmingham to take charge of the military orthopaedic centre there. After the war he used his exceptional training and experience in the development of orthopaedic schemes in the Midlands. He built up a large consulting practice and began to attract as pupils and assistants a succession of young men who found in him the qualities of leadership. His pre-eminence in his specialty led to his appointment by the University of Birmingham as lecturer in orthopaedics. Among the many hospitals which sought his services three became the main objectives of his life work—the Woodlands Hospital in Birmingham, the Warwickshire Orthopaedic Hospital at Coleshill, and, after the death of Sir Robert Jones, the Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry.

Naughton Dunn was one of the original members of the British Orthopaedic Association and for a number of years served on the executive committee, finally becoming president in 1938. He also held the office of president of the Orthopaedic Section of the Royal Society of Medicine, and became a corresponding member of the American, French, and Australian Orthopaedic Associations. The honour which he valued most of all was the degree of LL.D. conferred on him by his own university in 1937. During the years which followed the last war he maintained a steady output of contributions to surgical literature on practical and clinical aspects of orthopaedic surgery. His most notable contribution, which brought him an international reputation, was his work on the operative treatment of paralytic deformities of the foot.

"N. D.," the name by which he was affectionately known to his pupils, was an outstanding personage in the profession of medicine in this country. He had a genius for creating friendships among both his contemporaries and his juniors, and as a host he was unrivalled. His white hair, rugged countenance, and twinkling smile made him a conspicuous figure in all gatherings of orthopaedic surgeons at home and abroad. On first acquaintance he created the impression that he lived only in the present, so leisurely and deliberate were many of his activities. But behind a singularly attractive personality there was a keen and critical mind which enabled him always to see several moves ahead in matters of important policy. His death in the prime of life leaves a gap in the ranks of British orthopaedic surgeons which cannot easily be filled, and he will be affectionately remembered by a great number of colleagues in the United States and the Dominions.

Dame Agnes Hunt, D.B.E., R.R.C., writes from the Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry:

The hospital, training college, and after-care mourn the death of Naughton Dunn, senior surgeon of the hospital and loyal pupil of the late Robert Jones. Very many of the past and present patients of this great hospital have cause to love his name, I among them. Never a strong man, he made light of his ailments; even when the dread disease from which he died had fastened its grim tentacles upon him he still came to minister to us, forgetting his own pain and weakness in order to help us who were not nearly as ill as he was. To Naughton Dunn's love and loyalty to the hospital we owe very much. He never missed an opportunity of speaking well of our scheme and interesting people in the hospital and in the various branches of its work. But perhaps the greatest work he did for crippled humanity was by passing on Robert Jones's teaching to younger orthopaedic surgeons, training them in the work he loved so well.

[The photograph reproduced is by Elliott and Fry, Ltd.]

Dr. F. Hernaman-Johnson (London) writes: I should like to add my tribute to the memory of Dr HENRY AUGUSTUS ELLIS. We were colleagues on the staff of the Margaret Street Hospital for Diseases of the Chest for twenty years. A mutual friend once remarked to me, "None of us was ever as young as Ellis; none of us will ever be as old as Ellis." This was indeed a true saying, for Ellis combined an extraordinary freshness of outlook with the wisdom of an elder statesman. Coming to London when he was nearly 60 he performed the remarkable feat of establishing within a few years a quite considerable consulting practice. His therapeutic methods so far as they applied to the body were original and often successful; but he was also a master in all that pertains to the action of mind on body. He did not confine himself to the usual case history, but induced patients to tell him their intimate thoughts and feelings. I have known many instances in which his sympathy and understanding turned despair into success. Ellis never spared himself, either mentally or physically. His medical friends believe that his experiments on himself with strange drugs laid the foundation of the cardiac weakness to which he ultimately succumbed.

Dr. WALTER GRAHAM REYNOLDS, who died at Chatham on November 16 at the age of 53, was educated at Marlborough College and in Switzerland, and studied medicine at St. Mary's Hospital, qualifying M.R.C.S., L.R.C.P. in 1912. He then held three house appointments in succession at St. Mary's, and after the war worked as clinical assistant at the Samaritan Hospital for Women. In 1921 he went out to China and was appointed visiting surgeon to the Canton Hospital, medical officer to H.B.M. Consul-General, port medical officer for Canton and to the Chinese Maritime Customs and Postal Service. "H. A. B." writes: Dr. Graham Reynolds had been aware for some months that his life could not be of long duration, but with exceptional courage and cheerfulness he had carried on, hiding from all except his intimate friends the knowledge that must have been ever present with him. On the staff of the Canton Hospital he did much good surgical work. His kindly and generous treatment of the various missionaries with whom he came in contact brought him the grateful thanks of the Bishop of Hong Kong when the time came for him to leave the East. He also received the thanks of the Consul-General for his work in connexion with the British Concession. In 1930 he came to Chatham, where he soon established for himself a position of reliability and affection, not only among his own patients but also with his brother practitioners, and was until recently chairman of the local Division of the British Medical Association. Outspoken perhaps, but full of kindliness, he was ever willing to lend a friendly hand to all and sundry, and his integrity was unalloyed. Well may it be said of him, "He loved his fellow men."

Dr. CHARLES JOHN CADDICK died suddenly at Nakuru, Kenya Colony, on November 10, aged 65. He was born in 1874, the second son of Mr. Alfred Caddick of West Bromwich, and educated at Edinburgh University, where he graduated as M.B. and C.M. in 1897, also taking the F.R.C.S.Ed. in 1902, the D.P.H.Cantab. in 1904, and the D.T.M. of the London Colleges in 1920. He served in the South African War of 1899–1902 as surgeon to the Imperial Yeomanry Hospital, and in the war of 1914–18 with the rank of major in the R.A.M.C.T.; and afterwards in the Colonial Medical Service in Kenya. He had also been consulting surgeon to the Walsall General Hospital. He joined the British Medical Association in 1898, over forty years ago.

Universities and Colleges

UNIVERSITY OF OXFORD

At a Congregation held on November 25 the degree of Bachelor of Medicine (B.M.) was conferred on J. N. Macdonald.

UNIVERSITY OF CAMBRIDGE

Committee for Medical Radiology and Electrology

The Faculty Board of Medicine has appointed Dr. G. S. Graham-Smith, Dr. G. H. Orton, Dr. Ff. Roberts, Dr. F. G. Spear, Mr. G. Stead, Mr. R. Williamson, Dr. P. J. Kerley, Dr. W. P. Philip, Dr. Russell J. Reynolds, and Professor Sidney Russ to be members of the Committee for Medical Radiology and Electrology for the year 1940. The report of the Committee for the year 1938–9 has been published in the *University Reporter* of November 21. This recalls that at the end of September, 1938, the university lectureship in physics as applied to medical radiology became vacant by the resignation of Mr. Stead. It was decided not to appoint a new lecturer and to discontinue diploma teaching in Cambridge. As in previous years, courses in physics were given in London at the Middlesex Hospital Medical School and at King's College. Lectures in radiology, electrology, and pathology were given at the British Institute of Radiology, and clinical instruction was provided in the radiological departments of various hospitals.

Medical Examinations in War Time

In Congregation on November 24 it was resolved that students otherwise qualified to present themselves for the first or second part of the Final M.B. Examination in December, 1939, whose evidence of medical and surgical practice with clinical instruction falls short by not more than three months of that required by Regulation 30 (*e*) or 32 (*a*) for the M.B., B.Ch. degrees, may nevertheless present themselves for that examination if their candidature shall have been approved by the Faculty Board of Medicine. (The Faculty Board will satisfy themselves that candidates who seek this temporary concession have been prevented from completing the last three months of their clinical instruction by circumstances arising from the war and for no other reason.) It was further resolved that students other than those covered by the above provision who wish to present themselves for the first or second part of the Final M.B. during the present academical year, but are unable to produce all the evidence required by Regulation 30 or 32, may nevertheless present themselves for examination if their candidature shall have been approved by the Faculty Board, provided that they shall not be allowed to proceed to those degrees until they have produced the evidence required by those regulations. (Certain candidates may have difficulty in obtaining such facilities for instruction and practice as would justify their being granted the necessary certificates, although sufficient instruction to justify their candidature may be available. The Faculty Board have undertaken to satisfy themselves that candidates who seek this concession have been prevented from obtaining the necessary evidence by circumstances arising from the war and for no other reason.) In accordance with a further recommendation of the Faculty Board, a student may be allowed to take both parts of the Final M.B. in his eighteenth term, inclusive (not exclusive) of his first term of residence, and to take either part in his sixteenth term, inclusive (not exclusive) of his first term.

Additional qualifying examinations in anatomy and in physiology will be held in December, 1939, and in March, 1940, and additional examinations in pharmacology in December, 1939, and in June, 1940, the dates to be fixed by the Board of Examinations.

At a Congregation on November 24 the following medical degrees were conferred:

M.D.—J. C. F. Lloyd-Williamson.
M.B., B.CHIR.—*J. Aspin, C. P. Petch.
M.B.—*J. W. Landells.

* By proxy.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

The Harveian Oration (postponed from St. Luke's Day) will be delivered by Dr. R. A. Young on Friday, December 15, at 2.30 p.m., in the large Library of the College.

Medical Notes in Parliament

Before Parliament was prorogued on November 23 the Royal Assent was given to the Official Secrets Act and the Restriction of Advertisement (War Risks Insurance) Act. Prorogation ended a session which began on November 8, 1938.

The Speech from the Throne with which the King opened a new session of Parliament on November 28 announced that measures would be submitted such as seemed necessary for the welfare of the people as well as for the prosecution of the war.

Mr. Chamberlain intimated on November 28 that he would bring in a Bill to suspend the operation of certain Acts of Parliament. One of these is the Collecting Charities Act, due to take effect on December 1.

Mr. W. S. Morrison announced on November 28 that the rationing of bacon and butter would begin on January 8 at the rate of 4 oz. a week of each commodity for each individual consumer. Consumers were asked to restrict purchases of sugar to 1 lb. per head per week, though sugar was not included in the rationing scheme.

Reorganization of the E.M.S.

Dr. Elliot, replying to Dr. Howitt on November 23, said he had agreed with the representative committee of the medical profession upon a scheme which would enable specialists at present employed whole-time in the Emergency Medical Service to engage in other work, whether in general hospitals or in private practice [see *Supplement,* November 25, p. 225]. Under the scheme there would be attached to certain hospitals part-time specialists and consultants at a salary of £500 a year. This salary would cover not only the part-time work required at present, but any additional work appropriate to the grade which might be required in air attack conditions. His agreement with the committee also secured that arrangements for providing medical services of all kinds for casualties should be adapted to varying types of hospitals, so that there might be the minimum interference with the ordinary medical work of the hospitals.

Dr. Howitt asked if Dr. Elliot would arrange for an adequate return of nurses and hospital almoners. Dr. Elliot said he trusted that as the work of the central hospitals extended the return of adequate staff would be secured.

Dr. Elliot informed Sir Ernest Graham-Little that the arrangements announced to Dr. Howitt for transfer of consultants and specialists from whole-time to part-time service were open to these classes notwithstanding that they might have accepted the part-time agreement hitherto in operation. Sir Ernest urged the transfer of members of the voluntary staffs of hospitals to the new scheme in view of the urgent need for providing teachers for the medical students returning to London schools in increasing numbers. He reminded Dr. Elliot that in 1938 there were over 10,000,000 attendances in the out-patient departments of the hospitals, and asserted that all this service was in abeyance in the London area. It was impossible to conduct out-patient departments without the honorary staff, which could not be properly replaced by junior and inexperienced officers.

Dr. Elliot said he would certainly bear in mind the need for getting teachers for the medical students, but he could not accept the suggestion that the out-patient services had been in abeyance at London hospitals for ten weeks. This was at variance with information supplied to him by London hospitals. To suggest the service was in abeyance discouraged people from applying, which was undesirable. He agreed that the higher the medical skill obtained by the out-patient departments the better.

Answering Sir Percy Harris, Dr. Elliot said the basis of employment in the Emergency Medical Service of house officers was at the outset £350 per annum, normally on a three-months contract, plus board and lodgings or an allowance in lieu. This flat rate was somewhat in excess of the rates paid by voluntary hospitals, which varied widely according to the type of hospital. It had not been agreed with the advisory committee that no further individual enrolments should be made of house officers in the Emergency Medical Service, but that hospitals should receive a payment equivalent to £200 per annum for each of their house officers required for whole-time work under the Emergency Hospital Scheme. The precise allocation of this payment would be a matter for the hospital authorities. Sir Percy Harris asked for an assurance that Dr. Elliot was doing nothing to undermine the great London voluntary hospitals. Dr. Elliot answered that he could give this assurance. The Government was working in the closest consultation with the voluntary hospitals.

ORIGIN OF LONDON HOSPITALS SCHEME

In a reply to Mr. de Rothschild Dr. Elliot said the war-time hospital problem had been first examined by a committee of distinguished medical men and of others representing the hospitals under the chairmanship of Sir Charles Wilson. Making full use of this committee's advice, the present scheme was worked out by the Ministry of Health under the authority of Section 50 of the Civil Defence Act. The Ministry had frequent consultations, formal and informal, with the hospital authorities, whose views throughout had been fully taken into account. He had arranged to meet specially those responsible for the administration of the hospitals. The group officers appointed to take charge of the hospital sectors into which London and the Home Counties were divided were chosen as representing the voluntary hospitals in the London sectors, on account not only of their professional distinction but also other administrative experience at the teaching hospitals. Their duties, in general, were to supervise the working of the emergency medical arrangements in their sectors. After due consultation these officers were appointed by the hospitals themselves.

Sir Ernest Graham-Little intervened to assert that the selection was not made either by the medical committees or by the governing bodies of the hospitals. He asked Dr. Elliot to take what measures he could to modify the selections.

Replying further to Mr. de Rothschild, Dr. Elliot said the hospitals in the London region which had been increased in staff and equipment under the Emergency Hospital Scheme were mainly municipal, because such hospitals had to be sought in the outer part of the region where were comparatively few voluntary hospitals capable of expansion. All the voluntary hospitals in the outer area which were capable of satisfactory expansion had been expanded. The majority of hospitals inside the county of London, whether voluntary or municipal, had been reduced in staff and equipment. Answering Mr. Isaacs, Dr. Elliot said the majority of the sector hospitals were adequately provided for the number of patients which they were intended to receive, but in several of them the equipment and organization required further improvement. To that end he was using the present period of quiescence.

Dr. Elliot further told Mr. Graham White that so far as might be the war-time organization of hospitals in the London sectors was of a character to enable medical officers to be liberated from financial and general administration and to concentrate on arrangements for treatment of patients. It was not possible to separate medical officers entirely from general administration.

Payment for Medical Care of Unaccompanied Children

Dr. Elliot said on November 16, in reply to Mr. Groves, that funds available for the medical attendance and treatment of unaccompanied children in reception areas would be distributed between the reception areas on the basis of returns showing the number of such children in each area. The local fund would be distributed to practitioners in accordance with a scheme prepared by the local emergency committee of the area. The schemes might provide for payments to be made to practitioners on such basis, whether capitation or attendance, as might be found convenient. The basis most commonly adopted was that of distribution in proportion to the number of children actually treated by the doctor during the period, irrespective of the number of attendances given.

Medicines in the Dark

On November 21 Mr. DAVID ADAMS asked the Home Secretary if he would permit chemists, doctors, dispensaries, and other persons or institutions connected with the health services to display a distinctive blue-lighted sign at night, both to enable people returning from work to get medical attention or to have prescriptions dispensed, and to ensure the provision of first-aid facilities for casualties in the event of air raids. Mr. MABANE said that the Home Secretary was arranging to permit the use of an illuminated sign in shops, including chemists. Hospitals and first-aid posts were already authorized to use night signs. He had received no representations that a similar concession should be made to doctors.

Medical Examination in Silicosis Cases.—On November 14 Mr. JACKSON asked the Minister of Health if he would cause instructions to be issued to approved societies to submit miners suffering from silicosis to a preliminary examination by the regional medical officers before their cases were submitted to the Home Office Medical Board, in view of the instructions in Circular A.S. 322. Dr. ELLIOT said that from paragraph 47 of the circular it would be seen that approved societies had already been informed that as a consequence of the suspension of the regional medical service the Silicosis Medical Board had been instructed that for the present they might entertain applications from workmen on payment of the reduced fee of 30s., if a certificate was produced from a qualified medical practitioner indicating that the workman was, or might reasonably be suspected to be, suffering from silicosis.

Unemployed Nurses.—Dr. Elliot has received representations that trained nurses are out of employment because certain public health and other hospital authorities had dispensed with temporary nurses. He does not think the unemployment extends to the permanent staffs of hospitals. The responsibility for staffing rests with the hospital authorities. No substantial number of nursing auxiliaries are undertaking hospital work

Medical News

We are asked to announce that the January meeting of the Pathological Society of Great Britain and Ireland will be held on January 12, 1940, in the Department of Pathology at Cambridge, and not at Guy's Hospital.

A meeting of the Medical Society of Individual Psychology will be held at 11, Chandos Street, W.1, on Thursday, December 14, at 2.30 p.m. A paper will be read by Dr. H. Crichton-Miller on "National Emergency: Discipline and Leadership."

On the proposal of Dr. H. Vincent the Académie de Médecine at its meeting on October 3 unanimously expressed the desire that the sale and consumption of absinthe or its substitutes should be rigorously prohibited to the civil population and army in France, its Colonies and Protectorates.

A memorial service for Dr. Jane Walker, C.H., was held at St. Barnabas's Chapel, East Anglian Sanatorium, Nayland, on November 17, the first anniversary of her death.

The twenty-fifth anniversary of the foundation of the Kitasato Institute for Infectious Diseases was celebrated on November 5 at the Institute, Shiba, Tokio.

Dr. Wilder Penfield, director of the Montreal Neurological Institute, has been elected President of the Royal College of Physicians and Surgeons of Canada.

La Presse Thermale et Climatique, which had hitherto been published twice a month, is now appearing once a month; and *Le Progrès Médical*, which appeared weekly, is coming out fortnightly. The weekly journal the *Gazette Hebdomadaire des Sciences-Médicales de Bordeaux* has been temporarily suspended. The last issue, which is that of September, contains the index only for the thirty-six numbers which have appeared in 1939.

The *London Gazette* of November 10 announces the voluntary liquidation of the British Health Resorts Association, following a decision taken at an extraordinary meeting of the company held at 28, Portland Place, W.1, on October 25.

Owing to the arrival of a large number of refugees in certain areas the French Minister of Public Health has reorganized the health services under the following authorities: Bezançon (tuberculosis), Roussy (cancer), Couvelaire (maternity), Nolécourt and Lesné (protection of children), Lévy-Bing (venereal disease), and Dujarric de la Rivière (public health).

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

Moderate increases in the incidence of scarlet fever, diphtheria, and pneumonia were recorded for the week in England and Wales, but in Scotland, Northern Ireland, and Eire changes were only slight; in some instances decreases were noted. The notifications of measles and whooping-cough in the current week are not comparable to those in the previous week, when the figures only applied to part of the week.

Memorandum on Influenza

That the rise in the prevalence of pneumonia (primary and influenzal) is chiefly due to an increase in influenza is suggested by the increasing number of deaths ascribed to influenza in the last four weeks.

In February, 1919, during the great influenza pandemic which surpassed all its predecessors in severity, the Local Government Board drew up a memorandum on the prevention of influenza. A few months later the Local Government Board became merged in the newly created Ministry of Health, and in the following December the Ministry issued to sanitary authorities a revised version of the memorandum. Early in 1927 a third edition was prepared, and now a further revision has been undertaken.[1] In its present form the memorandum is shorter than its predecessors, and the text has largely been rewritten. It is timely in its appearance. General epidemiological observations on influenza and influenzal pneumonia are followed by diagnostic hints on its early recognition and differentiation from colds and febrile catarrhs and by suggested measures for prophylaxis and personal protection. Gargles and masks are regarded as of doubtful efficacy, and bacterial vaccines may be employed if there is known liability to attack or to pulmonary complications. No mention is made of the employment of the virus isolated by Andrewes and his co-workers in the preparation of prophylactic vaccine. The need for immediate isolation of patients in bed and the value of good nursing and medical care are properly stressed under the treatment section.

Memorandum on Typhoid

The Ministry of Health has also issued a memorandum on typhoid fever.[2] After a historical note matters connected with dissemination and modes of infection and control are discussed briefly but adequately. During the past fifteen years, in forty outbreaks of typhoid and paratyphoid fever in which there were definite grounds for a decision, the vehicle of infection was found to be water in eleven instances, milk in twelve, and other foods in seventeen. It is significant that none of the milks in the outbreaks in question had been pasteurized. Although gross sanitary defects are nowadays infrequent, the need for improvement in the methods of handling and distribution of milk and other foodstuffs, and for constant vigilance in water control, is evident. Specific immunization is only required for those particularly exposed to risk—for example, for those going abroad, or if the disease has been prevalent in a particular locality in this country and its source has remained unidentified. Detailed instructions are given for laboratory diagnosis of both cases and carriers by cultural and agglutination methods. The modification of the Widal reaction suggested by Felix, in which the blood is tested for Vi-antibody, is not yet regarded as a practicable procedure in routine diagnosis of cases or detection of carriers.

No. 45

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 11, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for : (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for : (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases ; a blank space denotes disease not notifiable or no return available.

Disease	1938					1937 (Corresponding Week)

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The TELEGRAPHIC ADDRESSES are

EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*

SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Doctúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Parotid Swelling in an Infant

Mr. REGINALD T. PAYNE, M.S., F.R.C.S. (London, W.), writes: The history of Dr. Harper's case suggests that the infant has a mild pyogenic parotitis. I have seen many cases of parotitis starting in infants of a year or under, but never one which started in the first few weeks of life. Such cases are described, particularly secondary to thrush infection of the mouth. The evidence that thrush itself is actually responsible for the parotitis is unproven. In the cases which have been under my observation the parotitis has always been caused either by the *Streptococcus viridans* or by the pneumococcus. If in the case recorded either of the organisms is the causative one the prognosis is good as to life, but the patient is likely to have a troublesome parotitis with recurrent exacerbations. In the *Streptococcus viridans* group the exacerbations are likely to be mild, but in the pneumococcal group the exacerbations may be of a more acute and more serious nature, and may even pass on to the formation of intraglandular abscesses. Catheterization of the parotid duct is essential to confirm the bacteriological diagnosis, but this may be impossible in so small an infant.

Dr. A. N. M. DAVIDSON (Southport) writes: In your issue of November 18 (p. 1028) there appears a query by Dr. Colin H. Harper, Kenilworth, with reference to a small soft painless parotid swelling in an infant two and a half months old. Without seeing the swelling it is of course impossible to be certain, but the description is highly suggestive of what is known as a sucking pad. This is a small pad of fat occurring in the masseteric region, the object of which is to stiffen the cheek wall during suction. These pads are not at all uncommon. They are not to be regarded as an abnormality, and usually disappear spontaneously by the time the child has reached the age of 9 months.

Income Tax

Medical Students' Fees

"P. Q." has an income from a taxed trust fund. Can he claim any allowance for payment of fees as a medical student?

⁂ No. Expenses can be deducted only when they are incurred in creating the income. This is not the case, and in fact the fees are rather in the nature of capital expenditure to create an asset.

Allowable Expenses

"A. P." inquires with regard to the expenses mentioned below.

⁂ (*a*) Subscription to medical defence society—allowable. (*b*) Insurance of house property, ordinary insurance and against war damage—allowable so far as the insurance relates to the professional portion of the premises, equipment, etc. (Life assurance has, of course, special rules.) (*c*) Provision for "black-out" material for private house—allowable only as regards the professional rooms. (*d*) Provision of private air raid shelter—not allowable.

LETTERS, NOTES, ETC.

Fifty Years' Survival after Fractured Spine

Mr. ROBERT JACKSON, M.B., C.M., consulting surgeon to St. Helen's Hospital, sends a cutting from a local newspaper which records the death at the age of 82 of a man who fractured his spine when he was 34. Had he lived one day more he would have been a great-great-grandfather, a great-great-grandchild being born the day after his death. Mr. Jackson states that the patient fractured his spine on November 4, 1889, and that he applied a plaster jacket to the patient by the method described by him in the *British Medical Journal* of March 3, 1934 (p. 381). Death took place on October 25, 1939, within a few days of fifty years after the injury. In 1900 the patient commuted his claim against his employers for £25, and afterwards was employed for many years.

Leaflets for Child Care

Difficulties in reception areas have led the executive committee of the National Baby Week Council (29, Gordon Square, W.C.1) to produce two leaflets: *Think First of the Baby,* to meet the needs of mothers who may be contemplating return home and of householders who are tending to fail in a sympathetic interest in mothers and babies; and *Bed-wetting*—a disorder which has become very much more troublesome among children of all ages, particularly those who have left their homes. Simultaneously the Health and Cleanliness Council (Aldwych House, W.C.2) has issued a leaflet on the care of the hair (with special reference to the removal of vermin). All three leaflets, prepared by expert advisers, can be supplied free of charge to those interested in the care of children, on application to the addresses given.

"Foreign Pharmaceutical Products"

We are informed by Fassett and Johnson, Ltd., who distribute the goods of A. C. Barnes Company, that one of the latter's products —"argyrol"—is not a foreign product but is and has been for years manufactured in Canada. They state that there is no difficulty at all in obtaining supplies of argyrol brand of silver vitellin and that there are ample supplies in this country to meet all demands. Messrs. Fassett and Johnson, Ltd., state that their principals have for years pointed out that their argyrol brand of vitellin has no substitute, and that so far as they are aware there is no preparation which is similar or equivalent to it.

Dosage of Medicines

Dr. N. Z. KHAN (Calcutta) writes: The use of universally adapted Arabic notation instead of the Roman is urgently called for, considering that the same prescriptions have often got to convey fractional doses in Arabic figures and integral doses in Roman. This is a glaring inconsistency. Works on pharmacology and materia medica should be urged—rather, required—to give the average dose of medicine admissible in a given period of time and the total admissible in twenty-four hours, based on factors of assimilation, action, and elimination. To give dosage of such-and-such a drug in from so many to so many grains is irrational and unscientific.

Psychological Treatment Centres

Dr. J. L. BARFORD writes from the Mental Hospital, Ipswich: Is it not a sad reflection on the effect of modern "reform" in the treatment of the insane that your correspondent Dr. Allan A. Macdougall can write (November 18, p. 1020), "Let us save such people as we can from the *appalling fate* of ending their days in a mental hospital"! (italics mine).

Mustard Gas

Dr. E. T. LARKHAM (Birmingham) writes: To mitigate the ill effect of mustard gas and its like on the eyes immediate treatment is essential. Irrigation apparatus is rarely at hand, and in its absence a simple method is to open the eyes under clean water in a basin or bucket or under the water of a clean stream and move the head briskly from side to side.

Wanted—A Child for Adoption

Dr. E. W. DEWEY (Kingswear, London Road, Portsmouth) writes: A patient of mine is anxious to adopt a baby. I wonder if any of your readers know of any mother willing, or forced by circumstances, to part with hers. The child must be under 6 months and of good stock—not from the slums—preferably a girl. As my patient has to return to India in a few weeks the matter is of some urgency. I shall be glad if any medical man who knows of such a child available will communicate direct with me.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY DECEMBER 9 1939

CARCINOMA OF THE STOMACH

BY

SIR JAMES WALTON, K.C.V.O., M.S., F.R.C.S.

Surgeon to the London Hospital

In spite of the general progress of surgery carcinoma of the stomach still remains one of the greatest of human tragedies. It occurs so often that it concerns us all, in whatever branch of medicine we may be working. In England approximately 15,000 people die of it annually—that is, about forty a day—while in the United States of America the number is approximately 38,000. Of all varieties of carcinomata it is one of the commonest, sharing this position with carcinoma of the breast and uterus. In men it forms about one-fourth of all varieties, and in women about one-sixth. In the surgery of the abdomen it accounts for approximately one-quarter of all operations upon the stomach.

Only too often it slowly and insidiously attacks those who have apparently been in perfect health, and it occurs at an age when its sufferers are looking forward to and preparing for a peaceful and happy enjoyment of their retiring years. The progress of its treatment has not kept pace with that of other gastric lesions, and only too often its recognition is the harbinger of a rapid and miserable end. Yet, as I shall hope to show you, some progress has been made and radical treatment has restored many hopeless sufferers to healthy and happy people.

Incidence

It has often been stated that the disease is on the increase, but of this I am doubtful. Owing to the more careful and complete methods of investigation fewer cases are overlooked, and with an increase of the total population, and especially with an increase of those who reach the cancer age, more cases are certain to occur; but in my own series of 572 patients there has been an average of thirty new cases per annum during the past ten years. The condition is most frequently seen between the ages of 50 and 60, but a large number occur in the decades immediately above and below this, and, as shown in Table I, may even be found between the ages of 20 and 30, and over 80. Cramer has found that the incidence steadily increases with age, and that the infrequency in the later periods of life is solely due to the fact that there are fewer people of advanced age.

TABLE I.—*Age Incidence*

Years	No.	Years	No.
20–29	5	60–69	163
30–39	51	70–79	20
40–49	113	80–89	1
50–59	219		
		Total	572

The male sex is more often attacked than the female. In my own series there were 398 males and 174 females—that is, 69.5 per cent. males—a preponderance which is rather less than that seen with peptic ulcers, where in a total of 2,143 cases there were 1,654 males and 489 females. It used to be generally believed that the majority of cases were primary and occurred in stomachs which were previously healthy, there being relatively few that were recognized as being dependent upon some previous organic lesion. These few are, however, of very considerable importance, for I know of nothing more depressing than to operate upon an irremovable carcinoma of the stomach which has followed a benign lesion of many years' standing, and to realize that if only adequate surgical treatment had been performed earlier the carcinoma would have been prevented. I cannot help feeling that the modern fashion of treating all peptic ulcers medically has led to many carcinomata being overlooked by those who have not had enough experience to make the differential diagnosis.

A small percentage are undoubtedly secondary to adenomata. These benign lesions are relatively uncommon and often do not produce symptoms. In my own series only six cases were found in over 3,000 operations upon the stomach. Stewart in his post-mortem investigation found about one in 200 necropsies. Of the 572 carcinomata in my series twenty-seven were accepted as having started in adenomata or were associated with them. Occasionally a severe haematemesis may have occurred in the past history, but as a rule this variety is insidious in its onset. The importance of their recognition lies in the fact that they may give rise to a very massive carcinoma situated on the greater curve of the stomach, which may cause a big palpable tumour that is considered to be inoperable. The condition, however, appears to be relatively benign, for at operation it may be found to be quite movable and to have led only to secondary deposits in the local glands. For this reason it is my custom never to regard a case as inoperable simply because of the size of the tumour.

Relation of Carcinoma to Gastric Ulcer

The question whether carcinomata may be secondary to a previous gastric ulcer has in the past led to a great deal of discussion, and even to-day there is no unanimity of opinion as to its frequency. The majority of workers, however, accept Stewart's figures as being approximately correct, and my own experience very largely agrees with his. He finds that about 9.5 per cent. of ulcers become carcinomatous; but this change is likely to occur in one in four of ulcers situated in the prepyloric area. About 17 per cent. of the carcinomata start in an ulcer. It is my own custom to exercise a very strict supervision over the classification of the types of carcinoma, and only to accept as starting in a previous ulcer those cases which fulfil the following four requirements: They must have had a history suggestive of a past ulcer; the test meal must show the presence of free hydrochloric acid, often above the normal; at operation the lesion must simulate a chronic ulcer; and the microscopical report must indicate that this was the nature and origin of the growth. With these criteria sixty-one of my 572 cases are grouped as having arisen in an ulcer—that is, 10.5 per cent. This is rather less than Stewart's 17 per cent., but of course it does not include any of the cases that are already inoperable, for in this group the pathological proof cannot be obtained. It is on this question of the pathological appearances that probably the greater number of the disagreements have arisen. For a case to be accepted the four pathological points which Newcomb has stressed should be present. They are: a complete destruction of the muscle in the base of the ulcer, the presence of much fibrosis in and around the base, the presence of surrounding endarteritis, and a fusion of the muscularis and muscle coats at the edge of the ulcer. Whatever be the exact frequency is not of practical importance, provided we all recognize the fact that an ulcer may become malignant, and that many cases of carcinoma may in their early stages give a history suggestive of an ulcer. For this latter reason the percentage of those cases primarily diagnosed as ulcers which later become malignant is higher than the figures I have already given. In my own series 112 of the cases gave an early history which suggested a chronic gastric ulcer, and I am sorry to say that in a considerable number of these medical treatment had been persisted in for so long that when the patient sought my advice the condition was already inoperable. It is in this group, relatively small though it is, that I feel progress can be made by a more careful attention to the clinical details and a recognition of those points which are suggestive of the presence of carcinoma. In this consideration an interesting point is the relation of carcinoma to the scars of healed ulcers, and, to us surgeons more especially, the relation to the scars of ulcers which have been healed by previous operation. If such a relation was relatively common it would be a strong argument in favour of the more routine use of radical operations in the treatment of peptic ulceration. My own series throws interesting light on this point. There were in all twenty-three cases which had followed a previous operation for ulcer (Table II). In four of these the ulcer was so big that a palliative operation had alone been performed, and the carcinoma followed shortly afterwards. There can be no doubt that in them the condition was already carcinomatous at the time of operation. The error was of course of no importance, for the ulcer was inoperable and would have remained so even if it had been known to be carcinomatous. In the second group (nine cases) the carcinoma occurred in some portion of the stomach remote from the site of the previous ulcer, and did not take place until many years afterwards. It is manifest that these cases had nothing to do with the primary lesion, and although it is true that a partial gastrectomy might have prevented the onset of carcinoma, this would have been no more justifiable an argument in favour of its employment than it would be to suggest that such an operation should be performed in normal people in order to prevent them getting carcinoma later on. The third group is that in which carcinoma occurred at the site of the ulcer many years afterwards, and probably could have been prevented if the ulcer had been excised at the time of the first operation. There were ten such cases in my own series.

Table II.—*Carcinoma after Operations for Ulcer*

Shortly after	4
Remote from ulcer ..	9 (4, 7, 7, 7, 14, 15, 17, 20, 25 years after)
Later in ulcer site ..	10 (3, 5, 5, 6, 6, 12, 14, 15, 21, 29 years after)

Probably one of the greatest advances in our knowledge of the aetiology of this disease lies in the recent conclusions of Sir Arthur Hurst. His investigations have produced very strong evidence to show that the cases which were previously regarded as primary are dependent upon a gastritis. He believes that the achlorhydria is caused by the gastritis and is not due to the growth, for he found that in every case of undoubted ulcer-cancer free hydrochloric acid was present; and when there was no evidence of such a previous ulcer the acid was usually absent, even in very early stages of the disease. He states that he has in his own series five cases in which the achlorhydria was present before the carcinoma developed, and that he has found record of twenty-two similar reported cases. He does not believe the acid falls after the onset of the growth. This latter point is of very considerable interest. I had previously believed that with the onset of carcinoma a gastritis might be set up and the acid diminish, but in my own series, in which test meals had been taken previously and had shown a fall with the onset of carcinoma, a gastro-enterostomy had been performed, and therefore these observations were of little value. It is true that Comfort has investigated a series of cases at the Mayo Clinic in which he seems to show that the acidity falls with the progress of the carcinoma, and that cases have been reported by Robertson and Wilkinson where there appeared to be a definite fall in the acidity in test meals taken before and after the onset of the carcinoma. The evidence which Hurst produces, however, is very strong, and he concludes that carcinoma never develops in a healthy stomach; but if a patient with a constitution predisposing to carcinoma also has achlorhydria and gastritis he will probably develop carcinoma, and Hurst holds out a strong hope that the early recognition and treatment of the gastritis may do much to diminish the frequency of carcinoma. He lays stress upon the interesting fact that although the incidence of carcinoma is much the same in all countries, yet in England only 22 per cent. of the cases occur in the stomach, whereas in Holland this percentage is 55. He believes that this difference is due to the greater incidence of gastritis in the latter country.

If the achlorhydria is the primary factor then we should expect to see cases of carcinoma occurring in patients who had had pernicious anaemia. It is of course only in recent years that the sufferers from this disease have been kept alive long enough for such a possibility to occur. Sir Arthur Hurst states that he has seen six cases of carcinoma of the stomach with pernicious anaemia, and that he has knowledge of twenty-four others which have been reported. In two cases he has seen the development of carcinoma after the pernicious anaemia had been cured. In my own series there have occurred two cases with pernicious anaemia. In one the anaemia arose seventeen years after an operation for gastric ulcer, and two years later carcinoma occurred. In the second case the patient had had pernicious anaemia in 1927, which had been treated and apparently cured, and in 1930 developed a carcinoma of the stomach.

It would be of little practical value in this discussion to consider in detail the pathological types of carcinomata which may be found in the stomach; but I may point out that the rare cases of sarcoma and lymphogranuloma, four examples of which occurred in my series, are clinically indistinguishable from carcinomata.

Symptoms

The main difficulty in the successful treatment of carcinoma of the stomach is that nearly two-thirds of the patients only seek surgical help after their disease has become inoperable. I wish I could say that this was due to the fact that errors of diagnosis had been made in the earlier period, for then one could hope that with a wider recognition of the symptoms more cases would be cured; but unfortunately in many the symptoms may have been present for only two or three weeks, but the condition is already inoperable when advice is first sought. There are, however, still some cases where the symptoms, in the earlier stages, are so indefinite or may so resemble a non-malignant tumour that they are overlooked for too long and are treated medically. It is these cases that we can hope to save by earlier surgical treatment. I am still confident that, even with the modern methods of investigation in use to-day, the greatest certainty of diagnosis lies in a careful investigation of the clinical history, and that sometimes indeed the more modern methods may lead one astray after a correct primary diagnosis has been made. The first point of importance, which has been so often stressed before but which cannot be too often reiterated, is that a gastric ulcer practically never starts after the age of 40, and that if a patient over the age of 40 with a clear past history comes up complaining of dyspepsia he *has* got a carcinoma of the stomach unless the contrary can be definitely proved. Moynihan's clinical classification is still of the greatest value. He pointed out that these cases may appear in three separate groups—namely, carcinoma of the cardiac orifice, of the pyloric orifice, and of the body—and that the latter, which is the biggest group, shows three methods of origin: those with a sudden onset, those with an insidious beginning, and those which are secondary to a peptic ulcer. The frequency of these types in my own series is shown in Table III.

TABLE III.—*Clinical Types*

Pyloric obstruction		216
Cardiac obstruction		46
Body: Sudden onset	29	
Insidious	16	310
Secondary to ulcer	112	
Total		572

It is well to remember that carcinoma of the cardiac or pyloric orifice will generally lead to obstruction, and that in either case the symptoms of the obstruction entirely mask the underlying cause. A patient with a carcinoma of the cardiac orifice will begin to develop symptoms of difficulty in swallowing. The history will usually be short and steadily progressive, the obstruction being marked at first only for solid food, but later increasing until there is difficulty even in the passage of fluids. Such cases do not as a rule cause much perplexity, for it is universally recognized that a rapidly increasing difficulty in swallowing in a patient over the age of 40 is generally due to a carcinoma either of the oesophagus itself or of the cardiac orifice of the stomach. Their recognition is, however, becoming of greater importance, for not only are they relatively common—in my own series there were forty-six cases at the cardiac orifice over and above the true cases of carcinoma of the oesophagus—but operations upon this type of growth, aiming at its radical removal, although at present tentative and somewhat experimental, are beginning to be more and more successful and are giving us hope that the intrathoracic or the combined abdomino-thoracic operation may lead to the cure of a considerable number of these unfortunate sufferers.

PYLORIC OBSTRUCTION

When leading to pyloric obstruction the individual symptoms of the obstruction are indistinguishable from those caused by a stenosing ulcer or by involvement of the pylorus from some lesion without, such as a chronic cholecystitis, chronic pancreatitis, or carcinoma of the head of the pancreas; but here again a careful consideration of past history should prevent the possibility of error. The short and steadily progressive history is the factor of chief import, and it must always be remembered that the onset of pyloric obstruction in a patient over the age of 40 is due to a mechanical cause, and must be treated by early operation. In the early stages the patient chiefly complains of a feeling of discomfort and distension, which increases as the day goes on, and is soon associated with a loss of appetite and with occasional vomiting. As the disease progresses the vomiting becomes more marked and takes on the projectile character. The vomit itself becomes large, generally occurs in the evening when the stomach has been filled, and the emptying of the stomach gives very considerable relief. The physical signs are often definite, and three stages of obstruction can be recognized. In the first the stomach is dilated and atonic, the atony being shown by the presence of splashing over the stomach. This may be obtained on physical examination, or the patient himself may complain of it during movements. The evidence of the dilatation can be heard but not seen or felt. As the condition progresses the stomach undergoes a certain amount of hypertrophy, and tends to contract upon the large mass of its contents. On physical examination its outline may generally be felt as a distended bag. Later still the hypertrophy is accompanied by peristaltic waves, which may be so forcible that they are readily visible through the abdominal wall, and the outline of movements of the stomach can then be seen. Such a degree of obstruction may be associated with a considerable amount of gastritis, and thus an absence of free HCl may be found in the test meal even if the obstruction is not carcinomatous; but in my own experience the fall in acid is never so early and never so marked with the benign lesions as with the carcinomata. An *x*-ray investigation may again disclose only the pyloric obstruction, for the barium meal may be unable to pass into the pyloric canal, and thus will not show the irregularity and filling defects due to the growth. In other words, all the methods of investigation will reveal only the presence of a pyloric obstruction, and will not indicate its nature. This will be indicated solely by the age of the patient, the shortness of the history, and the progressiveness of his symptoms.

SYMPTOMS IN THE BODY OF THE STOMACH

When the lesion is in the body of the stomach the symptoms may arise with a suddenness of onset which is very deceiving. Fortunately such cases are rare. In my own series there were twenty-nine examples. A few may occur with a perforation, but these are so rare that they are of little practical importance. In my series there were only two. Sometimes the onset is with a large haematemesis, and I have known several such patients who after the collapse from the haemorrhage had been treated for many weeks or months for a supposed ulcer, until the carcinoma was hopelessly inoperable. If it had only been realized that even a haematemesis occurring in a man over the age of 40 with a clear past history was most probably due to a carcinoma this mistake would have been avoided. The interesting variety is that in which a patient partakes of a meal which is perhaps for him of a rather unusual character. It is followed by a severe indigestion, which persists from that time, and when he seeks advice he will date the whole of the symptoms back to that one meal. The danger is that the condition may be regarded as one of food poisoning and the possibility of carcinoma be entirely overlooked. The fact that he has a constant gastric pain which is not relieved by vomiting, that his appetite is completely lost, and that he has no diarrhoea should arouse suspicion. If he is fortunate his vomit may contain a small amount of blood, and the underlying nature of the lesion be suspected early. Even if this does not occur an investigation of the vomit will generally show the presence of occult blood. A test meal will reveal the absence of free HCl, and the radiograph will generally show a filling defect.

The greater number in this group have a slow and insidious onset, and it is this variety which may be regarded as giving the most characteristic evidence of carcinoma of the stomach. The symptoms are variable. At times they are entirely extragastric, and the man may seek advice not for his indigestion but because he is cognizant of an increasing weakness and loss of energy. When questioned he will usually admit that he also has a loss of appetite and that he has a certain amount of discomfort after his food. From the time of the onset his symptoms are steadily progressive; his appetite will decrease, his discomfort after food may become more severe and is always continuous, so that although it may be made worse by the taking of food it does not entirely disappear before the next meal. At the same time he may complain of the eructation of foul gas or of quantities of foul and bitter fluid. Later true vomiting is added, but it does not give complete relief to the pain. There is often a visible anaemia, and loss of weight, although by no means characteristic, may be present. The persistence of such symptoms for two or three weeks should at once arouse the suspicion of carcinoma, and an investigation should be carried out. Visible blood may be present in the vomit or stools, but even if this is absent it will nearly always be found on chemical examination. I feel that here one ought to issue a word of warning. If occult blood is found in the stools it is often the custom to treat a patient medically for a supposed ulcer, and only to consider the question of carcinoma if the occult blood fails to disappear. This is a loss of very valuable time, and medical treatment should only be persisted in if there is strong positive evidence, either in the past history or in the other methods of investigation, of the presence of a gastric ulcer. If the history is suggestive of carcinoma it should not be continued. In many such cases the *x*-ray investigation will give positive evidence of the presence of carcinoma; unfortunately, indeed, it may in some cases give evidence that the growth is already past surgical treatment. On the other hand, in very early cases the evidence obtained by these means of investigation may be indefinite. In such cases gastroscopy may be of value. The blood should be investigated: a low haemoglobin content is not only suggestive but may have to be corrected before operation is considered.

GROWTH SECONDARY TO GASTRIC ULCER

Even in that type of growth which occurs secondarily to a gastric ulcer a consideration of the symptoms is of very great value. My own experience has been that a positive diagnosis can often be made by a consideration of the history of the clinical symptoms, even when an investigation by the *x* rays and the gastroscope is still uncertain. It is important to realize this—for, as I have already pointed out, there were in my own series 112 cases which presented the symptoms of a past gastric ulcer—and to remember that ulcers in the pyloric antrum are specially prone to become malignant. The changes first to be looked for are in the nature of the periodicity. The patient will so often himself state that the last attack is different from the previous ones: it is longer and the symptoms may be different; the pain is more continuous throughout the day, has not the same close relation to the ingestion of food, is less severe but more continuous. He will note that whereas in previous attacks his appetite has remained good, in this attack it has begun to fail, and it is an interesting thing to note that this may be quite definite, although he still has a high acid content in the test meal. Vomiting often becomes rather more frequent, although the vomits are small; but if it was present in the previous attacks the patient may note that whereas before it relieved his pain it has now ceased to do so. The presence of such a group of symptoms should at once raise the suspicion of the possibility of a carcinomatous change. Personally, I would regard them as a definite indication for operative treatment, and I should be but little inclined to waste further valuable time in making prolonged investigations of the stomach content and the stools or in *x*-ray or gastroscopic investigation.

In this variety, as in those with an insidious onset, a careful examination of the abdomen may reveal the presence of a tumour. Stress must here be laid on the fact that a careful inspection may often show a tumour which can be felt with difficulty, and that, generally speaking, the lighter the palpation of the abdomen the more will be felt within it.

ACCESSORY METHODS OF INVESTIGATION

Although the greatest reliance is to be placed upon the careful taking of the patient's history and upon his clinical investigation, there is no doubt that in difficult cases much help may be obtained by the accessory methods of investigation. The presence of occult blood in the stools and test meal is of very considerable importance, and there are many physicians who state that the persistence of occult blood is indicative of carcinoma. My only criticism of this is that if too much reliance is placed on this test alone valuable time may be wasted. The presence of achlorhydria is suggestive, but it may be found with a simple gastritis. A careful screening and *x*-ray examination is of the greatest value, but it must be undertaken by one who is skilled in this type of work. One or two simple films may be of absolutely no value, yet a careful screening and a careful investigation of the mucosal contours may show a minute lesion. Gastroscopy carried out by one skilled in its use may in a difficult case be of inestimable value, and this is especially so, I think, in those cases of gastric ulcer which are showing a very early carcinomatous change. By its use Mr. Hermon Taylor has enabled me to carry out radical operations in a few extremely early cases of carcinoma. Nevertheless I am frequently seeing cases reported in the literature where a positive diagnosis ought to have been made on the history, and valuable time has been lost in making several gastroscopic examinations.

Treatment

In considering the indications for surgical treatment one must ever remember that without such intervention the patient is condemned to death. In the present state of our knowledge there is no other measure which can be said to offer any hope, and although it is true that the majority of these patients are poor operative risks, and that any operation which hopes to be successful must be extensive, yet the majority will be only too willing to accept a chance, slender though it may be. My own practice is to advise operation in every case in which there is no evidence of secondary deposits. It is even a debatable point whether an operation should not be advised where there is a suspicion of only one secondary deposit. It may sometimes happen that a palliative removal of a primary growth, even when there is such a secondary deposit, may give a prolonged period of comfort and happiness. Even in doubtful cases an operation should be advocated, for not only may very large tumours prove to be removable, but should removal be impossible it is a solace to the relations as well as to the patient himself to know that no chance of a cure had been missed. Unfortunately even to-day the percentage of cases in which a radical removal is possible is still relatively small. In my own series of 572 cases such a removal was possible in only 224—that is, a percentage of 39.1. In spite of the attention which is now given to this disease, I still feel that it should be possible to improve on this figure. I have already laid stress upon the fact that many patients are already in the inoperable stage when they first seek advice, but I still meet a considerable number of patients who have had medical treatment carried out for too long a period, either because the condition had been mistaken for an ulcer or because it had not been realized that there was an organic lesion of the stomach. It is probable that if an operation had been performed a few months earlier the disease might have been radically cured. In this respect, however, it is satisfactory to know that there has been a steady improvement. In my first seven years only 28 per cent. of the cases were removable. In the second seven years this had increased to 35 per cent., and in the third seven years to 44 per cent. It is of course possible that with increasing experience on my part I am attempting the removal in many patients whom in the earlier years I should have condemned as inoperable; but nevertheless I do feel that in large measure this progress is due to increasing care and skill on the part of the general practitioner. It is still probable, however, that the operability rate will be improved with a wider appreciation of the fact that any dyspepsia starting in a patient over the age of 40 is carcinomatous unless a rapid and full investigation has eliminated this possibility.

I do not propose to discuss the technical details of the operative steps. It will suffice to say that after the abdomen has been opened a rapid survey must be made to determine the presence of secondary deposits in the pelvis, in the glands, in the liver, and by local spread to the surrounding tissues. If the condition is favourable the resection of the stomach must be as wide as possible, and it must include all the lymphatics in the areas which drain the stomach. So wide a removal is bound to carry with it a relatively high mortality, especially as many of these patients are elderly and are already in a poor state of health. The majority of the published statistics show that the operative mortality is in the neighbourhood of 30 per cent., and in my own series it was only just below this figure. It is as well to remember, however, that any operation on these patients is bound to be serious. In my own series there were fifty-seven cases in which an anterior gastro-enterostomy to relieve obstruction was alone possible, yet this relatively simple operation was associated with a mortality of 42 per cent.; and even those cases in which the only resort was an exploratory laparotomy carried with them a mortality of nearly 18 per cent. As regards the operation of gastro-enterostomy, it is well to point out that this should only be performed if there is a definite pyloric obstruction. It will give little or no relief to a fungating growth in the body of the stomach, and the very high mortality is due to the fact that the patients are such bad operative risks. It is therefore not justifiable to undertake it unless the greater part of the symptoms are obstructive in nature. In lesions which are situated at the cardiac orifice, and are associated with a difficulty in swallowing, a gastrostomy is a justifiable and often a helpful procedure, but it is doubtful whether it should be performed in patients in the poorer classes of life, to whom feeding through a gastrostomy orifice becomes a difficult and even impossible procedure. In many cases a partial gastrectomy may be the best palliative procedure. Even if secondaries are present the removal of the large mass of fungating growth in the cavity of the stomach may make the patient's life much more comfortable, and he may be able to live in happiness for many months or in some cases for several years. At one time I was hopeful that the implantation of radium after opening the abdomen, and after the removal of the main mass of the growth, might diminish the possibility of recurrence. I found, however, that it added considerably to the risk of the operation, and was sometimes followed by the formation of duodenal fistula. I therefore feel that it is a procedure which is of very little value.

Results of Treatment

Compared with the results of carcinoma elsewhere those obtained in treatment of carcinoma of the stomach are very disappointing. This is mainly due to the fact that in any big series so large a proportion of the cases are inoperable; but even in those in which the growth can be taken away one has to be content, owing to the anatomy, with a more local removal than would satisfy us in many other forms of carcinomata. As a general rule the growth spreads chiefly along the lesser curvature of the stomach, which is so short that even in our widest removals we are often only an inch or less beyond the margin of the growth. Increasing technical knowledge has led to wider resections, and not only can the greater part of the stomach be taken away but the glands around the coeliac axis and elsewhere can be more widely removed, with a greater chance of a more successful issue. At the same time such operations are likely to increase the mortality, and therefore there arises the apparent paradox that the greater the surgeon's experience is the higher his mortality is likely to be. In my own early series the operative mortality for resection was 26 per cent., but in my later series it has risen to just below 30 per cent. Nevertheless I feel that it is the surgeon's duty to carry out a resection wherever it is possible, but the patient should be most carefully prepared for the operation. A blood transfusion may also be required, but in my experience it is only of value if the haemoglobin is reduced; so that a blood examination should always be regarded as a necessary investigation before operation is undertaken. Because of the small proportion of cases in which a radical operation is possible, and because of the high mortality, there are still many physicians who advise against operative treatment, but I feel this is a wrong view. With an operability rate of only 40 per cent. and a 30 per cent. mortality, it means that twenty-eight patients in every hundred will survive operation and will have a good chance of remaining free of their disease. It is surely better to give 28 per cent. a chance of life and happiness than to condemn the whole hundred to a slow and lingering death. It is to the actual end-results of operation, however, that we must look for its value.

It is one of the tragedies of this disease that one is unable to say with certainty that a patient is cured, as the recurrence may occur at very late periods after operation. In fact, one can only say that he has been cured of his carcinoma when he has died of some disease unconnected with his gastric lesion. It is usual, however, in evaluating late results, not to regard any patient as permanently cured, but to consider those who have survived for a five-year interval without any evidence of recurrence.

Many of my more recent patients have recovered from their operation and are at present in a state of good health, eating well and with no gastric symptoms; and it is possible that a considerable number of these may ultimately pass the five-year period. In my own series the patients who have been operated upon for five or more years number 422 (Table IV). In 150 (35.5 per cent.) a radical operation was possible. Of the total, 111, or 26.3 per cent., survived the operation, but of these 111 only twenty-seven have remained free from recurrence for over five years. This seems a very small proportion of the whole, and indeed one must admit that such results are extremely disappointing; but when one remembers that up to a few years ago a carcinoma of the stomach was regarded as an inevitably fatal disease one has to agree that some progress has been made. Of the 422 patients who sought relief 6.4 per cent. are as the result of surgical operation alive and well after five or more years. Of those in whom a resection was possible—namely, 150—18 per cent. are alive and well, and of those who survived a partial gastrectomy 24.3 per cent. are alive and well. This perhaps brings out more clearly than any other statement the importance of straining every effort to operate upon these cases in the early stage, for earlier operation gives us the one hope of raising the 6.4 per cent. to 24.3 per cent. If one keeps constantly in mind the fact that a dyspepsia arising in a man over the age of 40 is probably due to carcinoma, and that an ulcer in the prepyloric region of the stomach is very prone to become carcinomatous, it is probable that a large number will be operable and have a chance of being restored to complete health. The end-results of these cases are perhaps best shown in Table V, where it will be seen that patients are alive and well for 24, 23, and 21 years after operation. But even this table does not give a true indication of the length of cure, for some of the patients were elderly and have died of conditions not connected with their gastric lesion. Two, for instance, died respectively at ten and eleven years after operation from lesions quite distinct from carcinoma of the stomach.

TABLE IV.—*Results of Operation*

	Total	Resections	Operative Survivals
All cases	572	224 (39.1%)	143 (25%)
5 years or more	422	150 (35.5%)	111 (26.3%)

Late Results

	Alive and Well	% of All Cases	% of Resections	% of Operative Survivals
All cases	45	7.8	21	31.4
5 years or more ..	27	6.4	18	24.3

TABLE V.—*Survival Periods*

Years	No.	Years	No.
5	8	14	1
6	1	17	1
7	5	21	1
8	1	23	1
9	3	24	1
10	3		
11	1	Total	27

We must conclude, therefore, that although the outlook is still bad despite the results of surgical intervention, yet the figures are improving, and that cancer of the stomach, which is otherwise bound to be fatal, can in a certain number of cases be cured by surgical operation.

LYMPHATIC LEUKAEMIA

THE VALUE OF STERNAL PUNCTURE IN THE DIAGNOSIS OF ATYPICAL CASES

BY

M. C. G. ISRAËLS, M.Sc., M.D., M.R.C.P.

Foulerton Research Fellow of the Royal Society

(From the Department of Clinical Investigation and Research, University and Royal Infirmary, Manchester)

In classical lymphatic leukaemia the blood picture shows diagnostic changes; a typical overwhelming lymphocytosis—50,000 to 500,000 white cells per c.mm., of which 90 per cent. or more are lymphocytes. The sternal marrow merely reflects these changes; it is very cellular, and 70 per cent. or more of the cells are lymphocytes. But often some of the clinical signs may be missing: Naegeli (1923) listed ten variations, and the lymphocytes of the blood may not be significantly increased. In these patients sternal puncture will often provide the clue to an otherwise open diagnosis. The following records give five examples of this type of case. Detailed figures of the blood and marrow counts are given in the table.

Table of Blood and Marrow Counts

Case No.:	I	II	III	IV	V
			Blood		
Red cells, millions per c.mm.	2.570	2.470	4.526	2.480	4.680

* The nomenclature of the marrow cells is that adopted by Israëls (1939a).

Case I

A married woman aged 40 had noticed a swelling in the left side of her abdomen for three months. During the same period she complained of increasing weakness, palpitation and dyspnoea on exertion, dizziness, and loss of weight. On examination she was very pale and some purpuric spots were seen on the shoulders and arms. The spleen was large and painful; the liver was not palpable. No enlarged lymph glands were found. The blood count showed a moderate anaemia and a definite lymphocytosis—11,500 white cells per c.mm., with 91.5 per cent. lymphocytes. The marrow was normally cellular, but 87 per cent. of the cells were lymphocytes. The patient was given iron and arsenic, and for three months her condition showed little change apart from slight improvement in the anaemia. During the next six weeks the white cell count rose gradually to 30,600 per c.mm., the differential count being unchanged. Radiotherapy was begun, but it was soon discontinued because, although the white cell count was reduced, the red cells were seriously diminished. From this time the anaemia became progressively worse, and petechial haemorrhages appeared on the shoulders and legs. The lymph glands in the axillae and neck became definitely enlarged. Eight months after her first attendance the anaemia was severe (950,000 red cells per c.mm.) and there were 7,400 white cells per c.mm., 97 per cent. of them lymphocytes. Her death was reported shortly afterwards; there was no necropsy.

Case II

A woman mantle-finisher aged 48 had been treated for "anaemia" for some months. About three months before admission she began to complain of abdominal discomfort after food; vomiting soon started, and the patient became very weak and exhausted. Abdominal distension appeared and steadily increased. Loss of weight was considerable. Examination showed a pale wasted woman with a large and distended abdomen. The spleen was very large, hard, and firm, moving on respiration. The liver was palpable 3 cm. below the right costal margin; it was smooth and firm. Small but firm lymph glands were palpable in the axillae and groins. There were no other noteworthy abnormalities. The Wassermann reaction was negative. The blood count showed a rather severe anaemia; white cells were 6,800 per c.mm., with 63.5 per cent. lymphocytes. The sternal marrow was very cellular, and contained 75 per cent. lymphocytes and 0.8 per cent. lymphoblasts.

Iron and arsenic was given and radiotherapy begun. But it was soon apparent that these measures would be ineffective. The anaemia rapidly increased and the patient died after six weeks in hospital. The leucocytes fell at the end to 2,600 per c.mm., with 75 per cent. lymphocytes. Post-mortem examination showed typical leukaemic changes in the lymph glands, spleen, liver, and elsewhere.

Case III

A painter aged 46 had noticed gradual swelling of the glands under the lower jaw for twelve months. He felt quite well and continued his work. No haemorrhages occurred and there was no loss of weight. His doctor, however, sent him to hospital for diagnosis of the glandular swelling. Examination showed a thin but healthy man. Below the jaw and extending parallel with the vertical rami on both sides were discrete, movable, painless glands of a fairly hard consistence. The axillary and inguinal glands were also palpable but not very large. The cervical lymph glands were not enlarged. In the abdomen neither the liver nor the spleen was palpable. The lungs showed normal air entry and the heart was of normal size. No other unusual features were found. The blood count showed no anaemia; there were 9,800 white cells per c.mm., 75 per cent. being lymphocytes. A gland was removed for histological examination. The normal architecture of the gland was found to have been replaced by an intense proliferation of lymphocytes. A radiograph of the chest showed no abnormalities in the lungs, heart, or mediastinum.

The patient was treated with iron. His condition remained stationary for six months, but the white cell count rose to 28,800 per c.mm., with 88 per cent. lymphocytes. The lymph glands around the jaw were now uncomfortably large, and radiotherapy was applied in an effort to reduce them. The results were not very satisfactory, but the white cell count fell to 8,600 per c.mm., 80 per cent. being lymphocytes.

Case IV

A platelayer aged 55 complained of lassitude, loss of weight, dyspnoea and palpitation on exertion, and headache, of two months' duration; increasing pallor had been noticed. Shortly before admission he had had ulceration of the gums, but these had not bled and were almost healed. Examination revealed a tall heavy man, notably pale. On the left lower buccal mucous membrane there was a healing ulcer about 1 cm. across. No haemorrhages were noticed. The splenic dullness was increased, but the spleen was not palpable. The liver was not enlarged and there were no enlarged lymph glands. Nothing of note was found in the heart, lungs, or central nervous system. The urine was normal. A fractional test meal showed hyperacidity. The Wassermann reaction was negative. The benzidine test for occult blood in the faeces was positive on two occasions. The blood count showed a moderate anaemia; the white cell count was 3,200 per c.mm., 64 per cent. being lymphocytes.

The sternal marrow was more cellular than usual; it contained 30.4 per cent. lymphocytes and 22 per cent. primitive-looking lymphoid cells, probably lymphoblasts; the normoblasts were active, and mitotic figures were seen in the early types; the granulocytes were greatly diminished and no mitoses were present.

The patient was treated with iron and arsenic, and the anaemia improved. Six months later, on his own initiative, three teeth were extracted, and there was severe haemorrhage. However, two months later he had recovered quite well and his haemoglobin was 64 per cent. Throughout the period of observation the white cell count remained low, but the percentage of lymphocytes rose slowly to 91.

Case V

A "make-up" man aged 58 had a sudden attack of severe pain in the left hypochondrium radiating to the left shoulder. Two further attacks occurred during the next week. For a fortnight he was off work and was then admitted to hospital. Apart from the loss of 8 lb. in six months there were no other symptoms. On examination the patient appeared well nourished but rather pale; the conjunctivae showed no pallor. The spleen was much enlarged, extending to the left iliac crest; it was firm and tender in some areas. The liver was also enlarged. The inguinal lymph glands were definitely enlarged, and there were numerous soft, discrete, but not very large glands palpable in the axillae. No other noteworthy points were observed. The Wassermann reaction was positive (1 in 4) in the blood but negative in the cerebrospinal fluid. The blood count showed a slight anaemia; white cells were 12,400 per c.mm., 77.5 per cent. of them lymphocytes. The marrow showed increased cellularity, 64 per cent. of the cells being lymphocytes.

In view of the positive Wassermann reaction treatment with mercurial inunctions and potassium iodide was given for a time in addition to iron. The anaemia improved and the spleen diminished slightly, but the lymph glands became a trifle larger. During the eight months the patient has been under observation his condition has remained stationary except for slow enlargement of the inguinal lymph glands. The blood count also remains stationary.

Discussion

The first diagnosis in these cases was not usually lymphatic leukaemia: splenic anaemia, Hodgkin's disease, or some other condition was suspected. My own experience, and that of other workers, shows that while lymphocytosis of the bone marrow—that is, 50 per cent. or more lymphocytes—is typical of lymphatic leukaemia, it is not usually present in other conditions involving lymphatic hyperplasia. In Hodgkin's disease no lymphocytosis was found by Nordenson (1935) or by Bodley Scott (1939), who quotes several other similar reports. Of seven cases of lymphosarcoma Hynes (1939) found the marrow normal in six, but there were 61 per cent. lymphatic cells in the remaining patient's marrow. In a series of over 100 patients I have found lymphocytosis of the marrow in only two conditions besides lymphatic leukaemia; these are glandular fever and aplastic-type anaemias. In glandular fever the lymphoid cells in the marrow are increased—in one patient there were 55 per cent.—but if these are discounted all the other normal varieties of cells are present in their normal proportions. In aplastic-type anaemia there may be a marrow lymphocytosis of 70 per cent. or more; but this is only relative, and the raised percentage of lymphocytes is due to the decrease of all the other marrow cells.

Patients similar to those described here have been reported by Nordenson (1935), Schulten (1937), and Storti (1937). There seems, therefore, to be little doubt that the finding of lymphocytosis of the bone marrow is strong evidence that the patient has lymphatic leukaemia.

Clinically the patients fall roughly into two groups: an acute group (Cases I and II) with a fairly rapid course to a fatal termination, and a chronic group (Cases III, IV, and V) whose clinical and haematological condition remains stationary for long periods. In the acute group radiotherapy seems to be of little value; in the chronic group radiotherapy can be advantageously withheld for a long time, and, as in the somewhat similar myeloid leukaemia patients (Israëls, 1939b), treatment can be restricted to normal anti-anaemic measures so long as no severe anaemia occurs.

Summary

In patients with lymphatic leukaemia the sternal marrow shows a lymphocytosis even when the clinical signs and the peripheral blood pictures are atypical.

This lymphocytosis is strong evidence for the diagnosis of lymphatic leukaemia, since it is not usually found in other conditions.

The clinical course and the treatment of these atypical cases are briefly discussed.

I am indebted to Dr. John F. Wilkinson and the other members of the honorary staff of the Manchester Royal Infirmary who have made available the facilities necessary for this work.

Two new corporations have been established in Washington for the relief of war suffering in Great Britain and France. One body, the American Society for British Medical and Civilian Aid, will work for relief in Great Britain; the other, the American Society for French Medical and Civilian Aid, is designed primarily to provide funds for the American Hospital in Paris, which now has 500 beds. Funds for British aid, raised, as in the last war, by public subscription in the United States, will be converted into goods in America, and will then be dispatched, partly through the American Red Cross for military wounded and sick, and partly through the Personal Service League for civilian sick and wounded.

THE SPREAD OF RETROPERITONEAL EFFUSIONS ARISING IN THE RENAL REGIONS*

BY

G. A. G. MITCHELL, M.B., Ch.M.

(From the Department of Anatomy, University of Aberdeen)

Retroperitoneal effusions occur most commonly in the renal regions, and are the result usually of inflammation or trauma. The direction of spread of these accumulations depends on the arrangement of the fascia in the region, yet very few workers have ever attempted to determine accurately the fascial relations and attachments of the kidney. The really valuable contributions, such as those of Zuckerkandl (1883), Gerota (1895), Poirier (1907), and Southam (1922–3), can be counted on the fingers of one hand.

Experimental Investigations

In this investigation radiological methods were employed in addition to the usual anatomical procedures, and the observations are mainly based on the examination of twenty infants; many ordinary dissecting-room subjects have also been examined, though not by radiography. The method used was simple. A needle was inserted into the perinephric region through which a very fine barium emulsion was injected slowly under a pressure of about 75 to 100 mm. Hg. On an average each experiment occupied one and a half to two hours, and the spread of the emulsion was studied on the radiographic screen, plates being exposed at ten-minute intervals in most cases, or oftener if any interesting appearance was detected. After each experiment the specimens were dissected in order to determine accurately the position of the needle point and to establish that no barium had escaped into the peritoneal cavity, renal pelvis, or ureter. In twelve cases the needle point was in contact with the kidney or had penetrated or lacerated its surface, while in eight cases the point was in the paranephric fat behind the posterior layer of perirenal fascia. Seven experiments were failures and are not recorded.

The spread of the emulsion was remarkably constant. When the needle point lay close to the kidney in the perirenal space the barium emulsion, as shown by the shadow on the radiographic screen, soon assumed a more or less reniform appearance (Fig. 1), and it was established by subsequent dissection that the barium was outside the true renal capsule—between it and the perirenal fascia. At an early stage the space surrounding the suprarenal gland also became filled (Fig. 1), a graphic illustration of the fact that there is no complete fascial barrier, as some authors would have us believe, between the kidney and the suprarenal gland. Extension upwards was limited by the attachment of the perirenal fascia to the diaphragm, but the barium passed downwards, and to a lesser degree outwards, without any great difficulty. Sometimes there was an early spread downwards in the loose tissue around the ureter (Fig. 1), but more often the lower advancing edge of the barium covered a more extensive area. Laterally, as was established by dissection, the barium spread outwards to the level of fusion of the two layers of the perirenal fascia, but in a few cases the fusion was incomplete or the layers were readily disrupted, because the emulsion passed forwards for a variable distance between the transversus muscle and its fascia. Medially, strict localization to one side was a constant finding, the inner margin of the shadow being almost a straight line (Figs. 1 and 2). This unilateral spread was maintained until a late stage in the experiments, and then, often quite suddenly, a break-through occurred to the opposite side. This invariably took place in the lower lumbar region (Fig. 3). In five specimens no rupture occurred until the pressure was raised to over 200 mm. Hg, and in one case there was a break-through just below the diaphragm, but this did not happen until some time after the barium had broken through in the lower lumbar region. There was no indication of any tendency to spread upwards into the thorax through the various openings in and behind the diaphragm. Extension into the pelvis usually occurred with almost surprising ease in the loose retroperitoneal tissue, and in one case the barium passed downwards along the inguinal canal (Fig. 3). At first sight it appeared that the peritoneum must have been punctured and that the barium was distending a patent vaginal process, but dissection showed that the spread was in the extraperitoneal connective tissue and that the peritoneal sac was uncontaminated. In seven of the twelve cases in this group the barium spread *upwards* from the lower lumbar region around the inferior vena cava (Fig. 3), and it was curious and interesting to observe that in no case did the barium extend inwards alongside the renal or suprarenal vessels—an indication of the close attachment between the perirenal fascia and the adventitial coats of the vessels.

---

* Read in the Section of Anatomy and Anthropology at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

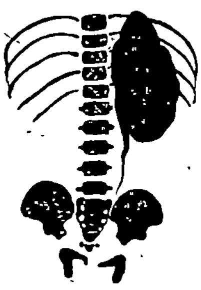

FIG. 1.

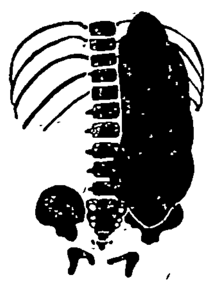

FIG. 2.

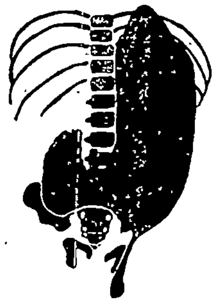

FIG. 3.

FIG. 1.—The barium emulsion has distended the space between the renal capsule and perirenal (renal) fascia. Note that the suprarenal compartment is also filled and that the barium has spread downwards in the loose periureteral tissue.

FIG. 2.—The barium has filled up the renal fossa and has spread downward to the pelvis. Note the strict unilateral localization, except in the lower lumbar region, where the break-through to the opposite side will occur.

FIG. 3.—The barium has broken through in the lower lumbar region and is extending upwards on the opposite side. Note the *upward* spread around the inferior vena cava, and the downward spread in the loose tissue surrounding a patent peritoneal vaginal process.

(These drawings are traced directly from the radiographs.)

When the needle point lay in the paranephric fat behind the posterior layer of perirenal fascia, the manner of spread was almost identical, except that diffusion appeared to be more rapid, the barium shadow did not outline the kidney and suprarenal, and there was no tendency to spread downwards along the ureter. The localization to one side was as distinct as before, and when extension to the opposite side occurred it did so in the lower lumbar region. There was still no invasion of the thorax, but there was less tendency to localization on the lateral side, the barium passing into the flank between the transversus muscle and transversalis fascia. Below, the barium passed between the iliacus fascia and muscle in several cases, and in one specimen it passed into the thigh postero-lateral to the femoral artery. The explanation of these results is to be found in the arrangement of the fascia.

Analysis of Results

Correlation of the experimental results with the appearances found on subsequent dissections has confirmed the general accuracy of Southam's observations, and it will be clear from the following brief description of the fascial arrangements why retroperitoneal effusions originating in the renal region should spread in the manner described above.

The kidney and suprarenal are surrounded by a loose investment of thinnish fascia, which is separated from the contained viscera by a variable amount of perinephric fat. This perirenal fascia consists of two layers: an anterior between the peritoneum and the renal capsule, and a posterior between the renal capsule and the fascia overlying the diaphragm, psoas major, quadratus lumborum, and transversus abdominis (Fig. 4). Poirier first cast doubts on the statement, still current in many textbooks, that the anterior layer extends across the front of the kidney and its vessels, to become continuous over the aorta and inferior vena cava with the corresponding layer of the opposite side, and he pointed out that perirenal suppuration remained localized to the side of origin, whereas it would spread readily to the opposite side if the anterior layers of perirenal fascia were continuous. He stated that the fascia can be traced as far as the pancreas and the root of the mesentery, there to become lost in the connective-tissue elements present in this situation, and Southam supports this statement. My experiments confirm the view that the two anterior layers are discontinuous, but they show that the anterior layers actually became attached to the bodies of the lumbar vertebrae and intervertebral disks a short distance in front of the attachment of the posterior layer of perirenal fascia (Fig. 4), and that this union is firm above but becomes progressively weaker as the lumbo-sacral junction is approached. The posterior layer is carried medially in front of the fascia covering the quadratus lumborum and psoas muscles, but separated from them by a variable amount of adipose tissue known as the paranephric fat. Near the mid-line, where the fatty tissue is less plentiful, the posterior layer merges with the psoas fascia, and also becomes attached to the sides of the lumbar vertebral bodies and intervertebral disks, immediately anterior to the origin of the psoas major (Fig. 4), but, like the anterior layer, the attachment is firmer above than below.

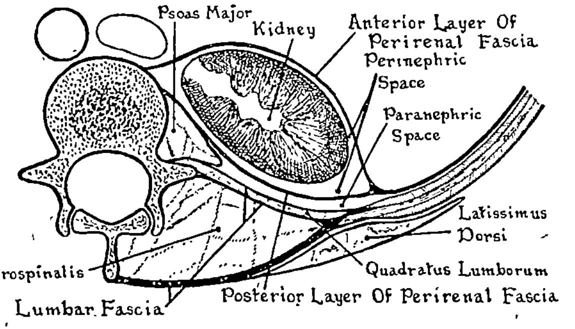

FIG. 4.—A transverse section to show the arrangement of the perirenal (renal) fascia and the perinephric and paranephric spaces. Note the attachment of the anterior layer of perirenal (renal) fascia to the bodies of the lumbar vertebrae.

Above, the perirenal fascia includes the suprarenal gland, a fact proved by the almost simultaneous filling of the renal and suprarenal loculi in the experiments (Fig. 5). This showed further that the fascial layer between the two organs is incomplete, or so tenuous in parts as to present no significant barrier to the spread of fluid. The anterior and posterior layers of perirenal fascia become fused above the suprarenal gland and gain attachment to the fascia on the under aspect of the diaphragm (Fig. 5), a union which is usually very firm, as Southam has emphasized. Laterally the two layers unite at a short distance from the outer renal margin, forming a vertical ribbon-like fascial condensation which merges with the transversalis fascia (Fig. 4). Southam states that this well-marked band is constantly present, but this is not so, either in infants or in adults; nor is the union laterally between the two layers always as firm as he asserts, for in some experiments the barium escaped without great difficulty from the perirenal pouch on the outer side. Inferiorly, as most writers state, the two layers remain discontinuous, the anterior gradually fading into the extraperitoneal tissue in the lumbo-sacral region, and the posterior blending with the iliacus fascia (Fig. 5).

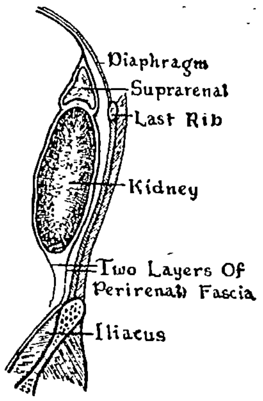

FIG. 5.—A sagittal section through the renal region showing the arrangement of the perirenal (renal) fascia.

Summary and Conclusions

A description is given of the spread of fluids: (*a*) from the perinephric space, included between the two layers of the perirenal fascia; and (*b*) from the paranephric space, lying between the posterior layer of perirenal fascia and the fascia overlying the muscles behind the kidney and the suprarenal gland.

The experiments detailed proved that there is no complete barrier separating renal and suprarenal fascial compartments.

It is shown that the spread is strictly limited to one side until a late stage, and that extension to the opposite side invariably occurs in the lower lumbar region.

Sometimes extension occurred downwards relatively early in the loose periureteral tissue, and invasion of the pelvis often took place with almost surprising ease. There was a tendency to *upward* spread along the lower part of the inferior vena cava, but no sign of invasion of the thorax through any opening in or behind the diaphragm.

The experiments proved that there is no continuity between the anterior layers of perirenal (renal) fascia on the two sides, and that these anterior layers, contrary to the usual description, gain a direct attachment to the lumbar vertebrae and intervertebral disks.

The experimental findings are correlated with those found at subsequent dissections, and a brief description of the arrangement of the fascia in the retroperitoneal regions is given.

I am indebted to Emeritus Professor A. Low and Professor R. D. Lockhart for permission to use the *x*-ray equipment in the anatomy department of Aberdeen University; and to Dr. Middleton Connon, radiologist to the department, for help in the interpretation of the skiagrams. The expenses of the investigation were defrayed by the Medical Research Council.

ADVANTAGES AND DISADVANTAGES OF ENDOTRACHEAL ANAESTHESIA*

BY

ROSALIND M. P. MILNE, M.B., Ch.B., D.A.

AND

J. ROSS MACKENZIE, M.D., D.A.

Department of Anaesthetics, Medical School, University of Aberdeen

This is a subject with which anaesthetists are familiar. We cannot pretend to add anything new except our point of view. Endotracheal anaesthesia has had a vogue. Within recent times it might even be said that in some quarters it had become fashionable and was used where simpler methods might have been equally efficient. There are surgeons who welcome endotracheal anaesthesia even when it is far from essential. And there are surgeons who are content, and even prefer, to work amid difficulties to themselves and dangers to the patient rather than have intubation anaesthesia. Both enthusiasm and prejudice have long been equally powerful impediments to the progress of medical science.

We consider that the routine application of the same anaesthetic agent or the same method of its administration in a series of surgical cases without regard to the condition of the patient or the work of the surgeon is quite wrong and cannot be defended on scientific grounds. From the anaesthetist's point of view there is a definite group of surgical cases in which endotracheal anaesthesia is essential to the safety of the patient.

Advantages of Intubation

It is our intention merely to note some of the advantages that specially appeal to us in endotracheal anaesthesia. By means of intubation the anaesthetist is, once and for all, rid of the dead space of mouth and pharynx, as well as the essential factors in reflex respiratory spasm —the glottis and anoxaemia. As a result of intubation we have the perfect airway which is not affected by the mechanics of the dead space. Thus we have at all times absolute control of the depth of anaesthesia with the expenditure of a minimum of anaesthetic agent.

In the surgery of the upper abdomen and of the pelvis the advantages of intubation anaesthesia are often very conspicuous. The patient and the operation table, except the operation area, are completely covered with sterile sheets. The respiration is shallow and the recti are completely relaxed. The expenditure of energy by the patient is reduced to a minimum, and in prolonged operations, such as gastrectomies, splenectomies, and hysterectomies, strength can be maintained by artificial respiration with oxygen until transfusion of blood or gum saline has been accomplished. We are convinced that in prolonged and difficult operations with severe surgical shock and loss of blood many patients can be saved and others protected against a stormy convalescence by means of endotracheal anaesthesia.

---

* Read in the Section of Pharmacology, Therapeutics, and Anaesthetics at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

In the repair of a cleft palate where a pharyngeal ridge has been prepared in an attempt to close the nasopharyngeal space from the oropharyngeal space during speech it is essential that an endotracheal tube should be passed through the glottis either before or after operation, and should be left *in situ* for twelve to twenty-four hours to tide the patient over the period in which acute oedema of the glottis may occur. Some cases have been lost on account of supervening oedema and others have been saved by an immediate tracheotomy. The presence of an endotracheal catheter in the glottis for twenty-four hours does not necessarily render the patient free from the danger of oedema of the glottis, but in the vast majority of cases in our experience this protection has been adequate. Intubation is the ideal type of anaesthesia for oral surgery, and with a gauze pack saturated with liquid paraffin forms an effective barrier against foreign bodies or septic material reaching trachea or bronchi.

In cardiac surgery generally, but particularly in such proceedings as cardio-omentopexy, intubation anaesthesia with differential pressure is a very great advantage to the patient and to the surgeon. A pressure of 10 mm. Hg is kept up until the phrenic nerve has been crushed, when the pressure is allowed to drop to 5 mm. Hg. This fall in pressure allows the paralysed leaf of the diaphragm to come into view. As soon as the omentum is coupled to the heart muscle and the incision in the diaphragm closed the intrapulmonary pressure is raised to 10 mm. Hg, and this pressure is maintained to the end of the operation.

In cervical sympathectomy where an accidental pneumothorax may occur, and in excision of the oesophagus, the use of some kind of intrapulmonary pressure is essential. It is a great advantage in such cases to be able to maintain positive intrapulmonary pressure for several hours after the patient has returned to bed. This can be done by means of a stream of oxygen through the endotracheal tube left *in situ*, and helps to prevent the very considerable risk of post-operative atelectasis. Intubation permits of a highly efficient method of artificial respiration in cases of sudden collapse on the operation table.

Disadvantages of Endotracheal Anaesthesia

Certain sequelae may occur as the result of the passage of a tube through the glottis into the trachea. Granulomata on the vocal cords are not very uncommon and have been reported by R. J. Clausen (1932) and by Blair Gould (1935). Tracheitis may result from a hard tube impingeing for a period on the same area of the tracheal mucous membrane, and this is aggravated by a constant stream of irritating anaesthetic vapour on this area. Laryngitis and tracheitis are apt to occur if for any reason the tracheal tube is left *in situ* for several hours after the operation. Trauma to the nasal passages as evidenced by haemorrhage followed by adhesions and scarring is not so very infrequent. Laryngitis with loss of voice in some degree arises in a number of cases, and instances have been reported by Dawkins (1936). Is there anything that we anaesthetists can do to prevent these complications? They occur more often in nasal than in oral intubations. Coughing and spasm of the glottis following the passage of a tracheal tube result in most cases from an insufficient depth of preliminary anaesthesia, local or general, and may cause damage to the glottis.

We are of the opinion that blind intubation should be done only in the rare cases where direct vision cannot be employed because of deformities of the neck, lips, tongue, teeth, or pharynx. Blind intubation was used in the majority of reported cases of trauma to the nose and of laryngitis and granulomata of the cords. We consider that blind intubation should never even be attempted if direct vision can be employed, because it is a haphazard method of performing an operation which can be done with precision. We are convinced that oral intubation is the route of choice even in cases of oral surgery, provided the tracheal tube does not seriously hamper the work of the surgeon, and that in nasal intubation the catheter should be picked up in the pharynx with a forceps and passed through the glottis under direct vision.

The tendency in the modern teaching hospital is for a still larger proportion of the surgical cases to be done under expert methods of anaesthesia. The demands of patient and surgeon for the anaesthetic agent and the method of its administration at once safest, most efficient, and least likely to disturb convalescence or in any degree to initiate post-anaesthetic complications are opposed to the claims of the undergraduate. It is essential that the medical student, in his own interests as well as those of the public, should be taught methods of efficient anaesthesia which require simple apparatus and portable agents. There can be no doubt that a considerable percentage of the anaesthetic mortality of to-day can be traced to the inexperience of the administrators. Neither the patient, the surgeon, the undergraduate, nor the science of anaesthetics need be wholly sacrificed. Our own practice (Mackenzie, 1932) has been as follows. If the condition of the patient or the nature of the operation demands expert methods of anaesthesia, then the undergraduate must not be considered; but a balance is struck in his favour in all surgical cases in which simple and portable agents, such as ether, or ethyl chloride and ether, or even chloroform, can be used with safety to the patient and comfort to the surgeon.

Reports of sequelae would appear to have deterred both anaesthetists and surgeons from subjecting their patients to endotracheal anaesthesia. An analysis of 1,253 cases of endotracheal anaesthesia with Magill's rebreathing tube at this school during the past eighteen months—1,103 in adults, 150 in infants and children—shows that convalescence is uniformly good and compares favourably with that following other methods of anaesthesia. None of the cases has exhibited any of the sequelae which have been reported.

We believe that certain precautions in the technique of administration will do much to prevent these sequelae. These precautions are: (1) Suitable length and bore of endotracheal tube for the individual patient. The tube must not reach near the bifurcation of the trachea lest it enter either bronchus, with consequent collapse of the other lung. The bore of the tube should be such that it will not be in constant contact with the vocal cords. (2) Lubrication of the endotracheal tube with sterile paraffin wax or with a 10 per cent. percaine base ointment.

(3) Application to the nose and pharynx of a 10 per cent. or 20 per cent. cocaine spray combined in equal parts with ephedrine. (4) Careful lubrication of nasal passages with sterile liquid paraffin. (5) Intubation to be done, apart from exceptional cases, by direct vision.

A PLEA FOR BETTER ENDOSCOPIC TRAINING*

BY

G. EWART MARTIN, M.B., Ch.B., F.R.C.S.Ed.
Surgeon in Charge of the Ear, Nose, and Throat Department, Royal Infirmary, Edinburgh

Great advances have been made in the field of thoracic surgery within the last few years, and the operative risk is being reduced to a minimum. There is now a possibility of eradicating malignant disease of the lung, but operative measures must fail unless the disease is recognized early. The clinical diagnosis of primary carcinoma of the lung lies in the hands of the bronchoscopist.

For the last five years the records in the department under my charge in the Royal Infirmary, Edinburgh, and my own private records for the same period, include thirty-four cases of malignant disease of the lung diagnosed bronchoscopically, and of these one patient is alive over a period of two years and three over a period of one year. In every case the final diagnosis was made too late for operative intervention. The implantation of radium and radon seeds has been tried without success. *X*-ray therapy has as yet failed to cure, although it has in some cases retarded the progress of the disease. During the same period in the surgical and medical wards of the Royal Infirmary, Edinburgh, 182 cases (apart from those mentioned above) have been diagnosed as carcinoma of the bronchus, either clinically and radiologically or after a post-mortem examination. None of these was referred to the bronchoscopist for confirmation of the diagnosis. Operative intervention was not considered possible. *X*-ray treatment was tried in many cases without any cure.

It would seem either that there is a lack of co-operation between the physician and the bronchoscopist, or that patients are too late in reporting to the physician for treatment. Early symptoms may be overlooked, but if there is a suspicion of the presence of malignant disease reference should be made to the bronchoscopist for diagnosis. The physician in the past has tended to rely for confirmation on *x*-ray findings. A commencing carcinoma of the bronchus which could be revealed on bronchoscopic examination may show clinically only as an occasional haemoptysis and not at all on the *x*-ray film. To wait for a shadow on an *x*-ray plate before completing the diagnosis may be rendering operative eradication of the disease impossible. Thus the onus of early diagnosis rests with the bronchoscopist to whom the case is referred. Is our endoscopic training sufficient to justify this responsibility?

The Advance of Endoscopy

Twenty years ago the possibility of examining the inside of the lung was unknown to many. When Chevalier Jackson spoke at a meeting at Bath in 1925 only a few laryngologists possessed the necessary armamentarium for bronchoscopy and still fewer had the experience. The science of endoscopy has advanced rapidly. It is recognized by the physician as a definite practical means of diagnosis, but yet it seems that this form of diagnostic examination has not been developed on wide enough lines.

In America endoscopy has been established as a branch of laryngology, but has also been developed on lines apart from its mother specialty. There is a bronchoscopic clinic attached to a great many of the larger hospitals where cases can be referred for diagnosis and treatment. In this way operative training can be obtained, as well as the practical experience necessary for efficient diagnosis. Many from this country have taken advantage of the training offered in these clinics and have afterwards developed a specialty of bronchoscopy on their own lines, but always as a part of oto-laryngology. Cases referred for bronchoscopic examination have to take their turn with all the other cases of a busy oto-laryngological department.

Establishment of Central Endoscopic Clinics

Financially the establishment of similar clinics in this country is impossible until State medicine presents a Utopia where work would be the first consideration—the State supplying the means to live. It might be possible, however, for the several oto-laryngological departments, say in one town or in one area, to combine to form a central endoscopic clinic to which cases could be referred direct on specified days. This would allow of the segregation of the endoscopic from the purely oto-laryngological cases. More time could be given to these cases, and those working in that department would therefore gain more experience and obtain a better training. The necessary armamentarium could be enlarged instead of being so often a bare minimum, and special beds might be available.

A precedent for such clinics already exists in the formation of orthopaedic clinics and neurosurgical clinics in the department of surgery. In some centres thoracic surgery is being established as a specialty. There it might be possible to develop endoscopy and thoracic surgery side by side. The need for early and efficient diagnosis no longer allows of a place for the occasional bronchoscopist.

Unfortunately in this country we are unable to establish training centres such as exist in America and Paris, where operative technique can be taught on the cadaver and living animals, such as dogs. Here we can learn to pass the bronchoscope on the cadaver; but owing to various Home Office regulations we can only pass a bronchoscope on living animals under licence, using a general anaesthetic. If we employ a local anaesthetic we lay ourselves open to outside criticism, although it has been demonstrated that the bronchoscope can be passed without pain or harm to the living model.

There can be no doubt, however, that greater experience could be obtained and teaching be benefited if we had specialized centres instead of numerous small clinics. We have a great opportunity for the organization of endoscopic centres in the hospitals given over entirely to diseases of the chest (apart from phthisis). In these hospitals the physician carries out his own bronchoscopy as part of his routine examination. It must be remembered, however, that no bronchoscopy should be performed without thorough preliminary examination of the nose, nasopharynx, and larynx. The truth of this precept, which has been emphasized by Chevalier Jackson, has been borne out in my own experience. Many cases referred to my department as bronchiectasis have proved on examination to be chronic bronchitis with some dilatation of the bronchi secondary to a post-nasal discharge as the result of an ethmoid infection with nasal polypi, or an antral infection. The elimination of the cause has very often cleared up the chest condition without the necessity for endoscopy.

---

* Read in opening a discussion in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

The Practice of Bronchoscopy

Unfortunately there is a tendency in this country to consider bronchoscopy a difficult operation requiring the aid of a specialized anaesthesia, whereas it is a simple though specialized examination of the oesophagus and the lower air passages with a view to aiding the physician or thoracic surgeon as cystoscopy aids the abdominal surgeon. The operative field of bronchoscopy and oesophagoscopy is practically limited to the removal of tissue for pathological report and the removal of foreign bodies. The removal of a foreign body is attempted by many without much previous training, and yet all of us who have worked with Chevalier Jackson know that his removal of a foreign body from the bronchus in thirty seconds required hours of practice before the operation, to make certain that his eye, hands, and forceps were perfect.

This practice can be obtained quite effectively by the use of a mannikin in which one can reproduce the position of the foreign body seen in the radiograph and practise its effective removal. Fortunately, perhaps, in this country very few cases of foreign bodies in the bronchus occur. Why there should be this difference from other countries has never been explained, although it suggests that our diagnosis is incomplete—another plea for closer co-operation between physician, radiologist, and bronchoscopist.

Summary

To sum up, the need for earlier diagnosis of carcinoma of the bronchus must be recognized by everyone. In recent publications the thoracic surgeon has proved that mortality in chest surgery is almost negligible. The deep *x* ray therapist has to admit failure. In a few apparent cures the presence of malignant disease has been demonstrated by only *x* rays—the findings have never been histologically confirmed. In other words, the case has never been referred for endoscopic diagnosis. It would therefore appear that the bronchoscopist must give the initial and final diagnosis, and then, along with the radiologist, judge which cases might be referred to the thoracic surgeon with a hopeful operative prognosis. The need for training and for co-operation is very evident. Training and co-operation are impossible unless endoscopic cases can be centralized to special departments. Whether this department should remain under the specialty of laryngology or become a branch of thoracic surgery may yet have to be decided. Personally I cannot envisage an endoscopist who is not a trained laryngologist.

Ozaena.—According to Halász, ozaena is caused by lack of a "tonsillar hormone" which is similar to acetylcholine. A method of treatment is described.—Some New Data concerning Pathology and Treatment of Ozaena. H. G. Halász.—*J. Laryng.*, May, 1939, **54**, No. 5, 245.

Clinical Memoranda

Multiple Fractures without Patient's Knowledge

The following case is worthy of record as one in which multiple fractures of several long bones occurred without the knowledge of the patient.

CASE REPORT

A married woman aged 64 was admitted to the Buxton Clinic for Rheumatism and Allied Diseases on July 20, 1937. She gave a history of pain in the muscles of the back, the ribs, shoulders, and arms for about five years; the pain was always worse in winter. In August, 1936, she knocked her right leg, which became very swollen and painful; the diagnosis was inflammation of the bone. In 1914 she had a great deal of pain in the legs, and red blotches and lumps, which lasted for months, appeared. Apart from an operation for gastric ulcer in 1926 she had been healthy all her life. Her father, mother, and sister had suffered from rheumatism, but otherwise the family history was of no medical interest; she had had seven children.

When admitted she had been using crutches for six months, and complained of stiffness and pain in the arms, legs, and back; that lifting weights hurt her; and that slight knocks produced pain. On examination the movements of the joints were good; the right tibia was bowed, and there was deformity and unnatural mobility, accompanied by pain in the upper third of the right tibia. The bones and muscles of the left leg below the knee were very tender on palpation, the trochanter of the left femur was thickened and tender, and nodules were palpable on the left ulna and the ribs in the left axilla. Apart from some myocardial degeneration the circulatory system was normal. The blood pressure was 190/120. The sclerotics were not blue and there was no deafness.

X-ray examination revealed fractures, sometimes multiple, in most of the long bones: the right ulna had three fractures and the left a single one, the radii being intact but very porotic, with only a faint cortical outline; the right tibia and fibula showed fractures about six inches below the knee-joint which had united at an angle of about 160 degrees; the right fibula had also been fractured above the ankle. The left tibia showed a fracture below the knee-joint, and several fractures were observable in the middle and lower thirds of the fibula. There was a fracture in the neck of the right femur, while the left one was intact but porotic; the hip-joint spaces were slightly narrowed. The pelvis was malacic in type, with a flattened cavity and symmetrical fractures of the inferior rami of the ischii. The vertebrae were somewhat decalcified, but the joints were clear and there was no evidence of ligamentary calcification. The skull was normal.

The fractures had healed in most instances without the formation of the normal amount of callus, the union being apparently of a fibrous nature.

Laboratory Examinations.—Serum calcium, 9.1 mg. per 100 c.cm.; magnesium, 2.2; inorganic phosphorus, 3; phosphatase, 0.89 units (normal, under 0.25); icterus index, 2 units. Suspension stability after one hour, 89 per cent.; red cells, 4,900,000 per c.mm.; white cells, 7,700 per c.mm.; haemoglobin, 62 per cent.; colour index, 0.63; polymorph neutrophils 63 per cent., eosinophils 2 per cent., small lymphocytes 23 per cent., large lymphocytes 6 per cent., monocytes 6 per cent. Urine (twenty-four-hour sample): total nitrogen, 6.2 grammes; P_2O_5, 1.17 grammes; calcium, 0.103 gramme; magnesium, 0.084 gramme. No alkaline tide could be found, and the patient was therefore probably achlorhydric.

At the date of the examination the patient was not excreting an abnormal amount of calcium in the urine, and the Ca:P of the blood was not sufficiently subnormal to account for the malacic condition of the bones. It must be concluded that the activity of the disease process responsible for the osteomalacia had ceased, and no explanation of its aetiology can be suggested. The patient was placed on a diet rich in calcium and vitamins, supplemented with concentrates, and was kept at rest in bed. She was discharged on August 3, 1937, to her home, and advised to continue with a rich vitamin diet reinforced with A and C concentrates. On May 31, 1939, she reported that she was very well, had no pain, and could walk up and down stairs without help, although she used a crutch at times as a precautionary measure.

The condition was evidently an osteomalacia of unknown origin so active as to produce a bone picture indistinguishable from fragilitas ossium.

I am indebted to Dr. J. A. Harburn for permission to publish this record, and to Mr. J. Race, biochemist to the Devonshire Royal Hospital, who undertook the laboratory investigations.

Eleanor O'Donovan, L.M.S.S.A.Lond.,
Late House-physician, Buxton Clinic for Rheumatism and Allied Diseases.

A Case of Hydatid Disease

The incidence of hydatid disease is so rare in this country that the following case is worthy of notice.

Case Report

The patient, a man aged 72, consulted me in May, 1939, and stated that he had been "in poor health on and off for over thirty years." On interrogation he said that he had noticed the passage of small grape-like structures in the urine every spring and autumn since 1900, and that for the past two years he had suffered from periodic attacks of abdominal pain, unrelated to the intake of food and not relieved by any medicine or powder which he apparently had been in the habit of taking. Specimens of urine were submitted to the Clinical Research Association Ltd., and the following laboratory report, dated March 14, 1903, was obtained.

"The specimen received March 13, 1903, has been examined. The centrifugalized deposit from the urine contained traces of pus and blood, with a good many vesical squamae and a very small number of calcium oxalate crystals. The specimen contained in the urine was an entire hydatid cyst, and in the fluid within it both scolices and large numbers of the characteristic hooklets were found."

On August 8, 1939, the patient coughed up a tablespoonful of blood and complained of some dyspnoea on exertion; the left side of his chest was absolutely dull on percussion and the heart was so displaced to the right side that the apex beat was palpable in the right sixth intercostal space. From that date his dyspnoea gradually increased and he had occasional slight haemoptyses. Two months later he died, and a post-mortem examination was conducted by the county pathologist.

Pathological Report.—The left pleural cavity was full of semi-purulent fluid and contained a number of large lens-shaped hydatid cysts. Owing to the intrapleural pressure the left lung was completely collapsed and there was a purulent secretion in the bronchial tubes. The right kidney was hypertrophied but otherwise normal. The left kidney tissue had been replaced by a large number of hydatid cysts about the size of marbles; some contained cloudy fluid, some were full of caseous material, and a few were calcified. The left ureter was intact and, apart from some thickening of its walls, appeared normal. Two coils of small intestine were firmly adherent to the capsule of the left kidney, and were probably responsible for the spasms of abdominal pain from which the patient had suffered for two years. No other organ showed evidence of hydatid disease.

Reviews

THYROID DISEASE

The Diagnosis and Treatment of Diseases of the Thyroid. By James H. Means, M.D., and Edward P. Richardson, M.D. (Pp. 367; 51 figures. 21s. net.) London: Oxford University Press. 1939.

The thyroid gland is sufficiently obvious to have given rise to comment through the ages both in medicine and in art. But there is no doubt that environmental conditions lead to much variety in manifestations of thyroid affections in different countries. Drs. Means and Richardson have collated the experiences of the Thyroid Clinic of the Massachusetts General Hospital on the patients under their care since the institution of the clinic in 1913, and at the same time have filled in the background of the various conditions of thyroid disease by a summary of present-day knowledge. It may be said at once that the case histories and personal experiences are of much greater value than the general comment, which often appears to be undigested. This may be because there is still much more to be known of thyroid disease.

Thyroid function in health is that of a catalytic process accelerating oxidative processes in all tissue cells, and increasing especially the nitrogenous, respiratory, and inorganic salt metabolism. The source of the thyroid hormone is not clear, and a purely pathological classification according to changes in parenchyma, colloid, or stroma is not yet attainable. Certain clinical entities in which these several changes may occur are recognizable, though there is a gradual transition from diffuse colloid goitre, adenomatous goitre, and exophthalmic goitre, so that there are many intermediate forms. It is perhaps too early to recognize one form of hyperthyroidism with partial advances and regressions; the authors do not attempt this synthesis.

After a general chapter on the principles of diagnosis and treatment of thyroid diseases, embracing notes on the anatomical relations of the gland and the methods of examination at the bedside, the various operative procedures and possible post-operative complications, the authors discuss systematically the types of enlargement and excessive or diminished activity of the gland. Colloid goitre is a common malady. Its most striking feature is its geographical distribution; in general the regions that are goitrous are geologically either mountainous or old glacial areas, though it may occur sporadically in non-goitrous districts. It is held to be associated with deficiency of iodine; but the lack of iodine is relative, not absolute, and may be brought about by infection. Symptoms are non-existent, but there may be associated over- or under-function of the thyroid, resulting in thyrotoxicosis or myxoedema.

The authors approach the subject of exophthalmic goitre from the clinical side, the diagnosis being usually apparent. A long discussion of the pathology follows but is without conclusion or value. They find that evidence in support of the pituitary hypothesis of exophthalmic goitre is negative: there is little reason to maintain that the pituitary is hyperfunctioning in ordinary cases of exophthalmic goitre. To English views the artificial separation of cases of exophthalmic goitre from toxic adenoma is not satisfactory, and the authors themselves comment on the intermediate cases. There is a distinct improvement in the firmness of writing and soundness of judgment in the authors' statement on treatment and the description of actual case histories. But the chapter on adenomatous goitre is unclear, including as it does the conditions we recognize as toxic adenoma or secondary thyrotoxicosis and the true adenoma, foetal adenoma, which can only be treated satisfactorily by surgery. And this chapter is separated from that on tumours, especially malignant tumours, of the thyroid by descriptions of myxoedema and cretinism. The book is therefore variable in its clarity and appeal, representing an individual attitude. This may have been aimed at as an expression of the opinions of the gifted workers at the Massachusetts General Hospital. Some of the authors' expressions are infelicitous, but these do not seriously detract from an honest attempt to clear the ground for what may in time be a useful description of thyroid diseases.

THE ORIGIN OF LIFE

Life's Beginning on the Earth. By R. Beutner, M.D., Ph.D. (Pp. 222; 80 figures. 12s. 6d. net.) London: Chapman and Hall. 1939.

After Wöhler in 1821 broke down the barrier between organic and inorganic chemistry, science took up the question, hitherto only answered by mythology, of the origin of life. The doctrine of spontaneous generation from putrefaction and fermentation had considerable support until overthrown by Pasteur, and even then lingered on into the eighties of last century. For a good many years after that, although the battle for and against vitalism continued to rage, both sides in that combat seemed to lose interest in the origin of life itself, so fully occupied were they in investigating its phenomena. Now that vitalism is in full retreat and biochemistry is rapidly advancing it is not surprising that the old problem is rising again in a new form. Dr. Beutner's book *Life's Beginning on the Earth* is an interesting contribution to the study of that problem, though the author does not seem quite to have made up his mind whether he is writing for a scientific or for a popular audience.

As he points out, the hypothesis that life was sprayed on to the earth by some passing meteorite is no solution, since it merely throws the question a step further back. He starts with a comparison between vital growth and crystallization, quoting some curious observations of Pfeiffer on the modifications produced in the shape of crystals by the addition of plant juice. Thus the addition of a single drop of an extract of water-lily to a solution of copper chloride causes the subsequent crystallization to imitate the shape of a water-lily. Evidently chemical influences help to determine the familiar shapes of living tissues and can be conveyed to lifeless material. Pfeiffer is now trying to apply this method to the recognition of the toxins formed in disease, but so far his deductions are decidedly speculative. Our author calls attention to many other interesting simulations of vital structures by dead matter, including the amoeboid movements of oil-drops. This merely shows that organic and inorganic material obey similar physical and chemical laws, and prepares the way for his thesis that crystallization is compatible with life, as demonstrated by W. M. Stanley's success (1935) in crystallizing the virus which produces the mosaic disease of the tobacco plant. Even if the crystallization of the virus is repeated ten times its activity in producing the disease is unimpaired. The outstanding property of living matter is the ability to grow and propagate itself in an environment different from itself, and a virus is capable of transforming its food material and of propagating itself so long as there is suitable food available. And yet it is a chemically pure substance, as evidenced by its capacity to adopt crystalline form. It acts like an unorganized enzyme, and is certainly not cellular. He thinks that this is the simplest thing which can be called alive, and that once such a self-regenerating enzyme has arisen the ordinary processes of differentiation by evolution could start. His suggestion as to the way in which such an enzyme originated from the substrate of carbon compounds formed during the cooling of the earth may strike us as highly speculative, for he invokes the aid of lightning, relying on Haber's work on the organic compounds formed by the passage of electric discharges through carbon-containing gases.

Dr. Beutner quotes Oparin's interesting speculations (1938) based on the reasonable assumption that as the boiling-points of carbon and heavy metals are extremely high they would be the first to solidify as the earth began to cool, with the formation of carbides. In the presence of overheated steam vapour interactions between carbides and steam would result in the production of enormous amounts of hydrocarbons. This, by the way, is a cheering thought, suggesting that we are by no means dependent merely on the coal-measures for our supplies of the mineral oils of which we are now so prodigal. The atmosphere of the earliest earth must have contained large amounts of ammonia, and this interacting with the primary carbon compounds would lead to the production of amino-acids, the basic constituents of protein. The chemistry sounds plausible, but we should like more evidence concerning the " vital spark."

PHOTOGRAPHY OF THE FUNDUS

Atlas Clinique d'Ophtalmoscopie Photographique. Syndromes Cliniques du Fond de l'Œil. By Henri Tillé and A. Couadau. (Pp. 194; 202 figures. 280 fr.) Paris: Masson et Cie. 1939.

There is something peculiarly attractive in an atlas of fundus drawings of the human eye. Many of these are real works of art, as well as treasures of observation and careful record. To mention only one of many of these atlases, that of Adams Frost might be taken as a perfect example of what can be done and has been done in this regard. These former atlases were full of pictures in colour reproduced by lithography or colour photography from drawings made by the observer. He looked into the eye with his ophthalmoscope and first drew outlines of what he saw as accurately as he could, and then coloured it to make it as nearly like the actual fundus as possible.

To-day a new fashion has come into vogue. Direct photography of the fundus is the aim. A fine atlas of such photographs has been published in France by Henri Tillé and A. Couadau. It contains no fewer than 202 figures—photographs of all sorts of fundus conditions. The skill of the photographers is shown in the size of the pictures, many of which measure six inches in diameter, and in all there is a complete absence of the white patches which were such a trouble in the early photographs. Every photograph has a clinical note of the case or of the condition, and the name of each is given in both French and English.

As an example of fundus photography this atlas represents a triumph of industry and skill on the part of its producers. But when we come to consider it as a record of fundus appearances it must be confessed that it is sadly disappointing. The photographic picture is as little like the appearance of the fundus as seen by the eye of the observer with an ophthalmoscope as a smoke-grimed cellar of a boiler-house is like the vivid picture of a sunlit landscape. In truth, the contrast is greater, for not only are the photographs in dull black printing-ink instead of in the real colours of the fundus, but there is in all of them an entire lack of that marvellous definition and clearness of outline and detail which are seen in most fundus observations—indeed, in all save those where the media of the eye are clouded. The photographs are blurred in outline and consequently convey a very poor impression of the real fundus appearances.

It is right to try to secure photographs of the fundus. If good photographs could be obtained they would allow of records being made at successive periods in cases where it is desirable or necessary to secure a greater accuracy of definition than can be presented by the artist. But for educational purposes, for teaching medical students what they should see with an ophthalmoscope, we doubt if photography will ever be able to compete with the work of the artist, and particularly with the work of the ophthalmic surgeon who is himself the artist. Nevertheless, we repeat that as an atlas of fundus photography this book is a great piece of work and is a credit to its authors.

A STUDY OF GESTURE

The Language of Gesture. By Macdonald Critchley, M.D., F.R.C.P. (Pp. 128. 5s. net.) London: Edward Arnold. 1939.

Dr. Macdonald Critchley has followed Bacon's injunction to study "The Doctrine of Gesture or the Motions of the Body with a view to their Interpretation." He has cast his net wide and collected information from differing ages and races, with some interesting results. He concludes that gesture can be broadly divided into two main groups. The first are symbolic, conventional, or empirical gestures which require interpretation; these are utilized for obvious reasons by members of secret brotherhoods, and in the language of religious symbolism. The second is composed of those signs which bear an obvious interpretation, age-old and universal; they constitute a silent *lingua franca* within the comprehension of all and can readily express emotion but not abstractions. They often need reinforcement by a number of empirical signs really belonging to the first category. Such a hybrid sign-language is found in the gestural systems of the deaf and dumb. Both these types, symbolic and instinctive, are of great antiquity, but the latter are more primitive and fundamental, often falling within the comprehension of animals, of young children before the acquisition of speech, and of mental defectives. Gesture, then, is a kind of italicized speech, while pantomime is silent acting.

On the way to these conclusions we are led along several pleasant by-ways, such as the distinction between voluntary though instinctive gestures and the involuntary emotional expressions of the autonomic nervous system, the relation of gesture to the origin of speech, and the evolution of drama from emotional expression in the dance, now sophisticated into the ballet. For the medical man perhaps the second of these topics has the most direct appeal, since he finds the speech centre so closely linked with that for the gestures of the right hand. The two hypotheses of the origin of speech were flippantly labelled by Max Müller the "bow-wow" and the "ding-dong." The first corresponds to the theory of onomatopoeia and the second to Sir Richard Paget's view that all speech is an elaboration of buccal-labio-lingual gesture. This approximates to the "yo-heave-ho" hypothesis, according to which speech is the outcome of man's muscular exertions in which the laryngeal muscles share. Dr. Critchley does not express any opinion on the theory that it is an early but temporary activity of an originally bilateral speech centre which accounts for the reduplicated syllables of a child's first verbal utterances—"da-da," "mam-ma," "nan-na." This finds expression later on not only in the "cocky-locky, henny-penny" tautology of nursery literature, but in a good deal that has recently been written presumably for adults.

STRUCTURE BY THE LIGHT OF FUNCTION

Anatomie Générale. Origines des Formes et des Structures Anatomiques. By H. Rouvière. (Pp. 192; 96 figures. 70 fr.) Paris: Masson et Cie. 1939.

The trend of this work on "general anatomy" and "the origin of form and anatomical structure" is, as these terms imply, the treatment of anatomy and development from the general standpoint rather than from the particular. Thus the structural details of any particular part are considered simply as illustrating general principles, such as the dependence of structure partly on heredity and partly on function and also the influence of physical and chemical factors. The author shows how development occurs by differentiation which is dependent on characters transmitted in the germ but which only become manifest at different stages in ontogeny. He demonstrates that differentiation of tissues or organs is usually in advance of the special functions which each tissue or organ will at a later stage of development be destined to perform. Thus muscle fibres and glands are developed before contraction or secretion occurs. With reference to these observations, he discusses the problem of how certain somatic changes induced by pressure or other causes have become inherited—for example, the sternal and pubic callosities of the ostrich, which are developed before the chick is hatched—or the orientation of the bony trabeculae, in the lower and inner part of the neck of the femur of young infants, in the same directions as in the adult; that is to say, following the lines of pressure and strain which the bone is subjected to in the adult, although in the young infant the bone is not yet subjected to these forces.

Professor Rouvière in successive chapters discusses such topics as the mechanisms by which bony ridges or depressions are produced; the articular expansions at the ends of a long bone; the arrangement of fibres in ligaments and tendons; the direction of muscle fibres, and the relation of tendinous intersections in muscles to their nerve supply; the reasons for the presence or absence of elastic fibres in ligamentous bands; the structural variations which exist in the walls of arteries, veins, and lymphatics, and the nature of fissuration and lobation of such organs as the lungs and liver and in the kidneys of certain animals.

The book is a philosophical treatise of great value; it gives a mechanical explanation and a precise meaning to many details of anatomical structure, and it should be read by all those who are interested in evolution and inheritance, and the correlation and dependence of structure on function.

Notes on Books

The Primer of Allergy, with its subtitle "A Guidebook for Those who Must Find their Way through the Mazes of this Strange and Tantalizing State," is intended for the patients, and not for the instruction, of the medical practitioner. But it differs from most publications designed for lay consumption in more respects than one. It is written by the author, Dr. WARREN T. VAUGHAN, of an exhaustive and serious treatise on the *Practice of Allergy* (reviewed in our issue of November 4); it came out at the same time as the professional work, and supplies in a light and bright dress the information given for the patient's guidance in the earlier editions of this treatise. It is indeed a rather unusual gift to be able to address two different audiences with equal success. The author has felt the want of such a book to hand to patients, and probably many medical practitioners will find their time can be saved by recommending this *Primer* to their allergic patients. It is published at 7s. 6d. by Henry Kimpton.

There are many excellent textbooks of gynaecology, and to justify its publication a new one should make some worth-while contribution to the subject. Written primarily for final-year students at Sydney, Dr. HERBERT H. SCHLINK'S *Gynaecology* (London and Sydney: Angus and Robertson; 32s. 6d.) records the teaching and practice at the Royal Prince Alfred Hospital, but contributes little that is new. Many excellent results are claimed, but the methods used are not always those generally adopted, as, for example, the performance of a Wertheim hysterectomy for carcinoma of the body of the uterus. A major criticism of the book is that alternative methods, even though widely practised elsewhere, are often not mentioned. Endocrinological aspects of the subject are for the most part not well discussed, and the author's experience of hormone therapy has been unfortunate. The need for a sound pathological background is well stressed, and throughout the book pathology is simply described and well illustrated, though on two occasions (Figs. 64, 65) the key to the illustration has been omitted. The chapter dealing with the examination of the patient and ethical problems is filled with excellent advice and may be compared to the pearl in the oyster.

Dr. RODERICK HEFFRON'S book on *Pneumonia* is the third of a series on the subject planned by the Massachusetts Pneumonia Study and Service conducted by the State Department of Public Health and financed by the Commonwealth Fund. What a monument of industry it is can be gathered from the facts that there are nearly a thousand pages of text and seventy-six pages of bibliography containing 1,471 references. It brings together a comprehensive review of investigations dealing with the inciting agent, the lesions produced, the clinical aspects, and the factors influencing prevention, prognosis, and treatment. The results of specific therapy in a large series of collected cases are a special feature of the book, and these details provide a useful guide to the practitioner embarking on that hitherto rather uncharted sea. Starting with pneumonia as found in Egyptian mummies and going on to the latest bacteriological findings and most recent views on anti-pneumococcic serum, it is difficult to believe that any single relevant fact can have been omitted. Happy the country that can provide the funds for such painstaking and meritorious research. The book is published in London by the Oxford University Press at 24s.

That Drs. L. E. H. WHITBY and C. J. C. BRITTON'S *Disorders of the Blood,* which originally came out in 1935, has already reached a third edition is convincing evidence that it is widely recognized as fully meeting the need for an up-to-date and authoritative work of reference on this rapidly advancing subject. Although it is only two years since the second edition appeared, a number of additions have now been made, especially on the haemolytic anaemias, technique, including that of sternal puncture, and the new pigment methaemalbumen. The publishers are J. and A. Churchill, and the price 21s.

In *Die Kreuzschmerzen der Frau: Ihre Deutung und Behandlung Gynäkologische Orthopädie,* Professor HEINRICH MARTIUS of the Göttingen University Women's Clinic contributes an interesting study of backache taken as a definite gynaecological entity. In the first half of his treatise he deals with the pathological causes in the pelvis; in the second and larger portion he treats it as an orthopaedic problem. Dr. Martius begins with an interesting and careful study of the finer anatomy of the pelvic organs, and shows that the sacrum has an abundant supply of spinal nerve receptors. The sympathetic and parasympathetic fibres, though only occasionally themselves conveying pain, can convey, via the plexuses, sensations of pressure or tension from the rectal or genital organs to the spinal nerves. Pain will be referred to the parametrium fixed over the sacrum, though possibly originating on one or other side. Apart from gross tumours and inflammatory lesions, the importance of correct diagnosis in order to secure correct treatment is insisted upon. That backache may be psychogenic is admitted—a bad conscience, a memory of injury, etc.—but the possibility of spasm of smaller muscle bundles such as that in the utero-sacral ligaments, or of the pyriformis, has to be remembered. Also varicosities within the pelvis, or even thromboses; and, of under-development, for which radiological treatment is advised. The author's main interest, however, lies in the orthostatics of the human female body, built for its great purpose of propagation; and he strives by bands and belts and exercises to correct the mistake of having assumed the upright position. The sketches of muscle and joint action are delicate and beautiful. There is much that is of use and value in the argument and teaching given. The publisher is Georg Thieme of Leipzig.

Preparations and Appliances

PLEURAL DRAINAGE TUBE

Mr. P. R. ALLISON, Ch.M., F.R.C.S., honorary assistant surgeon, the General Infirmary at Leeds, honorary surgeon, Leeds Public Dispensary and Hospital, writes:

The type of tube used for the draining of an empyema cavity must be chosen in each case according to the particular shape and size of the cavity. A tube which is useful when the cavity is first drained may have to be altered frequently during the course of healing. No one tube, therefore, can be recommended for general use, but the accompanying illustration (Fig. 1) shows a tube which has been made for me by the Genito-Urinary Manufacturing Company and one which I have found useful in selected cases. It is a simple form of self-retaining catheter with a prolongation of the tube beyond the flanged end. The flange is set at an angle to the shaft of the tube as shown. Holes can be cut in the distal part of the tube to suit individual cases.

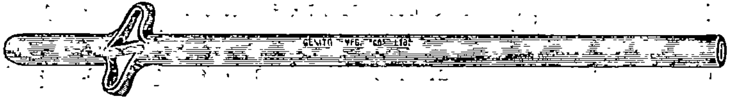

FIG. 1.

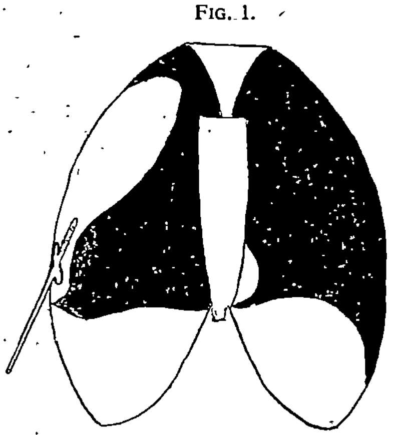

FIG. 2.—Illustrating use of tube in empyema cavity, which has healed more quickly at base than at apex.

I have used the tube particularly in the first week or fortnight after a lower lobe lobectomy, when the prolongated end helps to prevent the pleural cavity being shut off from the site of drainage by expansion of the upper lobe and elevation of the diaphragm. I have also used it in those cases of empyema where the basal part of the cavity heals more quickly than the apical part (Fig. 2) and where the more usual types of self-retaining tubes tend to become obstructed.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY DECEMBER 9 1939

NUTRITIVE VALUE OF RAW AND PASTEURIZED MILK

Five years ago the Milk Nutrition Committee planned a series of experiments to find out as definitely and as authoritatively as possible whether any real difference existed between the nutritive value of raw and of pasteurized milk. Three reports have already been issued. The first dealt mainly with observations on rats, and the third with observations on calves. The second was an interim report describing the effects of dietary supplements of raw and pasteurized milk on the growth and health of school children. The fourth and last report, which is just published, completes the second, and furnishes a summary of the results of all the experiments together with the conclusions to be drawn from them.[1]

The observations on school children were intended to provide not only a comparison of the relative values of raw and pasteurized milk but a justification of the milk-in-schools scheme. It was desired, in fact, to obtain some quantitative estimate of the beneficial effect of a milk supplement to the diet of growing children. Altogether 8,435 children, aged 5 to 14 years, distributed in five centres in England and Scotland, participated in the test. They were taken by classes and divided at random into four groups, the first of which received biscuits of very low nutritive value, the second one-third of a pint of pasteurized milk, the third two-thirds of a pint of pasteurized milk, and the fourth two-thirds of a pint of raw milk. The supplements were given during school hours for a year, excluding Saturdays, Sundays, and holidays. At the beginning, at the end, and twice in between, the children were examined medically by specially trained observers. The material for the present report was taken from 6,097 children who attended all four medical examinations, and from 695 who attended the first and second. Briefly, it was found that the milk supplements produced in both sexes, irrespective of age, increments in height, weight, and chest circumference greater than those which occurred in the control group on biscuits. These increases were greater in the groups receiving two-thirds of a pint of milk than in those receiving only one-third of a pint, but the absolute increases were very small. Thus in the boys the average increase in height of the two groups receiving two-thirds of a pint of milk over the biscuit group was only 0.089 inch, and in weight 0.584 lb., while in girls the corresponding figures were 0.088 inch and 0.913 lb. The growth-promoting power of the milk appeared to be exerted mainly in the early part of the test, and contrary to expectation was greater in children who were assessed clinically as above the average than in those who were poorly nourished at the start. Assessment of the posture, the complexion, and the condition of the tonsils, the conjunctivae, and the eyes yielded irregular results, there being a downward shift during the course of the experiment. The committee attributes this to an alteration in the standard of the medical observers. On the other hand, they attach significance to an almost equally subjective test—namely, the general state of nutrition, which was found to rise in the groups receiving milk to a greater extent than in the group on biscuits. Similar weight is given to the greater increase in intellectual capacity among the milk groups during the course of the year as estimated by the teachers. What exactly is meant by intellectual capacity it is difficult to say. If the expression refers to innate intelligence, which is doubtful, it should have been possible to measure it by proper intelligence tests. If mere increase in mental alertness and animal spirits is intended, then the subjective element in assessment comes in again, particularly when it is realized that the teachers, unlike the medical examiners, knew to which group the individual children belonged. On the whole, the results of these various subjective tests are difficult to interpret, and too much stress should probably not be laid on the committee's conclusions.

So far as a comparison of raw and pasteurized milk is concerned, no constant differences could be detected between the growth-promoting effects of the two-thirds of a pint of raw and two-thirds of a pint of pasteurized milk in either height, weight, or chest circumference. The only constant difference that could be established was in muscular strength, as estimated by the dynamometer test, and this was in favour of pasteurized milk. The differences, though uniformly in the same direction, were small, and could not be considered statistically significant. The general conclusions to be drawn from the feeding test on children are that milk has a stimulating effect on growth, and that there is no detectable difference in this respect between raw and pasteurized milk.

Summarizing the experiments on rats, the committee draws the following conclusions. Commercial pasteurization did not affect the total nutritive value of the milk or the availability or nutritive value of the protein, calcium, or phosphorus; it reduced the vitamin C content of the milk by about 20 per cent. and the B complex—presumably the B_1 fraction—slightly, but did not alter the content of vitamin A or of its precursor, carotene. The effect on vitamin D was not tested, but as this vitamin is known to be very resistant to heat it may be presumed that it is not affected by pasteurization. The fall in vitamin-C content occurs only, it will be remembered, when the milk has been previously exposed to light. Pasteurization of milk drawn into and kept in opaque vessels free from copper has no effect on vitamin C. The calf-feeding experiments again failed to reveal any significant difference between the nutritive value of raw and pasteurized milk. In relation to the observations on children and calves, it may be argued that there were defects in the pasteurized milk, but that they were neutralized by other foods. The committee's answer to this is that it is not small defects which are important but only those which become manifest under strictly practical conditions. Such defects might be of importance in infants fed purely on cows' milk, but since cows' milk is not a perfect food for infants it is usual now to add iron and vitamin C, even when the milk is given raw. Since the best way of giving iron is in the form of egg-yolk, and since egg-yolk contains in addition vitamin A, carotene, vitamins B_1, B_2 complex, and D, any slight defects in pasteurized milk which might exist would almost certainly be neutralized by this means.

---

[1] *Milk and Nutrition: New Experiments Reported to the Milk Nutrition Committee.* Part IV. Price 2s., post free, from the National Institute for Research in Dairying, Shinfield, Reading.

The main result, therefore, of the research work carried out during the past five years by the Milk Nutrition Committee on rats, calves, and children is to show that milk has a stimulating effect on growth and that no detrimental effect of any practical importance is brought about by holder pasteurization. The conclusions of such an authoritative body, taken in conjunction with similar conclusions reached by other independent workers in different parts of the country, will, it is hoped, dispose once for all of the erroneous statement that pasteurization destroys the nutritive value of milk. At a time such as the present, when large numbers of children who have been brought up on pasteurized milk in our large towns are now being fed on raw infected milk in the country districts, the importance of safeguarding their health by adequate heat treatment of the milk cannot be too strongly emphasized. Medical officers who have hitherto hesitated to introduce pasteurized supplies from the neighbouring towns on account of a lingering fear that the nutritive quality of the milk was less than that of raw milk may take courage from the fact that such a fear is entirely without scientific foundation.

RECENT WORK ON VITAMIN C

Research on the physiological action of ascorbic acid and on the daily requirement by the human being continues. In the past there has been much contradictory evidence on the reserve of vitamin C in the human foetus and placenta. According to the latest work of Muller[1] on fourteen animals (cow, pig, horse, man) the vitamin-C content of the liver of the foetus was, with one exception, equal to that of the liver and placenta of the mother. There was no evidence of a synthesis of vitamin C in the foetus, which received it from the blood stream through the placenta. Winkler[2] has found in rabbits a fluctuation in the amount of ascorbic acid excreted daily during the first few days of pregnancy, a steady slow rise till the fourteenth day, and then a more rapid decline till the day before parturition, when the amount excreted rose; on that day and on the day of parturition it was very large indeed. On the succeeding days it fell to normal level. Winkler concluded that the ascorbic acid was retained as an activator of the hormones needed during pregnancy, and when no longer required for this purpose it was excreted. Snelling and Jackson[3] have demonstrated a slight fall in the ascorbic-acid content of blood plasma towards the end of pregnancy, and a higher content of ascorbic acid in the foetal blood than in the maternal blood just before parturition. They advise giving extra vitamin C to a breast-fed infant if the mother's milk does not contain at least 2 mg. per 100 c.cm. A level of ascorbic acid lower in prematurely born than in full-term newborn infants was observed by Steinebrei,[4] but whether this was normal for such infants or slightly pathological he did not know. The mothers of the infants examined were almost all from the peasant class. Examining the vitamin-C content of different regions of the brain Diehl and Neumann[5] discovered that the parts with the lowest vitamin-C content were those having no direct relation to the vegetative functions—for example, the cerebrum, cerebellum, and corpus callosum. On the other hand, vital centres contain a large store of vitamin C. That these differences were not found in the brains of infants is understandable when it is realized that at birth the vegetative centres are already fully developed, whereas the "higher" centres do not mature until later.

All growing tissues require large supplies of vitamin C. Diehl and Kirchmann[6] observed that the rise in blood sugar of a patient taking 100 grammes of glucose by mouth was greater after high dosage with vitamins B and C than after no vitamin therapy. They believe that the water-soluble vitamins are necessary for the normal functioning of the glands of internal secretion. Injections of large amounts of vitamin C followed by smaller daily doses were found by Papayanopulos and Schroeder[7] to produce a rise in the thrombocyte count up to 450,000 and 530,000 per 100 c.cm. of blood in two patients. They believe, however, that this is due to a stimulation of the bone marrow and not to the "vitamin character" of the ascorbic acid. Reporting the beneficial effects of big doses of vitamin C on patients suffering from lead poisoning Holmes, Amberg, and Campbell[8] consider that it unites with the toxic lead ions to form a poorly ionized and much less toxic compound which is probably absorbed by the liver and passed into the bile, for it is found in the faeces, as is the lead compound formed during "de-leading" with potassium iodide. It has been claimed that large amounts of ascorbic acid lessen the anaphylactic shock resulting from the injection of antitoxic sera into susceptible persons, but Szirmai[9] has been unable to confirm this. He injected 0.1 c.cm. of solutions of 50 to 150 mg. of ascorbic acid in 1 c.cm. horse serum into sensitized animals. The effect of this was not different from that of horse serum alone. Meyer[10] has extracted ascorbic acid from human and ox tonsils and identified it by its melting-point, crystalline form, and two microchemical reactions. The amount in the tonsils was raised by giving large doses of the vitamin, and Meyer claims that it stops the growth of pneumococci and streptococci and apparently raises the phagocytosis value of human blood. It is therefore one of the factors necessary for resisting infection. According to Zacko[11] the capillary resistance of the skin of scorbutic guinea-pigs was nearly restored to its normal level by ascorbic acid and completely restored by citrin. Intestinal haemorrhages disappeared when citrin was added to the diet, but it did not prevent the death of scorbutic guinea-pigs, nor did it make them live any longer than the negative controls. His citrin was prepared from rose-hips.

An average ascorbic-acid content of the blood serum of 0.22 mg. per 100 c.cm. of blood in the spring and 0.9 mg. in the summer was found in 326 healthy persons by Dagulf.[12] In the spring 94 per cent. of his subjects had less than 0.5 mg., the amount usually regarded as necessary for health. He concluded that the figure 0.5 mg. per 100 c.cm. of blood is too high for the Swedish people and probably also for the whole of the Scandinavian population. Of 255 tuberculous patients whom he examined and whose vitamin-C intake during the greater part of the year was not over 30 mg. per man per day, the average was 0.1 mg. per 100 c.cm. of blood in the spring and 0.47 mg. in the summer. Yet during the last twenty-five years the mortality rate from tuberculosis in Sweden has dropped 50 per cent. Neuweiler[13] has concluded from many examinations that 30 to 35 mg., or preferably 50 mg., of ascorbic acid should be taken daily by the healthy adult, but in special circumstances—for example, sickness and pregnancy—this should be increased to 60 to 70 mg. He also believes that the other constituents of the diet—for example, fatty acids and vitamin D—influence the amount of vitamin C required. Goldsmith and Ellinger[14] consider that the renal threshold value of reduced ascorbic acid is 1.4 mg. per 100 c.cm. of blood. They suggest that the significance of a partial depletion of the ascorbic-acid content of the body in disease should not be overrated, as mild vitamin-C deficiency is extremely prevalent in apparently healthy individuals. Stepp and Schroeder[15] contend that individuals vary greatly in their requirements for vitamin C, and that the higher the metabolism (as in growth, exercise, and pregnancy) the more is the need for the vitamin. According to these workers the amount necessary to keep a person in really robust health is very much greater than that for the prevention of signs of avitaminosis, and they think that an intake of as much as 300 mg. ascorbic acid a day is desirable. Thus all evidence tends to show that it is almost impossible to take too much ascorbic acid and that there is a real danger in taking too little.

THE CLEANSING OF WOUNDS

There is an unsatisfactory lack of uniformity in the methods employed for preventing wound infection. This applies as much to methods for clean operation wounds as to those employed in accidental injuries presumed to be infected. Not only are many different reagents used for pre-operative disinfection of skin, but proposals have recently been made for protecting the wound against contamination from sources other than the patient's skin during the course of the operation. We have referred previously[16] to Hart's device for irradiating the field of operation with ultra-violet light. This method is based on the assumption that post-operative suppuration in what should be clean wounds is due to their contamination by staphylococci from the air, these staphylococci being supposed to originate in the throats of the theatre staff. Apparently quite inconsistent with this hypothesis were the results of very detailed observations by Devenish and Miles,[17] who not only found that the numbers and rate of deposition of pathogenic staphylococci in the air of an operating theatre were so small as to constitute an almost negligible risk, but showed that an admittedly exceptional series of post-operative wound infections was due to contamination from the surgeon's hands through minute glove perforations. Another much simpler proposal[18] for obviating this risk is now made by R. H. Jackson and R. H. Jackson, jun., who also take it for granted that the air is the source of these infections, and, indeed, present some evidence of their own to this effect, obtained by suspending open plates of culture media above the field of operation: these yielded growth including staphylococci and haemolytic streptococci after three hours' exposure, but neither counts nor further species identification were attempted. The procedure advocated by these authors is simple cleansing of the wound with soap and water before closure. They argue that fragments of blood-clot and fibrinous exudate in a wound "catch and hold bacteria and dust as would fly-paper," and that the mere mechanical removal of these possible foci of bacterial growth is all that is needed. Rough bacterial counts of washings before and after the process appear to show that nine-tenths of the bacteria in the wound are in fact removed. The soap used is said to have little germicidal action, a somewhat surprising fact in view of the known capacity of soap for killing bacteria, particularly the pyogenic cocci. In the authors' hands this method has reduced the frequency of post-operative wound infection from 4 per cent. and often much more almost to *nil*. Its simplicity is certainly a great advantage, and it might well be given a trial in accidental as well as operative wounds. The possible merits of the method are unaffected by any view which may be taken of the usual source of bacteria in operation wounds, but these authors' sweeping statement that "the air of every operating room is practically always badly contaminated with staphylococci and streptococci" can fortunately not be accepted.

EXPEDITION IN G.M.C. BUSINESS

The 150th session of the General Medical Council was probably the shortest in its history, certainly the shortest in the recollection of any of its present members. A body sometimes accused of dilatoriness disposed of eight disciplinary inquiries in three hours, during which time, after due consideration, it erased the names of three practitioners from the *Medical Register* and decided that the other five should remain. It is true that most of the cases arose out of police court proceedings for drunkenness and cognate offences, in which it is necessary to do little more than prove the convictions and hear any mitigating plea the respondent may make; but there was one charge of conspiring unlawfully to procure miscarriage, and another of committing adultery with a patient, both the practitioners concerned being struck off. A decision which marked a departure from the usual procedure was the erasure of the name of a practitioner against whom three convictions (two for being in charge of a car whilst under the influence of drink and one for being drunk and disorderly) had been recorded in 1937 but none since, and he had been for two years on probation. The reason which actuated the Council in arriving at its decision may have been the neglect of the respondent to give the usual assurances as to his future behaviour, but the case may indicate a stiffer line in dealing with charges of drunkenness. The Council showed an equal celerity over its educational business, which occupied less than an hour. It was stated on the agenda that the Council would receive oral reports from the chairmen of two committees *in camera*. The chairman of one of these committees gave his report in public in one of the most entertaining speeches ever heard in the Council, but at its conclusion another member "spied strangers," and after the question of the exclusion of strangers had been considered *in camera* the Press and public were recalled and asked to turn a deaf ear to what had so far occurred. To make up for the lapse of taking a report in public which should have been taken in private the Council took a report in private which should have been taken in public. This was the report of the Pharmacopoeia Committee, which presumably recommended the appointment of Professor J. A. Gunn as the new chairman of the Pharmacopoeia Commission. It would be a pity if, as happened on this occasion, all the business of the Council except its disciplinary inquiries were to be taken behind closed doors. The Council at this session was crowded into the small chamber of the Dental Board to avoid the difficulties of blacking out its own large chamber, but the speed with which the business went through was such that the precaution proved wholly unnecessary, and the only "black-out" was in the Press gallery.

IS LEUKAEMIA A NEW GROWTH?

Last year we reviewed Forkner's important monograph on leukaemia and allied disorders in man,[1] and this may be supplemented with profit by Engelbreth-Holm's review[2] of the results of research on leukaemia in recent years. No further advances have come from the clinical study of the disease apart from some improvements in the classification of leukaemia and the differential diagnosis, the latter due mainly to the introduction of sternal puncture and to some extent to routine *x*-ray examination of the bones in obscure anaemias. The prognosis remains uniformly hopeless, and the newer radio-active substances prepared with the cyclotron do not offer any great promise of superiority over thorium, radium, and *x* rays. Nor are technical changes such as the use of general rather than localized irradiation likely to be revolutionary. The well-known observation that local irradiation of the spleen, even with very small roentgen doses, produces a striking change in the condition in leukaemia offers a problem that still awaits solution. Clinical observation strongly suggests that leukaemia is a form of new growth. There is every transition from classical leukaemia to tumours such as chloroma and lymphosarcoma. The metabolism of the leukaemic cells and the morphological abnormalities they show are identical with those of neoplastic tissues. The diffusion of the lesion is a consequence of the diffuse location of the blood-forming organs and their lack of fixity as tissues. Moreover, it can be paralleled in quite different tissues, and Engelbreth-Holm gives such examples as neurofibromatosis, multiple primary cancer of the lungs, bilateral suprarenal tumours, and multiple carcinoma of the small intestine. If clinical observations allow us only to presume that leukaemia is a form of new growth, the observations on experimental animals amount almost to proof. Spontaneous leukaemia has been observed in most vertebrates, including the common domestic animals, but because of the high incidence and the ease of transference it has been most closely studied in the fowl and the mouse. The predisposing factors appear to be heredity, external environmental factors (irritation), and a virus. About twenty-five human families are known in which more than one case of leukaemia has been observed in near relatives. It is striking that twenty-two out of the twenty-seven cases collected by Petri were lymphatic in type, whereas on the average lymphatic leukaemia constitutes only 30 per cent. of all cases of leukaemia. It seems certain, therefore, that the familial incidence of leukaemia is more than a coincidence. Pure strains of mice have been bred in which the spontaneous incidence of leukaemia reaches 90 per cent., while in other strains leukaemia has been bred out so that its incidence is little over 1 per cent. Experiments in which after roentgen irradiation the spontaneous incidence of leukaemia in a strain rose from 2 to 20 per cent. indicate with absolute certainty that uninherited external factors also play a part. In the strains in which 90 per cent. of the mice succumb to leukaemia the remaining non-leukaemic animals apparently owe their freedom to external factors, for they transmit the leukaemic disposition to their descendants in as high a proportion as the mice which die of leukaemia. External agents known to produce or to increase the incidence of leukaemia in animals are radium and x rays, tar, and the carcinogenic hydrocarbons. A number of human cases have been published which suggest an increased incidence of leukaemia in men and women, such as radiologists and physicists, whose occupation repeatedly exposes them to radiation. In the fowl many of the spontaneous leukaemias can be transmitted to healthy birds by cell-free filtrates. This is probably a phenomenon of a different character from the induction of leukaemia by physical or chemical irritants. The virus acts much more rapidly and it is reproduced during the growth of the cells, which does not happen in the case of the carcinogenic hydrocarbons. Several groups of investigators have reported independently of each other on leukaemic strains in fowls where one and the same filterable agent can produce both leukaemia and sarcoma. In Engelbreth-Holm's strain intravenous administration of the agent was usually followed by the development of leukaemia, while subcutaneous or intramuscular application of the same agent more commonly induced fibrosarcoma. Although leukaemia in mice can be implanted from one animal to another it cannot be transmitted by a cell-free filtrate, but recent experiments suggest that cell-free transmission is not beyond the bounds of possibility and that there is no fundamental difference between leukaemia in birds and in mammals.

ACTIONS OF VERITOL

During the last few years a number of sympathomimetic amines have been introduced for clinical use as analeptics. In this group is the compound veritol, the chemical name for β-para-oxyphenylisopropyl methylamine, which has been the subject of a number of favourable clinical reports; but the exact nature of its pharmacological action has been a matter of controversy. Veritol causes a prolonged rise in blood pressure, and some authors have attributed this to vasoconstriction and others to increased cardiac output. Drs. Pona and Muratori,[1] in an investigation of this problem among normal persons and persons suffering from cardiac and other diseases, found in all cases a rise in systolic pressure accompanied by decreased cardiac frequency. Blood volume increased in the majority of cases, presumably because of the emptying of blood stores such as the spleen. Analysis of the individual responses, however, showed no certain relation between the extent of the rise in blood pressure and the increase in the blood volume. In those cases in which there was no increase in blood volume there was nevertheless a rise in blood pressure. This latter, the authors concluded, was due to at least three factors: a direct cardiac action, vasoconstriction, and increase in blood volume by mobilization of the blood stores. The action of veritol on the circulation is, therefore, complex, but the rise in blood pressure without increase in the heart rate is an important clinical feature.

HOSPITAL FUND FOR THE PROVINCES

Lord Nuffield announced on December 5 in a letter to the Minister of Health his intention to place in the hands of trustees a million share units of Morris Motors Ltd. to encourage the development of hospital regionalization outside the metropolitan area on the general lines laid down by the Sankey Commission on Voluntary Hospitals. These shares (now worth about £1,250,000) would be the nucleus of a central hospitals fund for the Provinces; in the London area there already exists in the King's Fund a central authority for the co-ordination of hospital finance and policy. Lord Nuffield hopes that through the new fund for the Provinces and the King's Fund in London there will ultimately emerge a truly national hospital service, "which will embrace all that is best of both public and voluntary effort with the maximum of economy to the State and to the private purse." This project already has the warm support of the Provisional Central Council of the British Hospitals Association, and the Minister of Health in expressing deep appreciation of Lord Nuffield's munificence and public spirit welcomes the conception underlying his proposal —"the conception of a co-ordinated hospital system which will look to the needs of the country as a whole and will cover as far as possible appropriate regional units." He agrees with Lord Nuffield that the Local Government Act, 1929, can rightly be taken as laying the statutory foundation of the conception.

For the time being the British Medical Association will continue the publication of its special journals, the *Archives of Disease in Childhood*, the *Journal of Neurology and Psychiatry*, and the *British Heart Journal*, and contributors are asked to send their papers to the editors of these journals at the following addresses: Dr. A. Moncrieff, F.R.C.P., The Middlesex Hospital, London, W.1; Dr. E. A. Carmichael, F.R.C.P., Hurstwood Park Hospital, Haywards Heath, Sussex; Dr. J. M. H. Campbell, O.B.E., F.R.C.P., Orpington War Hospital, Orpington, Kent.

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation

INJURIES OF THE SEMILUNAR CARTILAGES—I

BY

A. G. TIMBRELL FISHER, *M.C.*, F.R.C.S.

Injuries of the semilunar cartilages are somewhat frequently encountered in practice, and their prompt recognition and effective treatment are of considerable importance. There is probably no subject which is more apt to cause damage to the practitioner's reputation or to present the osteopath or bone-setter with a gratuitous advertisement.

Definition and Pathology

The term "displaced cartilage," although often used, is perhaps misleading, as in the great majority of cases a definite fracture of the cartilage occurs, and the most striking symptoms are due to the behaviour of the fractured portion and not to displacement of the whole cartilage. Hypermobility of a semilunar cartilage without actual fracture may be present under certain conditions, but is much rarer than is sometimes stated. The types of fracture are very varied, but longitudinal cleavage, either complete or incomplete, occurs most frequently (47.54 per cent. in my series). The complete longitudinal fracture is often called the "bucket-handle" type (Rutherford Morison). Next in order of frequency are fractures involving the anterior (27.86 per cent.), posterior (13.93 per cent.), and middle thirds. Injuries of the internal semilunar occur most frequently. The proportion of external semilunar injuries ranges in published statistics from 7 per cent. (Sir Robert Jones) to 20 per cent. (my figures) and even 28.4 per cent. (Dunn).

Mechanism of Semilunar Cartilage Injuries

In flexion and extension of the knee, and when the femur forms the fixed and the tibia the movable arm of the lever, the semilunar cartilages remain in contact with the upper surface of the tibial head but move slightly forwards in full extension and slightly backwards in full flexion. When the tibia is the fixed arm of the lever, as in certain stages of walking or running, the femoral condyles roll and glide over the upper surface of the tibia and semilunar cartilages. Rotatory movements, which are possible when the knee is flexed, take place on the inner side principally between the internal femoral condyle and the internal semilunar cartilage; but on the outer side a good deal of the movement occurs between the external semilunar cartilage and the tibia, and the cartilage moves to a great extent with the external femoral condyle.

The deep fibres of the internal lateral ligament are firmly attached to the inner convex surface of the internal semilunar cartilage just behind its centre. This ligament normally assists in preventing excessive rotation inwards of the femur upon the fixed tibia or external rotation of the tibia upon the fixed femur. A sudden rotation inwards of the femur upon the fixed tibia with the knee in partial flexion may cause a rupture of some of the deep fibres of the internal lateral ligament, and a sprain results.

When the ligamentous injury is of a more serious nature the inner side of the joint is opened up, permitting the internal semilunar cartilage to move to a variable degree towards the centre of the joint and, in a continuation of the rotatory movement, the cartilage is ground between the internal condyles of the femur and tibia. Actually, of course, this combination of events takes place in the fraction of a second. The internal semilunar cartilage is thus subjected to both compression and torsion strains and various types of lesion result, particularly the bucket-handle type and lesions of the anterior portion. The bucket-handle lesion is more likely when abduction is a well-marked feature.

This combined form of strain explains the peculiar shape of the fractured surfaces, which often overlap like the approximated blades of scissors. If, however, the attachment of the internal semilunar cartilage to the deep fibres of the internal lateral ligament remains intact this portion acts as a hinge, and the anterior part of the cartilage may be torn, or various forms of tear may occur opposite the fixed portion of the cartilage. Injury to the posterior end of the internal semilunar and some types of bucket-handle lesion are probably caused by forcible external rotation of the femur upon the fixed tibia when the knee is slightly flexed, or, conversely, by internal rotation of the tibia upon the fixed femur. These movements are also probably responsible for injuries of the anterior portion of the external semilunar cartilage. Injury to the posterior portion of the external semilunar cartilage is probably due to internal rotation of the femur upon the fixed tibia, and vice versa, and buckle-handle lesions of the external semilunar to either mode when adduction is prominent.

Signs and Symptoms

There are two principal modes of onset. In the first and most common the early symptoms are severe, and any recurrences tend to become more frequent but associated with less reaction. In the second, symptoms are slight at first but gradually become more definite, until locking occurs, when the onset of the first class is simulated and a similar sequence of events follows. In the first class the patient experiences acute pain, usually more severe over the affected cartilage, and may fall to the ground. Mechanical locking often occurs, and usually takes the form of an immediate inability to straighten the knee completely. It is sometimes very difficult at the time of the original accident to distinguish between this mechanical block to extension and the limitation due to muscular spasm, which is always present in any acute injury to the joint. In some cases of injury to the posterior part of a semilunar cartilage there may be a mechanical block to full flexion. Tenderness over the semilunar cartilage is experienced, its position depending upon the site of the injury. Synovial effusion ensues rapidly in severe injuries and more slowly in the less severe types. In the former the effusion is largely haemorrhagic.

In the second class there is usually a history of recurrent attacks of pain with or without effusion or of "giving way" of the knee before true locking occurs. It is probable that in this class the attachments of the cartilage are gradually stretched and a certain amount of hypermobility of the cartilage precedes the actual fracture. In recurrent cases a history of attacks of mechanical locking or sudden "giving way" of the knee is important, and physical signs between attacks may be few. Tenderness over the semilunar cartilage can frequently be elicited, together with cartilage crepitus on deep palpation. McMurray's test is sometimes positive, and there is often a certain amount of synovial effusion and wasting of the quadriceps extensor. Radiography gives no clear guidance in semilunar cartilage cases; but this should never be omitted, since by means of it we can ascertain whether some coincident condition, such as fracture of the tibial spine, loose or foreign body, osteoma, or osteoarthritis, is present.

Treatment of the Original Injury

This should be carried out on the following lines: If locking is present the displaced portion of the cartilage must be replaced by manipulation without delay. This is followed by rest from weight-bearing until the acuter symptoms have subsided, combined with firm bandaging of the joint over a thick layer of wool. The use of strapping, plaster-of-Paris, or splintage is not advised, although the purely temporary use of a back-splint may be necessary if the patient is restless. Physical treatment in the form of radiant heat, massage of the limb, and careful active movements is instituted from the first, and, provided all rotatory movement is avoided, is of value in aiding the absorption of traumatic effusion, in alleviating pain and spasm, and in preventing adhesion formation and muscular wasting. In the absence of locking, this treatment (which closely resembles that for a severe sprain of the knee) is begun at once. In an average case, when the acuter symptoms and synovial effusion have appreciably diminished, a little walking may be allowed, the compression bandage being still worn. Physical treatment in the form of massage and re-educational exercises for the thigh muscles is continued and steadily increased, although all rotatory movements must be avoided.

MANIPULATIVE TECHNIQUE

The replacement of the fractured portion of the semilunar cartilage may be easy or, in cases such as some varieties of the complete bucket-handle type and when the displacement has remained unreduced for several days or weeks, extremely difficult. Replacement without the aid of anaesthesia is quite possible, but it is made more difficult by associated muscular spasm and is a painful procedure; an anaesthetic is therefore advisable. Gas or gas-and-oxygen, if skilfully administered, usually suffices in early cases. Intravenous evipan or pentothal is a valuable alternative, but should not be given in the surgery or the out-patient department, admission to nursing home or hospital for a short period being desirable. If the cartilage has remained unreduced for some time ether or chloroform may be necessary.

Method 1 (Figs. 1, 2, and 3).—The patient lies upon his back on a couch or operating table. Assuming that we are dealing with the internal semilunar cartilage of the right knee, the practitioner grasps the sole of the patient's right foot with his right hand and the affected knee with his left hand. He first fully flexes the knee and, while abducting to open up the inner side of the joint, rotates the tibia inwards and outwards. This movement may be repeated with the knee flexed to 90 degrees. In some cases the mere movement of flexion reduces the displaced portion, but usually this takes place during rotation or during the final movement. This consists in a rapid movement of extension accompanied by internal rotation. In the case of the external semilunar cartilage the outer side of the joint must be opened up by adducting the

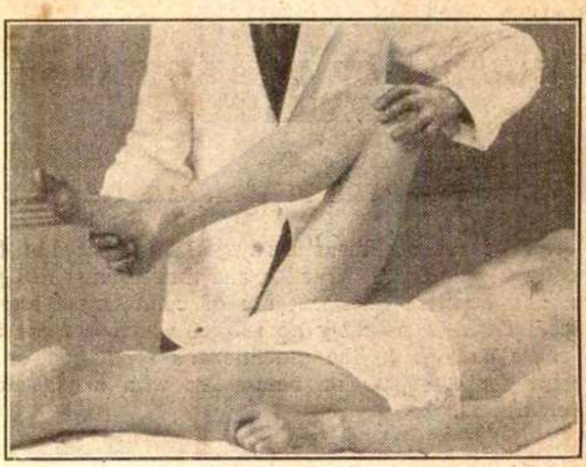

FIG. 1.—Method 1. Manipulation of right knee for fracture-dislocation of internal semilunar cartilage. Stage 1: Full flexion.

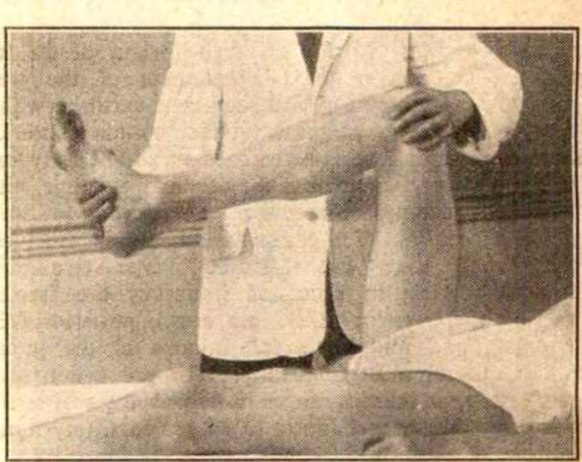

FIG. 2.—Method 1, Stage 2: Rotation combined with abduction.

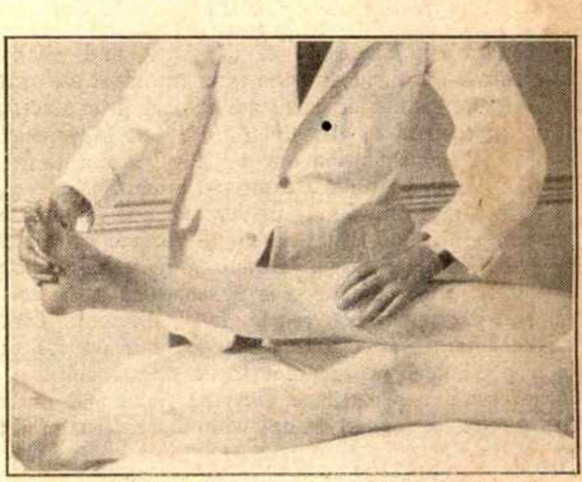

FIG. 3.—Method 1, Stage 3: Extension terminating in internal rotation.

leg, and the final movement is one of extension combined with external rotation.

Method 2 (Fig. 4).—The above method usually succeeds in original cases of average severity. When it fails a more effective method of abducting or adducting the joint and bringing about the necessary rotation should be tried. In the first method described above it is a disadvantage that the abducting and rotating forces are not applied directly to the tibia. The following method overcomes this difficulty, and once the technique is acquired it is extremely effective. In fact, I have often reduced displacements by this means without an anaesthetic when previous attempts elsewhere under anaesthesia have failed. The patient either sits in a chair or lies with the leg hanging over the end of the operating table. The practitioner grasps the upper end of the patient's leg just below the knee with both hands and grips the patient's foot between his thighs. The knee is first flexed through 10 to 15 degrees, and in the case of the internal semilunar cartilage he strongly abducts the joint with his thighs, aided by his hands. Then with the knee in partial flexion and well abducted a very strong movement of external or internal rotation is communicated to the tibia by the practitioner's hands. Replacement is usually accompanied by an audible "snap" which is quite characteristic. The knee should then be extended, particular attention being paid to the "screw-home" movement at its termination, and if the manipulation has been successful this movement should be full and free. The most satisfactory test of reduction, however, is that the patient can forthwith perform the movement of full extension either painlessly or with a minimal amount of pain. This is an important sign, and if active extension is still restricted and painful the displacement has not been rectified. After reduction a firm compression bandage should be applied and the after-treatment described above should be carried out.

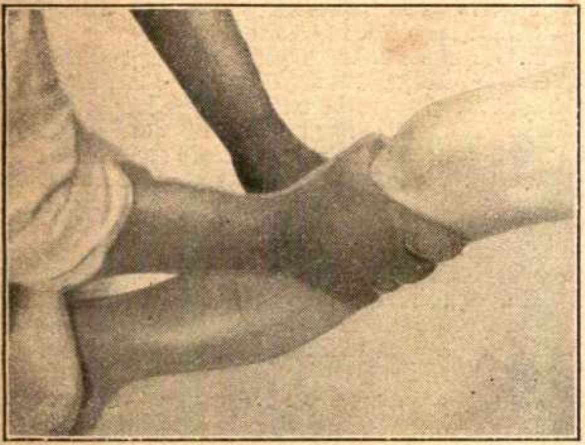

FIG. 4.—Method 2. Manipulation of left knee for fracture-dislocation of semilunar cartilage.

THE QUESTION OF EARLY OPERATION

The treatment by manipulation and suitable after-treatment of every original injury of a semilunar cartilage associated with locking has been described. It must be clearly borne in mind, however, that in a somewhat high percentage of cases the original displacement is followed by recurrences, particularly when delay in replacement has occurred and when the lesion has been a serious one. This fact should be explained to the patient, and in view of the extremely satisfactory results following removal of the damaged semilunar cartilage by an experienced surgeon it may well be that the future will see earlier recourse to operation in certain cases. For example, I was asked to see an international association footballer who severely damaged a semilunar cartilage in the first match of the season. Locking was present, and as this player was a "key" man in the team immediate removal was advised. This, however, was declined by the authorities and manipulation only performed. This was followed by the appropriate after-treatment, and six weeks elapsed before the player was able to take the field. Shortly afterwards the knee broke down again, and I was then asked to remove the offending cartilage. A further eight weeks elapsed before the player was able to resume, so that for the greater part of the season he was incapacitated. If the original advice had been taken the player would have been available for the cup final, and, owing probably to his absence, the cup was won by a rival club. Many managers of football teams now insist on early operation. Every case must, however, be treated upon its own merits. Patients are not all professionals engaged in strenuous and exacting forms of exercise, and in most cases manipulative replacement of the original semilunar cartilage injury associated with locking appears to be at any rate the best short-term policy.

REGIONAL HOSPITAL ORGANIZATION

[FROM A CORRESPONDENT]

In planning for the future there are two distinct lines, followed according to individual temperament. In the one case will be set down what seems to be an ideal plan for providing what is needed. In the other case attention is first and chiefly given to the existing factors, and the question asked is how they may be brought to the state of efficiency required. The history of successful planning is on the side of the second method: existing factors are stubborn elements in any situation, and have a way of taking their revenge if neglected.

Recent Hospital Planning

In the last thirty years several plans of hospital organization have been worked out and offered to the British public. Some of these have made no reference to existing establishments; some have been based upon one existing system and have disregarded others. As the problem is how to produce a system out of our own resources an examination of these resources is surely the first step towards laying our plans. Certain people would, however, have us treat our resources as indefinite, if not infinite. Some among these would scrap the present controls, and therefore their experience, and start anew with a National Control, which for their argument they assume would exercise its powers at least better than any of the present controlling bodies, if not perfectly. It does not need a training in logic to realize that such taking of something as given which is not given robs a scheme of what every sound scheme needs—namely, a foundation in experience.

The efforts which have in fact produced hospitals in this country have been of two sorts—those of people who, in communities small and large, have combined to establish and maintain out of their own pockets the hospital their community needed; and those of people elected to govern, in Parliament and local councils. Efforts of the first sort have been made and sustained in London for centuries, and elsewhere for generations, and have been partly medical, partly lay. Here and there by this means we are still able to build and equip and maintain hospitals which are the equal of any in the world; but over the country generally there is difficulty in maintaining the "voluntary" hospital, and, having regard to the sources from which its finance has been derived, these difficulties are likely to increase. Efforts of the second sort culminated in the Bill of 1929, which required counties and county boroughs to administer the Poor Law hospitals transferred to them, and empowered them to extend and develop these hospitals, outside the Poor Law.

Those who are willing to base their plans on the actual factors in a situation and on calculated probabilities are likely to accept the estimate that, in general, the financial resources of those who have built and supported voluntary hospitals in the past have been diminished by taxation and are likely to be further diminished. It would be imprudent and improvident to turn a blind eye to this fact. Its consequence is obvious enough. People cannot be forced to provide "voluntarily" and cannot be persuaded to do what they are unable to do; in general the share in providing hospital treatment taken by the donation-and-subscription-supported hospitals will diminish, that taken by the hospitals provided by public funds will increase. The reaction to this probability of some of those who are interested is to declare that "the voluntary hospital system must be maintained at all costs." A system can be maintained by legislative regulation or by persuasion. Persuasion will not enable men to do what they cannot do; legislative regulation means here superseding the financial foundation of the voluntary hospital system by another.

The Public Hospital

Does legislative regulation of the British hospital system mean that "all is lost," as some would have us believe, that the best and most distinctive features of our treatment principles will thereupon disappear? The answer "Yes" is based on an assumption that has no validity—the assumption that these best and distinctive features cannot be displayed in a system provided by public funds. Medical opinion is divided on this question; the uncompromising "Yes" has come chiefly from those who represent the lay management of the voluntary hospital. They base their argument on the fallacy that the public hospital must be taken as it is at present, and cannot be improved to incorporate the best features of the best of the voluntary hospitals to-day. This fallacy can only be entertained by those who disregard their own and the public hospitals' history.

An example of the kind of argument that is used is as follows. The method by which medical appointments are made to hospital posts in the voluntary hospitals is one that ensures that the best men only will be appointed. They are chosen virtually by their colleagues, and the critical judgment of their colleagues is the best available. Accepting this view as correct, history does not show that this "ideal" method is inherent in the voluntary system, nor is it universal in this system to-day. A generation ago a man who was a candidate for an honorary post in a voluntary hospital sent his application to, and canvassed, the "governors," who might number several hundreds. The plan was improved when "electoral bodies" were substituted for the general mass of governors; but, even so, a candidate could not afford to abstain from canvassing, although this could only be indirect. Admitting that the more instructed selection of to-day is still better than this, the history of the change proves nothing more than that methods of selection can be improved. What it certainly does not prove is that the defects that may exist to-day in the system of appointment in the public hospitals are incapable of removal and must be considered unalterable. All the main arguments of the "all is lost" attitude of the voluntary hospital lay supporter are similarly based. He assumes that the county and county borough hospital system, which is ten years old, has stopped growing and that its ability to learn has come to an end.

The "Voluntary" System

General medical opinion would catalogue the following as among the virtues of the "voluntary" system:

(*a*) *Regional Organization.*—The voluntary system was organized regionally, though in a somewhat haphazard fashion, and no serious barriers prevented patients from going to the hospitals and the men best able to deal with their complaints. It must here be remarked that the regional pattern has been less in evidence since the 1914–18 war than before. Attempts at self-sufficiency on the part of small provincial towns and a reluctance to allow patients to travel have been characteristic of the period, show no sign of diminishing, and are not guided and controlled. The voluntary institutions of many small centres have attempted this self-sufficiency, and co-ordinated regional effort is to-day conspicuously absent. The result is waste, failure, and misdirection. On the other hand, no one who cares to talk with responsible members of council hospital committees and with medical officers of health will be ignorant of the fact that they look upon regional organization as a course upon which they are already set, and expect the Ministry of Health to help them in developing it. Considerable progress along this line has already been made by the London County Council; there is good reason to hope that provincial regions will be able to follow.

(*b*) *Contact between Patients and Hospital Medical Officer.*—Contact has been personal and close because the patient and his doctor chose the hospital officer who should be consulted. With the development of out-patient clinics in the public hospitals a start has been made in many which encourages this personal contact, and there is nothing in the administration of these hospitals which prevents this contact being maintained when the patient enters on his convalescence.

(*c*) *Facilities for Teaching and Training the Medical Student.*—There are those who plan to confine the teaching of the student to the "voluntary" hospital. It may well be asked, Is this done in the interest of particular institutions or in the interest of medical education? If it is desirable that the medical student should be given as wide a clinical view as he can digest, if it is desirable that he should see the commoner complaints as well as the rarer, then the advantages attached to taking him into the public hospitals cannot be denied. Indeed, these advantages have been widely recognized by teaching staffs already. They are so obvious that neglect of the opportunity must come under suspicion of being interested—that is to say, dictated by some consideration or scheme which is not primarily based upon affording the student the maximum of practical clinical culture.

The Policy of the Medical Profession

The amount of financial support that is at present being afforded to the voluntary hospitals, and the amount which they may expect, vary much from one town to another, from one part of the country to another. If in one place the signs are not such as to lead reasonable judgment to believe that new buildings and increasing income will be forthcoming, wherein does wisdom lie for the medical profession? Does it lie in the leaders of the profession keeping themselves apart from the public hospital, maintained on Government order, and with all the substance of a City Corporation supporting it? Only wishful thinking will deny that development and extension of service on the part of the public hospital is the prospect. Is it too much to say that only wishful thinking will imagine the maintenance of a parallel system, alongside but apart? Who will maintain it? The Government? Apart from what has been created and is being maintained by its own order?

But upon what fundamental idea will the Government proceed? Will not this be, and must it not be, the providing of hospital treatment for the people? Unless it can be shown that the "virtues" of the old voluntary system cannot be introduced into the public system there is no argument for maintaining a parallel system apart from the latter, and medical teaching and clinical research will have to adapt themselves to the unified hospital order. The expectation of those who look for a second system maintained apart, for the convenience of a teaching staff and under special governance, is likely to be disappointed. The medical profession need lose nothing in any given area by this change if it opens its eyes to what is occurring and plans its policy accordingly. If it shuts its eyes and delays, holds on to expectation of some financial *deus ex machina,* who will intervene to maintain the existing state for some secondary and subsidiary reason, then it will make a mistake that will be difficult to retrieve and lose a chance which may be hard to recover.

A public hospital system, regionally organized by a Ministry of Health, with Government support for teaching and research, is a prospect that need dismay no one, least of all the doctor who determines to do what he can to bring into it the traditions of personal intimate service to the patient that have been characteristic of British medicine. In these days of an Emergency Medical Service there is an opportunity of doing this that should not be missed.

THE STATE OF THE PUBLIC HEALTH

SIR ARTHUR MacNALTY'S REPORT

The Chief Medical Officer of the Ministry of Health deserves sympathy in the circumstances in which his Annual Report for 1938[1] has had to be prepared and presented. It is a narrative of peace-time progress, but it makes its appearance at a time of war which must mean the postponement of many of the plans and aspirations its pages reveal. While the material was being passed for press events—like the German soldiery—had marched. Some parts of the report assume the continuance of peace, others suggest that war is imminent, and yet others—notably the section dealing with venereal disease—that it has already begun. The satisfaction felt in recording progress in so many fields must be seriously qualified by the knowledge of inevitable reaction, the crippling of certain services, the relaxation of certain vigils, the effect of the anxieties, the impoverishments, and, above all, the sheer boredom of war upon the mental and ultimately upon the physical health of the community. Apart from any direct effects of war itself, the evacuation of children and mothers from urban areas must alter the contours of the health picture, for better or worse, perhaps for generations to come.

Emergency Organization

The chapter on emergency medical organization describes only the preparations "should this great calamity befall us," but a footnote has to be added that since the chapter was written the hour has struck and the organization—or disorganization, according to the point of view—has come into existence. In writing of the emergency organization the Chief Medical Officer pays tribute to the voluntary hospitals and their medical staffs for their public spirit in so readily adapting themselves to the new situation. It is emphasized that an important point in the organization is that there should be no interference by the Department in the internal administration of any hospital. The individual hospitals, says the report, are to continue to arrange their own affairs and to be responsible for the treatment of their patients as in peace time, and many of their patients, even in danger areas, will continue to be the ordinary civilian sick. The Ministry also congratulates itself upon its success in obtaining the whole-hearted support of the medical profession and the advice of its leaders and experts in the difficult task of air raid precautions.

1938 was a year of health progress, and despite crises and international preoccupations existing health services were maintained and a new health service, relating to cancer, created. It was a year also of encouraging vital statistics. The death rate for England and Wales was lower than in any previous year except 1930, and the infant and maternal mortality rates and the death rate from tuberculosis were the lowest on record. Of the causes of death, diseases of the heart and circulatory system accounted for 327 out of every thousand deaths at all ages, and malignant disease for 143. If the working period of life be taken (ages 15 to 65), these two conditions retain their places, but the respective numbers are 234 and 182. The reason why the proportion of deaths from diseases of the heart and circulatory system is increasing is largely the growing proportion of older persons in the population. "A young man *may* die, an old man *must* die." Deaths from violence totalled 22,780, and it is worth noting that twice as many men as women committed suicide—3,558 against 1,758.

Prevalence of Infectious Diseases

The number of notifications of diphtheria was 65,000, with 2,931 deaths. Artificial immunization against diphtheria continues to make slow but uninterrupted progress. Its value is undeniable, and not yet sufficiently appreciated by the public. Diphtheria is the principal cause of death among children of the ages of 4 to 10, and is high up in the list of causes in the group aged 10 to 15. It can be said to be the principal killing disease of school age. During the last few years the number of deaths from diphtheria has exceeded the number from measles and whooping-cough, but while no specific remedy has yet been found against these other diseases, with diphtheria it is far otherwise, for there are a number of prophylactics of proved worth, and only the willing co-operation of the public is lacking.

Notifications of scarlet fever numbered just over 99,000, but there were only 359 deaths. The large incidence of this disease, and probably therefore of other forms of streptococcal infection, continues practically undiminished. Deaths from measles and German measles numbered 1,641. Influenza was not epidemic in 1938, but there was a rise in the early part of 1939. It appears, however, that this increased prevalence was irregular in distribution, and that in some communities a substantial portion of the morbidity was due to febrile respiratory catarrh, sometimes of a severe type, and not to influenza. The number of cases of acute poliomyelitis was 1,489, the highest in any year since notification became compulsory in 1912, and the number of deaths was 172. There were eighteen cases of small-pox notified, nine being of the major variety, with one death. Eight cases of acute nervous disease following vaccinations were reported. Six of these were cases of primary vaccination in adolescents or young adults, and furnish additional evidence for the warning repeatedly given by the Ministry that primary vaccinations at school age and in adolescence, except in special circumstances, are to be deprecated.

The great decrease in incidence and mortality of enteric fever in this country is one of the most striking facts in the history of epidemiology. Both cases and deaths were at their lowest in 1938, but it is pointed out that the price of freedom from enteric fevers is constant vigilance, communal and individual. The co-operation of the individual with the community is necessary, for while the incidence of enteric disease may rightly be regarded as an index of the state of sanitary evolution at which the community has arrived, it is no less an index of personal hygiene, for infected persons may convey the causative organism to others by carelessness or lack of cleanliness.

Infants and Mothers

A certain qualification has to be made concerning the fall in the infant mortality rate. (By the way, the number of infant deaths last year, 32,724, was less than one-fourth of the number thirty-five years ago.) The fall is due to the reduction of deaths in the later months of the first year of life. The conditions which have caused this fall must either be inoperative in the earlier months, especially in the first month, or must be counterbalanced by other adverse factors. Stillbirths also showed little or no reduction, and the problem of the causation of stillbirths has much in common with that of neo-natal death.

---

[1] *On the State of the Public Health.* Annual Report of the Chief Medical Officer of the Ministry of Health for the Year 1938. H.M. Stationery Office. (3s. 6d. net.)

The total mortality from puerperal sepsis was 0.89 per thousand live births, and that from other puerperal causes 2.19, making a total puerperal mortality of 3.08, the lowest on record. The confidential reports received by the Ministry ascribed 1,468 deaths to pregnancy or childbirth and 289 to associated causes, the figures being lower than those given by the Registrar-General. The causes of death were:

Sepsis	293
Haemorrhage	241
Toxaemia	247
Embolism	162
Other causes directly due to childbearing	198
Ectopic gestation	38
Abortion	289
Associated conditions	289

Leaving out the cases of abortion and of ectopic gestation, the delivery in 726 of the fatal cases was in hospital, in 486 at home, and 220 women died undelivered. The nature of the delivery was as follows:

Natural	700
Forceps	329
Caesarean section	163
Craniotomy	32
Other operations	49

Local investigators report that in 622 of the total 1,757 cases there was an assessable avoidable factor, whilst in 630 cases no such factor existed. As to the remainder they express no opinion.

The highest maternal mortality in any administrative county was 8.86 per thousand births in Brecknockshire; the lowest was 1.07 in Cambridgeshire. The highest in a county borough was 7.5 at Chester, and the lowest 0.87 at Croydon.

Extended reference is made to the Ministry's midwifery schemes. In England 169 local supervising authorities under the Midwives Acts have inaugurated domiciliary schemes whereby over 7,000 midwives are employed, either by the authorities themselves or by voluntary associations. Although it is still early days for conclusions, it is claimed that on the whole the standard of practice has been raised. In Wales nineteen local supervising authorities employ 312 midwives directly, while 444 are employed through nursing associations. Medical practitioners are summoned in increasing numbers of cases in Wales; the 20 per cent of notified births in which practitioners were summoned in 1934 became 30 per cent. last year. Apart from the domiciliary midwifery schemes the most noteworthy development in the maternity service is the extension of in-patient accommodation and the provision of new departments. Local authorities in England during 1938 provided or subsidized 9,439 beds at 558 institutions, to which 177,000 patients were admitted.

Cancer and Tuberculosis

The new national cancer service gives special interest to the section of the report devoted to this subject. The total number of deaths from cancer in England and Wales in 1938 was 68,605, and the standardized mortality—meaning the figure after differences solely due to changed constitution of population in regard to age or sex had been eliminated from the crude rate—was 1,005 per million living. It is the deaths of males from cancer which are increasing steadily; the female rate since 1924 has been almost stationary, with an irregular tendency to fall. This may be due to the greater curability of cancer by modern methods as it affects women—for example, carcinoma of the breast and of the cervix uteri. The breast is the most frequent site of cancer in the female, the stomach of cancer in the male. The arrangements made by local authorities under the new service and the objects which the service hopes to achieve are fully set out. The guiding principle should be, says the report, the removal from the path of practitioners and of their patients of those difficulties which tend to prevent the latter from receiving the treatment best suited to their condition and receiving it at an early stage of the disease.

The statistical returns for tuberculosis are again encouraging. The general decline continues and the check to the fall in mortality in young adults which has caused concern for many years appears to be passing away. The deaths from respiratory tuberculosis last year numbered 21,930, or about half the average yearly number recorded during the last decade of the nineteenth century. New cases numbered 43,205, not many more than half the annual number just previous to the last war. In non-pulmonary tuberculosis there was a slight increase of notifications—from 12,661 to 12,810, with a fall, however, in the number of deaths. The increase is associated with the larger number of persons treated in residential institutions under county authorities. It is thought that the improved services in the counties may explain the increase. In Wales the death rate is also declining, but the decline lags behind the English figures.

"The Camp Follower of War"

Venereal disease, a problem of declining importance, comes forward again as "the camp follower of war." Increased sexual promiscuity due to the heightened nervous tension and excitement is a sufficient explanation. The shift of large numbers of people to areas hitherto sparsely populated may be associated with outbreaks of the disease in places unprovided with facilities for treatment. It will be necessary for county and county borough authorities in some areas to extend existing centres and in others to set up additional ones. It is suggested that the best way of meeting the difficulty would be to form mobile units, each consisting of a specialist in venereal diseases, a nurse, an orderly, and perhaps a clerk, with a motor vehicle containing equipment. Such a unit would take over the work of any existing centre which in the war emergency had been left without personnel if the gaps could not be filled from local reserves. It could also offer facilities for treatment in new places where outbreaks of venereal disease had occurred and the distance to the nearest centre was too great for those infected to attend it regularly.

Smooth Running

The Insurance Medical Service has reached the happy position of having nothing to report except continued efficiency. The number of complaints made by insured persons in respect of the treatment given by their practitioner is almost negligible. The cases investigated by medical service subcommittees last year numbered 141, but in only forty-one was any fine imposed upon the practitioner, and no practitioner was struck off the list. There were fifty-six other cases in which remuneration was withheld because proper medical records had not been kept or information furnished. When it is remembered that this is a service covering eighteen million people and employing seventeen thousand practitioners, and that the possibilities of misunderstanding inherent in the delicate relationship of doctor and patient—even when that relationship is not complicated by a doctor's bill—are constantly in the offing, the evidence of smooth working is truly remarkable. The regional medical staff of the Ministry dealt with 453,000 references, nearly all of them from approved societies, and nearly all for decision as to incapacity. The staff also paid just upon 12,000 visits to practitioners in connexion with their duty of administrative supervision of practitioners' prescribing, their certification of incapacity, and their keeping of records.

The report covers still other fields of public health. One of them concerns food control. Incidentally, a very large prevalence of avian tuberculosis has been found by inspectors in poultry markets. There is also recorded the discovery of a business (since closed down) in the Midlands in which dead one-day-old-chicks or dead unhatched chicks were used as a filling paste for pies. There were seventy-two outbreaks of Salmonella infection, with 230 cases and eight deaths. *S. aertrycke* was identified in thirty-seven of the outbreaks.

The story is also told of port sanitary work, which, like the British Navy, is a silent but ceaseless service. The work of guarding this country against the spread of epidemic disease requires "much toil and trouble on the part of medical officers of our national health organization, a wide experience of epidemiology, constant observation, the instinct of a detective for finding clues, and the patience of Job in conducting an investigation." During the year 1,068 vessels on which infectious disease was present or had occurred on voyage arrived at twenty-three ports in England and Wales. At these same ports over 10,000 rats were examined for indications of plague infection. Air ports are now added to the Ministry's responsibility.

Several interesting papers by members of the medical department of the Ministry are printed as appendices. The subjects include puerperal mastitis, an outbreak of toxic polyneuritis on a steamship, and an inquiry into hydatid disease in Wales. And there are enough tables to employ amateur statisticians for a winter of "black-out" evenings.

PREVENTION OF TUBERCULOSIS

The National Association for the Prevention of Tuberculosis held its annual conference in Belfast last summer, and the *Transactions* which have now been published are of interest and value to all who are concerned in any way with tuberculosis in the community. Among the subjects dealt with are: problems of organization and local administration of tuberculosis schemes, including arrangements for the induction of artificial pneumothorax and the after-care of patients so treated; tuberculosis in the adolescent; and architectural problems of tuberculosis institutions. Such a survey as these *Transactions* present is of much more immediate value than many textbooks on the treatment of tuberculosis, and certain suggestions put forward indicate some important issues. Thus it is urged that artificial pneumothorax involves the co-operation of a thoracic surgeon with a specialist physician equipped with full *x*-ray facilities. This procedure should be utilized in 50 per cent. of cases of open pulmonary tuberculosis, and hospital beds should be available for these patients. Large tuberculosis clinics should have central "filling stations" and a sufficiency of artificial pneumothorax apparatus, while after-care on sanatorium routine lines should follow in all cases. This operation should never be considered as a substitute for sanatorium treatment. It is pointed out that symptoms of tuberculosis in adolescents might be absent or slight, including a constant succession of colds, aphonia in young women, mental and physical lassitude, failure to increase weight with growth, erythema nodosum, amenorrhoea, and changes in disposition. Radiographic examination is essential, and the results may be very startling. The presence of tubercle bacilli in the sputum indicates that ulceration into a bronchus has already occurred and is therefore a late sign. The rising cost of building sanatoria is in some measure due to the unfortunate tendency to "go one better" than the last and does not necessarily make for greater efficiency of work and administration. The *Transactions* may be obtained from the offices of the National Association at Tavistock House North, Tavistock Square, London, W.C.1.

Cardiazol Shock.—This treatment was given to 207 schizophrenic patients, to twenty-four suffering from depression, and to fifteen cases of mania. Complete remission of the symptoms was obtained in all the patients in the last two categories as well as in a good proportion of the schizophrenic cases, notably in those whose mental disturbance was of recent date. Hahnemann tempers his praise of this treatment with the reservation that it needs to be supplemented by rational psychotherapy.—One Year's Clinical Experience of Psychoses treated with So-called Cardiazol Shock. V. Hahnemann.—*Ugeskr. Laeg.*, June 29, 1939, **101**, 771.

MEDICAL EDUCATION IN WAR TIME

EMERGENCY MEASURES

[FROM A SPECIAL CORRESPONDENT]

Anxious parents and others have been writing to the lay press about the disruption of medical education. The suggestion has even been made that the teaching of medical students is at a standstill. Upheaval there has certainly been, especially in the London area, with the considerable emptying of what have hitherto been known as the teaching hospitals and the transfer of their staffs to country hospitals in the sectors. But a position for which there was no precedent was met by the deans and other administrators with such resourcefulness that it now seems possible that the war, so far from having dealt a paralysing blow at medical education, may in fact establish it with an improved organization.

Medical education is being continued at not far short of normal levels. The students in some cases are suffering inconvenience due to dispersal, but it cannot be said that they are under educational disadvantage; indeed, in some respects they have opportunities which were denied to their predecessors. One of the several deans from whom was sought the information which follows, the Dean of the London Hospital Medical School, stated that the clinical material available to his students had been increased sixfold as a result of war conditions, without taking into account the number of chronic sick in public assistance institutions or the patients in mental and in fever hospitals. The number of teachers, he added, had also increased, with the result that the classes are smaller while the number of beds allocated to each student is larger. He acknowledged that his own hospital was in an exceptional position, as it was responsible not only for Sector I (Essex) but also for Sector II (North-East London and parts of Middlesex and Hertfordshire), with a considerable number of municipal and voluntary hospitals suitable for teaching purposes. This dean expressed the hope that the new arrangement which the war has precipitated would never be altogether abandoned. Another dean also referred to the value of the assistance now being rendered by people not normally on the staffs of hospitals and by staffs of hospitals not normally taking students. Admittedly there has been disarrangement of time-tables, a certain amount of what may be called geographical inconvenience, and a temporary contraction of facilities in some respects, but those may in the end prove to be small set-offs against a considerable educational gain.

London Medical Schools

The pre-clinical students of the London schools have been evacuated to other centres—Cambridge, Leeds, Bristol, Oxford, Glasgow, and the University of Wales, among others. The following brief statements of the position at the London schools relate only to clinical students.

St. Bartholomew's.—Clinical students are housed at thirteen institutions. The distribution in October was seventy-five at St. Bartholomew's itself, thirty-nine at five aid posts around the hospital, fifteen at the London Fever Hospital, four at St. Mark's, eleven at the Royal Chest, thirty at the Royal Northern, and 281 at seven other hospitals within the sector outside London. It has been possible to arrange for students at the outlying hospitals to go for instruction to the three centres: St. Bartholomew's, Friern (New Southgate), and Hill End (St. Albans). First-year students are stationed at Hill End, where a course of preliminary medical studies has been arranged, and dresserships and clerkships are taken there. At St. Bartholomew's itself the students in the intermediate years are taken in the special departments. At Friern the students in their final years receive tutorial instruction just before their examinations. Teaching in midwifery is spread out all over the sector; there are actually more midwifery cases than the college had in peace time. There are large units at Luton, St. Albans, and Highgate, and it is still possible to use the City of London Maternity Hospital and the district. Clinical cases are coming in large numbers. At the moment of writing (mid-November) there are 700 occupied beds in the sector (civilian and military sick). Out-patient material is somewhat meagre. From 400 to 500 out-patients attend daily at St. Bartholomew's, and out-patient departments have been opened there for ear and throat cases, eye cases, gynaecology, orthopaedics, dermatology, and tuberculosis. Arrangements have been made with a fever hospital. There are psychiatric specialists at all the hospitals where teaching is done, and at Friern 2,000 mental patients are available. Pathology is centred at Hill End, but some clinical pathology is taught at other centres. The Dunn laboratories at Bart's are kept open.

Charing Cross.—The principal centres of instruction are Charing Cross itself, and Stanmore, Watford, and Ashridge, where students are accommodated in large groups; there are smaller groups of students at other sector hospitals. About 20 per cent. are at the hospital in London. Lectures are given according to definite programmes for each centre. In some cases there are three lectures a day in addition to clinical work. Previously all experience of practical midwifery was obtained at Charing Cross. "External" facilities have now been found, and it is possible to provide all the work in this subject required by regulations.

Guy's.—Clinical studies are being undertaken at Guy's and at the county hospitals at Farnborough and Pembury. The distribution of students among the hospitals varies each quarter. During the present period approximately one-third are at Guy's, a quarter at Farnborough, a quarter at Pembury, and the remainder are divided between Orpington War Hospital and Joyce Green, Dartford. The students at Guy's itself are chiefly seniors in the last six months of study and first three months students. Systematic lectures are given at Guy's and also at Farnborough. The facilities available for teaching obstetrics include classes, out-patients, and wards at Guys and obstetric wards at Farnborough and Pembury.

King's College Hospital.—Clinical studies are undertaken at six hospitals in the sector, students being distributed proportionately according to the number of beds in each. About 25 per cent. of the students remain at Denmark Hill. Lectures are given according to the requirements of the various examining boards. Municipal and county hospitals are also affording instruction. Midwifery cases are attended by students at four hospitals in the sector, including King's College Hospital itself.

The London.—One-fifth of the students remain at the London Hospital. The remainder are distributed more or less in proportion to the number of beds at the various hospitals scheduled to receive casualties in Sectors I and II. Students have not been allocated to hospitals remote from London, such as Bishop's Stortford, Hitchin, and Colchester, and about half the students are at hospitals easily accessible to the London by bus or tram. Nor have the students been allocated to hospitals where no facilities for medical education exist, except in the case of a few hospitals in peculiarly vulnerable areas, such as Albert Dock and Tilbury. A number of the students work in the morning at the hospital to which they are attached, and come to London for systematic teaching in the afternoon. Systematic teaching is also in progress at King George Hospital (Ilford) and Southend General Hospital. At the London there is teaching in the out-patient departments in the morning, demonstrations in pathology at noon, clinical demonstrations in medicine, surgery, or obstetrics in the afternoon, and later still routine lectures. Clinical teaching in obstetrics is in progress at six hospitals and on the London Hospital district. Pathology is taught at four centres, but after Christmas the teaching in this subject will be centralized at the London. Every student is to spend one month at a mental hospital and one month at a fever hospital, an opportunity which has never occurred before.

Middlesex.—Clinical studies are undertaken at Middlesex and at nine other hospitals in the sector. The clinical students number 211, about fory of whom remain at Middlesex; five other hospitals have about twenty-five students each, and four others have about eleven each. Clinical lectures are arranged by the authorities at each hospital in the sector, according to facilities available. For other lectures certain centres have been selected, and students attend the nearest. Students attend for instruction in obstetrics first at Middlesex and later at St. Mary Abbots or Willesden Maternity.

Royal Free.—There are 151 students taking clinical studies at the Royal Free (of whom 37 are taking the finals in November or January), 44 at Three Counties Hospital, Arlesey, and a small number at St. Albans. A full time-table of lectures, etc., has been arranged at the Royal Free and at Arlesey, so far as possible in accordance with pre-war arrangements for clinical students. Students attend rounds at two L.C.C. hospitals. Lectures, demonstrations, and tutorials in obstetrics are arranged at the Royal Free, and students attend a maternity clinic and are on the Royal Free district for practical midwifery. Facilities are available for small numbers of students at three or four other places.

St. George's.—Clinical studies are being undertaken at the central hospital, where one-third of the students still remain, and at seven other hospitals, principally at West Middlesex County Hospital, Isleworth, and at Staines and Slough. Special acknowledgment is made of the assistance of the West Middlesex Hospital, which provides excellent material, and the members of its staff are most helpful in teaching. Facilities equal to the normal requirements for the teaching of obstetrics are available at one of the hospitals in the sector.

St. Mary's.—Of the 230 clinical students roughly half are at the four London hospitals in the sector. There are about four students for each hundred beds. The sector comprises a large number of county council hospitals. There has been no difficulty in arranging for teaching in obstetrics, which is available at several of the sector hospitals. A pathological course began at St. Mary's early in December. Arrangements have been made whereby students will be moved from place to place in rotation in accordance with the courses they require. Valuable assistance has been afforded by the staff of the British Postgraduate School and by some of the members of St. Thomas's staff at Park Prewett. In addition members of the staff of the London and Middlesex County Councils have helped in every way possible. Certain clinical teachers of St. Mary's are stationed at each hospital, and courses of instruction are given. There are regular lectures at each centre. The students are said to be thoroughly content with the teaching and clinical material at the various institutions, and on the whole it is the general verdict that while something has been lost in these novel war arrangements more has been gained, notably closer contact between patient and student and between student and teacher.

St. Thomas's.—At present the main clinical studies are being carried on actually at St. Thomas's and at Kingston County Hospital; there are 120 clinical students working at St. Thomas's, and roughly 24 students at four hospitals in the sector are carrying through a period of three months' study which will be credited to them in the examination schedules. Lectures are given both at Kingston (elementary clinical work) and at St. Thomas's, much in line with the systematic and clinical lectures of peace time. Kingston is providing facilities for clinical students beginning their studies, and instruction is given there by members of St. Thomas's staff and the staff of the hospital. Obstetrics teaching is being carried on with the co-operation of three hospitals, two of them L.C.C.

University College Hospital.—The medical school is using a considerable number of hospitals in the sector, for which purpose the sector has been divided into four groups. One group comprises University College Hospital itself, with five others, voluntary and municipal, in London, which are taking students. A second group of four hospitals works around Leavesden Mental Hospital as a centre. A third combines the Hampstead General Hospital, the North Western Fever Hospital, and New End Hospital, for general medicine and surgery and special departments, and, at New End, a little midwifery. The fourth group is centred at Edgware and includes three large hospitals. At U.C.H. there are 200 beds for casualties and 110 for civilian sick, with a considerable number of lying-in beds. Two-thirds of the midwifery is being done there. While the school is not turning students away, it is very near what would be considered full numbers. For the first month or so of the war students were distributed where it was thought they would be wanted for casualties, but during October the school arranged for every student to be doing the work he should be doing according to the educational programme. Some things cannot be done owing to shortage of patients and shifting of pathological facilities, but students are getting the education they ought normally to receive, and assistance is being rendered by people not ordinarily on the staffs of hospitals and by staffs of hospitals not ordinarily taking students. Lectures are being given at University College Hospital and at Leavesden and Hemel Hempstead.

Westminster.—Clinical studies are being undertaken at Westminster (89 students), St. Mary Abbots (6), Fulham (10), and St. Stephens (L.C.C.) (4). All the students are in London. A full programme of lectures is given at Westminster Hospital and facilities for teaching obstetrics are provided as in normal times.

Provincial Medical Schools

At the provincial schools there has been less disturbance than in London. At Birmingham clinical students are all allotted to the various units of the United Hospital. As the practical clinical work is on a smaller scale than in peace time rather more lectures and demonstrations are being given. Facilities for teaching in obstetrics are reduced but still sufficient. There is no reason why the time at which each student may appear for his successive examinations should be delayed by the rearrangements which have been made, and the school has every hope that the training will be as efficient as in peace time.

At Bristol clinical teaching is being carried on in the same hospitals as in peace time, and lectures are given exactly as under normal conditions. At Cambridge for their clinical work students go to London and provincial hospitals. At Newcastle clinical studies are taking place normally in four hospitals, mainly in the Royal Victoria Infirmary. Although the out-patient department was closed at the outbreak of the war, it was reopened within a fortnight. The necessary lectures are being given, with some readjustment of time-tables. At Leeds clinical studies are being undertaken at the usual hospitals, among which the students are distributed as in peace time. At Liverpool and Manchester teaching follows normal lines. At Oxford fifty students began clinical work in October and a certain number of more senior students have returned to Oxford from elsewhere. Lectures are being given as arranged by the committee for clinical teaching and approved by the Board of the Faculty. At Sheffield the usual programme is being followed. At the Welsh National School of Medicine work is continuing so far as possible under normal conditions. Certain of the beds at all the hospitals at Cardiff have been evacuated, but clinical teaching is being given at the main teaching hospitals—namely, Cardiff Royal Infirmary and two corporation hospitals.

Many of the provincial schools are acting as hosts to London pre-clinical and first-year medical students. Bristol has received pre-clinical students from the Middlesex. Cambridge has given facilities to the London and St. Bartholomew's students for pre-clinical work. At Leeds twenty-six students from King's College, London, have been admitted to the first-year medical course. Charing Cross pre-clinical students are also being taught at Leeds and at Glasgow. Manchester has over one hundred students from St. Mary's Hospital; London, for pre-clinical study in anatomy and physiology. Oxford has St. Thomas's pre-clinical students. At Sheffield thirty-five women students from University College, London, are taking anatomy, physiology, and pharmacology. At Cardiff a number of students from University College Hospital Medical School have been received for their first clinical year. Birmingham also, though an evacuation area, has received students from other schools.

Reports of Societies

CHEMOTHERAPY IN MOUTH INFECTIONS

At a meeting of the Section of Odontology of the Royal Society of Medicine on November 27, Mr. S. F. St. J. Steadman presiding, Professor A. FLEMING gave a paper on antiseptics and chemotherapy.

Professor Fleming first reminded his audience that there were natural anti-bacterial substances in the mouth, and that when chemical antiseptics were used the action of these on the natural antiseptics should be appreciated. There was a powerful anti-bacterial substance in the saliva, and in the mouth as elsewhere there were phagocytic cells which played a large part in resisting infection. Turning to the sulphonamides, he said the first thing to remember about them was that they were specific in their action; they would act on some organisms but not on others. They had little or no action when bacteria, even the most sensitive, were in large numbers. A third point was that peptone, as well as large numbers of bacteria, inhibited the action of sulphonamide. Finally, the chief action of these drugs was bacteriostatic, and it was the natural defence mechanism of the body which completed the destruction. The action would therefore be most dramatic when the infection was by a very sensitive organism such as the haemolytic streptococcus, and where there was no marked localization of the infection. If there was a localized infection, more especially an abscess, such dramatic effect need not be expected. In these cases the numbers of bacteria were likely to be large, and in the abscess tryptic ferments would be liberated from degenerated leucocytes with the consequent production of peptone.

There was one aspect of this drug therapy which might be important in war time. Surgeons were afraid formerly to excise wounds that were infected with the haemolytic streptococcus because of the danger of opening fresh tissues which the streptococcus would invade, thus giving rise to septicaemia. But sulphonamide could be administered to the patient so as to obtain a good concentration in his blood, and the surgeon could get rid of the sloughs, excising the wound without any danger of spread. As the body had to complete the destruction of the infected bacteria, it was clear that better results would be obtained when the natural defences were as efficient as possible. It was important, therefore, to use all possible means of raising the immunity. Several methods of doing this were available. It might be done passively by the administration of serum, or actively by vaccines. So far as odontological practice was concerned there were not many serums with any real bactericidal action on the microbes of the mouth, but an autogenous vaccine could be made with the greatest ease, and it should be possible to immunize the patient to a point at which the drug might be expected to have a much better effect than if used alone.

Dr. E. W. FISH said that one serious problem in dental practice was the danger of giving a bacteriaemia to a child who might have some incipient trouble leading on to endocarditis. It was not always convenient to carry out cauterizing of gum margins in a child before taking out a tooth. Unfortunately it appeared that certain organisms were not at all susceptible to the action of sulphonamide drugs, and he wondered whether Professor Fleming could indicate the organisms commonly found in the mouth which were susceptible and those which were not.

Mr. JOHN BUNYAN said that a healthy, perfectly formed mouth was one of the cleanest parts of the body, but unfortunately a healthy mouth was rarely encountered. It was commonly abused by unsuitable food, tobacco smoke, alcohol, the use of a hard brush, and patent antiseptics. The question of local antiseptics was an extremely important one to the dental surgeon, and one that had not been much investigated. He himself had tried all the antiseptics offered for use in the mouth, and had found hypochlorites most useful for what they were required to do—namely, to clean out the albuminous masses, dead bacteria, and the food debris. To use vaccines was to deal with the problem at the wrong end.

Mr. B. W. FICKLING said that at the Royal Dental Hospital there had been some investigation of the mode of action of these drugs, and many of the investigators considered that the concentration of the drug at the site of infection was important. Some work had been done on the concentration of M & B 693 (sulphapyridine) in the saliva, and it was found that whereas this drug was present in the mouth in all the cases it was only present in about one-third to one-fourth of the concentration in the blood. With regard to the use of these drugs in incipient submaxillary abscesses, he had analysed sixteen cases which had been admitted to the Royal Dental Hospital for this condition. Of this number twelve required incision no matter whether they had had sulphapyridine or sulphanilamide or had not, and only two cases could be called successes in the sense that when incision failed to cure the sulphonamide drug proved effective.

Professor FLEMING, in reply to Dr. Fish's question concerning the possibility of bacteriaemia after extraction, said that so far as his limited knowledge of the conditions in the mouth went the question of the sensitiveness of mouth microbes to these drugs had not been worked out. If the organisms were sensitive he had not the slightest doubt that bacteriaemia could be prevented. A question had been raised about the strength of the drug in the saliva. It was in the infected tissues, not in the saliva, that one wanted to kill organisms. Doubtless in the infected tissue outside a pocket one would get the drug in much the same concentration as in the blood, but it might be much weaker in the saliva and yet act perfectly well as regards the infection.

Chemotherapy in Gingivitis and Pyorrhoea

Dr. A. J. COKKINIS, in a short communication, described some work which he had superintended in a small chemotherapy clinic at St. Mary's. The object was to discover the value of chemotherapy in *S. viridans* infections, especially pyorrhoea. Cultures were taken from the patients' gums at various stages of pyorrhoea and gingivitis, and *S. viridans* was discovered in practically every case, sometimes in pure culture, very often mixed with non-pathogenic organisms, and in quite an appreciable proportion of cases mixed with *S. haemolyticus*. Over seventy cases had been treated with sulphonamide compounds—namely, sulphanilamide, sulphapyridine, and uleron. The last-named proved much less effective than the others. There was little difference between the first two, provided the sulphanilamide was given in rather larger doses. The majority of the patients showed some clinical response to treatment, however advanced their pyorrhoea. He was convinced that the obvious manifestations of acute gingivitis, whether localized or diffuse, could be made to clear up completely in about a week by oral administration of sulphanilamide or sulphapyridine, 3 to 4 grammes daily. The fetor and the morning stain on the teeth and lips completely disappeared. The oedematous interdental papillae shrank and the large lymph glands which had been observed in some of the cases subsided. This result could be produced by sulphonamide therapy without any adjuvant measures at all. But it was quite certain that one course of chemotherapy did not suffice to cure gingivitis, the condition relapsing a week or so afterwards. By giving further courses, however, and particularly by increasing the immunity response by preliminary and accompanying vaccine therapy, the infection could be indefinitely delayed for six months or more. In cases with a deeper infection, with pus pockets, apical abscesses, and loosening of the teeth, chemotherapy and immunotherapy could only play a secondary part, if any at all. There were evidences of anti-bacterial activity, however, even in these cases, the pain of a pulp infection being relieved or a pus pocket cleared up. But this was temporary, and cure could only be obtained through the odontological surgeon. An incidental benefit was the prevention and treatment of the septicaemia occasionally produced by the bacterial shower liberated into the blood stream after the extraction of several septic teeth. He had seen cases in which this septicaemia had cleared up quickly under sulphonamide compounds, and it was probable that vaccines and a short course of sulphonamide therapy would largely abolish these unpleasant complications of dental surgery.

Local News

IRELAND

Tuberculosis in Belfast

The report for 1938 of the chief tuberculosis officer for the county borough of Belfast states that 2,200 persons, notified as suffering from signs of tuberculosis in various forms, were examined during the year. Of these 36 per cent. were found to be tuberculous, and a further 7 per cent. suspect. The total number of patients who received treatment or who passed under observation was 7,842. It was found that 47 per cent. of new tuberculous patients examined had a definite opportunity of infection through contact with other tuberculous patients among their own family connexions. The report stresses the importance in avoiding infection of scrupulous care, not only in the disposal of sputum, but in the cleansing of the hands and of table utensils. It is suggested that every patient and attendant should have a separate set of table utensils for his own use. The application of P.P.D. (purified protein derivative) tests proved to be especially valuable in children. A positive reaction may provide early diagnosis; repeated tests at periodical intervals may furnish helpful guidance concerning the progress or regression of the disease. On the other hand, a negative reaction, especially in the higher dilutions of P.P.D., prevents sufferers from bronchitis or wasting being wrongly labelled as tuberculous. Application of the test to children of pre-school age may aid in the discovery of a hitherto unsuspected case of tuberculosis in the household.

Medical Research Council of Ireland

The Medical Research Council of Ireland has made the following awards: Dr. W. R. F. Collis and Dr. Oliver FitzGerald, each a grant-in-aid for special apparatus; Dr. Martin G. A. Little, part-time grant for one year from January 1, 1940, for an investigation of the nervous control of the digestive glands, the work to be carried out in the department of physiology, University College, Galway, under the direction of Professor J. F. Donegan; Dr. D. P. Murnaghan, grant-in-aid towards the expenses of his research training in the department of embryology, Carnegie Institution of Washington, Baltimore, U.S.A., under the direction of Dr. George Streeter. Whole-time grants have been renewed for further periods as follows: Mr. Patrick Boyle, one year; Dr. T. G. Brady, one year; Dr. P. J. Holland Clarke, six months; Mr. R. P. Cooke, one year; and Dr. Cecil Mushatt, five months. Part-time grants renewed are: Dr. Oliver FitzGerald, one year, and Dr. D. K. O'Donovan, one year. The grant-in-aid awarded to each of the following has been renewed: Dr. E. S. Duthie, six months; Dr. Ninian Falkiner, one year; Professors W. R. Fearon and R. W. Ditchburn, six months; Dr. Gerald FitzGerald, one year; Professor J. B. Gatenby and Miss O. E. Aykroyd, one year; and Dr. David Mitchell, one year.

SCOTLAND

Scottish Mental Pathology

The annual report for 1938 of the Scottish Mental Hospitals' Pathological Scheme gives a short summary of the work of Dr. Campbell, the pathologist, in collaboration with his predecessor, Professor Biggart, on the nature and incidence of the polio-encephalitis first described by Wernicke. The opinion is put forward that this disease is not necessarily restricted to cases of alcoholic excess, but may occur in a wide variety of conditions of bodily privation or exhaustion. A lack of vitamin B_1, whether or not associated with an infective focus, is regarded as a potent factor in its causation. The report points out the importance of this research with a view to the diagnosis and treatment of the many obscure, obviously organic cases of mental and cerebral deterioration. with no evidence of arteriopathic degeneration sufficient to account for the symptoms, which are received every year in mental hospitals. Among other researches mentioned are an investigation of the influence of the thyroid on the temperature disturbances produced by experimental lesions in the hypothalamus, an experimental study of the quantitative variation of the cerebral capillary bed under different conditions, and an investigation into the reactions of the cerebral vessels in normal and hypertensive animals. Routine work comprised 252 histological examinations, including examination of 221 brains.

Edinburgh V.D. Scheme

The annual report for 1938 of the City and Royal Burgh of Edinburgh Venereal Diseases Scheme describes the year under review as a period of transition from older and less efficient to recent improved methods of treatment. The adoption of the new chemotherapy for gonorrhoea produced a marked drop in the number of out-patient attendances, with the substitution of one interview with a medical officer every day for thrice daily irrigations. Sulphapyridine (M & B 693) is now given as the routine treatment of gonorrhoea in all its manifestations, including vulvo-vaginitis in young girls and ophthalmia neonatorum. The proportion of successful cases is estimated at approximately 90 per cent. The only disadvantage of the new form of treatment is that the symptoms subside so rapidly that patients too often fail to continue attendance for the prescribed period. With regard to syphilis the report states that increasing use is being made of the pentavalent arsenical compounds, acetylarsan and tryparsamide. The total number of cases during the year shows a slight increase. Routine Wassermann testing is advocated, a procedure which in Denmark has resulted in a striking decrease in the death rate from congenital syphilis. In follow-up work some difficulty is experienced regarding "problem girls," those who have had not only one but two or three illegitimate children. These girls readily become infected with venereal disease and are a source of danger to themselves and society. Although sterilization would prevent the production of children by irresponsible parents, it would only lead to further promiscuity and increased chances of the spread of disease. The provision of a suitable home or institution for this type of girl would contribute to the solution of the problem.

Correspondence

Cancer of the Lung

SIR,—In a letter in the *Journal* of April 2, 1938 (p. 755), I drew attention to the presence of some form of silica and iron in certain dusts that were under suspicion as causing cancer of the lung.

It was stated therein that experiments with mice were being conducted to study the effects of iron and silica dusts separately. These experiments, although not all completed, have reached a stage at which it is already established that exposure six times a day on five days of each week for one year to dust clouds consisting either of precipitated silica (SiO_2) or of iron oxide (Fe_2O_3) increases the incidence of primary lung tumours in mice, compared with that for control mice from the same stock and not specially dusted. About sixty mice lived to ages greater than ten months, and of these only 6 per cent. of the controls exhibited primary lung tumours compared with 20 per cent. of the sixty mice dusted with silica; this silica experiment is completed. The silica produced fibrotic nodules in the lymph nodes, but there was less indication of fibrosis in the lung tissue, much of the silica being removed by way of the trachea and by the lymph channels. With the iron oxide dust, although the experiment is not completed, the incidence of lung tumours is already sufficient to give over 20 per cent. for the total dusted mice living ten months or longer; all the mice are not dead yet. Thus the iron oxide seems more potent than the silica, but such fine conclusions may not be drawn, since the lungs seem to contain more iron oxide than silica.

In any case the increases due to silica and to iron oxide seem together sufficient to explain the 45 per cent. incidence of lung tumours obtained in mice exposed to road dust from which the tar had been extracted by benzene (*Brit. J. exp. Path.*, 1937, **18**, 215). The highest incidence (74 per cent.) occurred in the mice exposed to road dust containing tar (*Brit. J. exp. Path.*, 1934, **15**, 287; ibid., 1939, **20**, 122), and it might be considered that 74 minus 45 per cent.—that is, 29 per cent.—were due to the tar and the remainder of the excess of the 45 per cent. over the normal incidence might be regarded as being due to such inorganic constituents of the dust as silica and iron oxide. Since these constituents are also in the general atmospheric dust, it is not unreasonable to hold that some of the tumours present in control mice are due to similar causes. There is evidence that iron and silica may cause cancer of the lung in man (Dreyfus, T. R., *Z. klin. Med.*, 1936, **130**, 256; Kennaway, N. M., and Kennaway, E. L., *J. Hyg.*, Camb., 1936, **36**, 236; Turner, H. M., and Grace, H. G., ibid., 1938, **38**, 90).

It has been suggested by several observers that cancer may originate in cells suffering from anoxia. To test this in the lung an experiment has been conducted for nearly three years with mice bred and living almost continuously under low oxygen pressure (13 to 15 per cent.—mostly 13—of one atmosphere) in a chamber. Thirty-two of such mice older than ten months have died, and of these over 30 per cent. have exhibited primary lung tumours. They have not been specially dusted, but have been exposed to some dust from soda-lime (used to absorb carbon dioxide and moisture), and also to dust from the sawdust bedding and from the mixed grain-and-bread diet. Fifty-three controls which had been shut up in a similar chamber with soda-lime, etc., but with normal oxygen pressure—namely, 20.9 of an atmosphere—show an incidence of 15 per cent. for primary lung tumours, so that the anoxia appears to double the incidence. Primary lung tumours often seem to originate in a portion of collapsed or thickened lung, and presumably the centre of such an area might suffer from some degree of oxygen want, which might be one of the factors in tumour formation. The experiment is being continued, and full details of the above result will be published elsewhere.

To date 363 control mice have given 12 per cent. incidence of primary lung tumours; on the other hand, 542 similar mice exposed to various dusts under suspicion as causes of lung cancer in man have given 36 per cent. incidence.—I am, etc.,

London, N.W.3, Nov. 29. J. ARGYLL CAMPBELL.

The Intervertebral Disk

SIR,—Having recently spent ten months at the Mayo Clinic, and having been deeply impressed with the work there on protruded intervertebral disks, I was particularly interested to read Mr. Pappworth's article on the subject in your issue of November 25 (p. 1038). He raises, however, several points which seem to me to be controversial and worthy of discussion.

His use of the phrase "a critical review" as a subtitle seems hardly justified, for six of the seven articles which he uses as the basis for his arguments are from the same clinic, and, as he himself admits, they are concerned with the same series of cases. True enough, he includes one article from the Mayo Clinic, but refers to it only once apart from direct quotation. His main argument seems based upon the fact that he has discovered several statistical discrepancies in the six papers of the Boston group, and it should be made clear that there is no similar quarrel with Camp and Love's paper. Nor does it seem reasonable to maintain that minor inaccuracies (which might be due to a change in the opinion of the workers) invalidate the claim that prolapsed intervertebral disk is a clinical and pathological entity. It is fortunate that Dr. Love himself (*Proc. roy. Soc. Med.*, 1939, **32**, 1697) has recently restated with the utmost fairness the views generally accepted in America. This article itself is a complete answer to Mr. Pappworth, and should do much to advance knowledge on this side of the Atlantic. It is only necessary to emphasize several minor points.

It is by no means true to say that the appearance of the prolapsed disk after injection of lipiodol is "not clear." The smoothly rounded defect of an extradural type opposite an intervertebral space on the antero-lateral aspect of the cord is very characteristic, but it must be realized that if this defect is a small one it may be overlooked if the patient is not examined on a tilting table, when the actual flow of the oil can be observed. This point has been mentioned by Dr. Campbell Golding, and is one which may explain some of the failures of English radiologists to demonstrate the lesion.

Dr. Love explains that his cases at the Mayo Clinic are referred to him by the orthopaedic surgeons, but that the operation itself is a neurosurgical procedure. Mr. Pappworth views it from the orthopaedic angle, and asks if laminectomy is the only treatment. It should be clearly realized that the aim of operation is not to perform a laminectomy but to remove the prolapsed disk; that the orthopaedic approach is only a stage in the treatment. It is not too much to say that much of the odium which has been heaped on the operation in America itself is due to the efforts of orthopaedic surgeons, who have been content with simple decompression by a laminectomy without removing the disk, and who have been disappointed with the end-results. Indeed, I believe that in several cases the disk has been removed through the interval between adjacent laminae without touching the lamina at all.

To argue that a lesion which can so project into the spinal canal as to reduce its calibre by at least one-half and yet cause no compression of the cord or nerve roots is to me flying in the face of all commonly accepted principles. We have no great difficulty in visualizing that a subdural haematoma can compress the brain, and I cannot see that it is logical to imagine that the spinal canal, which is equally a closed space, will behave differently. And certainly to anyone who has seen the defects in the lipiodol column either under the screen or on the radiograph there can be no question that there is an encroachment of some sort upon the canal.

I therefore conclude that Mr. Pappworth has failed to make good his claims, and that, to quote Dr. Love, "intraspinal protrusion of the intervertebral disks is a pathological entity. . . . It has a fairly definite symptom complex . . . laminectomy with removal of the protruded intervertebral disk should be performed . . . the results in 300 cases justify the method."—I am, etc.,

Leicester, Nov. 27. E. PETER ALLEN.

Sir,—In an article in your issue of November 25 (p. 1038) a contributor discusses retropulsion of the nucleus pulposus. The paper appears to be based entirely upon the meaning which Mr. Sidney Pappworth reads into the well-known work of Mixter and Barr. I find myself at variance with almost every statement made in this piece of armchair criticism, but had perhaps better confine myself to dealing with the three questions which Mr. Pappworth raised and answered.

1. Can retropulsion of the nucleus pulposus cause symptoms? If by this term Mr. Pappworth means the small and often multiple lesions found by Andrae in post-mortem specimens the answer is, almost certainly, No. It is a rupture of an intervertebral disk which causes neurological disturbance—a much larger lesion than that described by Andrae. The latter has probably no clinical significance in the present connexion. Mr. Pappworth does not apparently understand the pathology of the symptom-producing lesion.

2. Is laminectomy the only treatment? If symptoms are severe and persistent and a ruptured intervertebral disk has been demonstrated its excision is the only treatment. If Mr. Pappworth had seen one of these large fibrocartilaginous masses removed at operation I think he would realize the futility of waiting until it was "absorbed or cicatrized." As an orthopaedic surgeon he had better consider waiting until a torn medial meniscus in the knee-joint has been absorbed or cicatrized.

3. Are the results of laminectomy such as to justify operation? One has only to study the figures of Mixter and Love to feel satisfied that the results more than justify laminectomy; they indeed indicate it. Anyone who has seen a patient entirely incapacitated over a period of many months immediately relieved of symptoms by the operation will realize the value of this new method of treatment in suitable cases.

In speaking of the diagnosis of disk lesions Mr. Pappworth remarks that "the true appearance of a disk lesion is not too clear." This is a surprising statement, as the radiological features have been clearly set out since Mixter's earlier papers and have also been described in detail by his radiological colleagues. I find myself in agreement with two of Mr. Pappworth's statements: the first, that there should be a close season for the writing of articles; the second, that he is fortunate in having had enough leisure to examine the claims for a new procedure before operating, for I am certain that an operation carried out without a proper understanding of the lesion it is designed to treat can lead only to the disappointment of patient and surgeon. In this particular case it will also tend to obscure the value of Mixter's excellent work.—I am, etc.,

London, W.1, Dec. 1. J. E. A. O'Connell.

Treatment of War Wounds

Sir,—Dr. Bhatia (November 25, p. 1062) raises the issue between plain gauze and vaseline gauze. I think everyone has experienced the disadvantage of the use of gauze with its wide mesh which can easily be penetrated by granulations. As a result the deepest strands of gauze are often built into the granulation tissue and can only be torn out by force with pain and haemorrhage. This happens to a considerable degree in spite of thorough impregnation with vaseline. To avoid this undesirable event I have for years laid on the deep surface of the saucerized wound a layer of ordinary thin linen bandage, about fifty threads to the inch. Until recently this, too, was impregnated with vaseline; now it is plain. Two or three six-inch lengths of four-inch or six-inch bandage will generally cover a moderate-sized wound. Each slightly overlaps the next. As the gauze packing is subsequently pushed gently into the wound it carries this thin linen "tablecloth" in front of it. The mesh is too fine for penetration by granulation tissue but offers no resistance to soakage. Weeks later it peels off the granulations far more easily than gauze, with little or no discomfort and much less bleeding.—I am, etc.,

Headington, Oxford, Nov. 28. G. R. Girdlestone.

Treatment of Wounds by Closed Method

Sir,—The remarkable results obtained by Dr. Trueta by the closed-plaster method of treating excised bomb wounds are arresting to those who gave thought to wound treatment in the last war.

It was obvious that the minds of many present at Dr. Trueta's lecture at the Royal Society of Medicine were groping for a satisfactory explanation of this revolutionary method. Much light is thrown on the application of the closed principle in an article in the *Australian and New Zealand Journal of Surgery* of July, 1939 (p. 72), by Fay Maclure, on mechanical principles in the causation and treatment of disease, under the heading of "Limiting and Enveloping Membranes." He writes:

> "Life is dependent on tension. . . . There must of necessity be a restraining or limiting layer of membrane. When the integrity of the enveloping membrane is destroyed, as, for example, in herniation of muscle through torn fascia, the mechanics of the contents is completely disordered. One of its principal effects is on the circulation. . . . The rebound mechanism whereby the energy of arterial pressure is transformed into an accessory pump, maintaining the flow of lymph and venous fluid, is dependent on a resistant layer. When that membrane disappears the area of loss becomes an area of failing circulation, and stagnation and oedema ensue. To restore the circulation in the affected part it is necessary

to reconstitute the limiting membrane or to replace it with an efficient substitute. . . . Pressure therefore becomes an essential in the treatment of all unhealed areas."

Excision of damaged tissue cuts out the dead and presents a living front line to the attacking organism. Pressure on the front line keeps it living and active and enables circulation to play its part in the contest. The lines of communication are then unimpeded.

It would appear that Dr. Trueta and Fay Maclure have established a further principle of healing which if practised will confer untold benefits on injured man.—I am, etc.,

London, W.1, Nov. 29. E. T. C. MILLIGAN.

Treatment of Gas Gangrene

SIR,—I shall be grateful if you will give me space to correct an impression that Professor Girdlestone (*Journal*, December 2, p. 1110) has gathered from my letter (November 25, p. 1058). It would ill become one who went from Liverpool to France in 1914 to "gird" at the Thomas bed splint, an invention which has done so much to alleviate human suffering. Indeed, I well remember the acute disappointment I experienced when, with numerous cases of fractures waiting for them, a large consignment of Thomas splints by some dreadful mistake turned out to be in children's sizes.

I quite agree with Professor Girdlestone that correct application is essential, and we were specially favoured at Royaumont, for with characteristic generosity my kind friend Sir Robert Jones sent out to us his most highly trained sister, who stayed for a month and gave many demonstrations on his methods. May I now too, even after this lapse of time, acknowledge with gratitude the value of the articles on fractures under war conditions by Sir Robert Jones which appeared in your *Journal* in 1916. They were read and reread until the pages were ragged!

If I appeared to be unduly severe on the plaster-of-Paris method, I think it must be stressed that the interval which is likely to elapse between the infliction of the wound and the complete operative treatment is of vital importance if there is a likelihood of the development of gas gangrene. This was shown in the tabulated list of cases of gas gangrene I recorded after the battle of the Somme, where the interval extended into days, not hours. In such cases even a tight bandage can be disastrous, and I have seen a gangrenous hand encased in a skin-tight bandage—a bandage which under ordinary conditions would receive special commendation at a V.A.D. inspection. I wonder if it would be out of place here to urge upon first-aid lecturers to teach the practical method of application of the Thomas splint, even in the first course of lectures.—I am, etc.,

Killagorden, Cornwall, Dec. 4. FRANCES IVENS-KNOWLES.

Psychological Casualties in War

SIR,—Although it is not quite clear whether he is referring to civilian or military life, Dr. R. D. Gillespie's letter in the *Journal* of December 2 (p. 1110) suggests that "wide advertising of the supposed inevitability" of war-time increase in psychological disorders "does more harm than good." While this may be true in relation to the general public, it can at least do no harm for doctors to recall some historical facts about these disorders as they occurred in soldiers during and after the last war. Excluding psychoses, pensions for psychological disorders were awarded to more than 100,000 men. The cost of these pensions, according to an estimate made by the late Sir John Collie of the Ministry of Pensions staff, must have been approximately ten million pounds per annum in the years immediately after the war, and amounts to over four million pounds this year. If, as seems possible in this war, civilians may be submitted to the stresses which precipitated in soldiers a group of psychological disorders of this size, these facts cannot be entirely without bearing on the potential incidence of such disorders in our war-time civilian population.

Dr. T. A. Ross's current plea for observation of recruits during early training (December 2, p. 1110) repeats the similar strongly worded plea made by Sir William Osler over twenty years ago. At that time findings of the later War Office Committee on Shell-shock (1922) were to some extent anticipated by Dr. T. W. Salmon, an outstanding American psychiatrist, who was sent to England from that country through the cooperation of the Rockefeller Foundation to study the problem of psychological disorders in the British Army. His report mildly indicated the difficulties which had arisen over what was then a novel problem. Speaking of the British Army experience, he pointed out that it "carries important lessons; more important than all others is the result of careless recruiting." "The importance of providing, in advance of their urgent need, adequate facilities for the treatment and management of nervous and mental disorders can hardly be overstated."

The problem of psychological disorders is no longer novel, and this time there can be little excuse if we fail to make an attempt to deal with it.—I am, etc.,

London, W.1, Dec. 4. A. T. M. WILSON.

SIR,—In your issue of November 4 Wing Commander R. D. Gillespie stated that he had never heard of any data which purported to show a rise in psychoneurotic illness during the war of 1914–18. If, as I suppose, he was referring to civilian sickness, it should be pointed out that there are no unassailable figures for the incidence of civilian psychoneuroses, either during or after the war. His statement that the incidence remains unaltered is not capable of either proof or refutation. It is not a fact but a belief.

In his latest letter (December 2) the belief has apparently widened in scope; for now he claims that mental illness *in general* was probably less during the last war than in peace time. There is some evidence to suggest that this may be true of certifiable mental illness. It is certainly not proven in the case of civilian psychoneuroses, and the belief is supported by no better evidence if it is extended to cover psychoneuroses in the Services. The true incidence of psychoneurotic illness in the Services in peace time is unknown. In the Army health reports it is obscured by the classing of such cases under such headings as "D.A.H.," "Disease of the Nervous System," "Disease of the Digestive System." Similarly, the incidence in the last war is unknown. Many such cases were treated at aid posts and casualty clearing stations and returned to duty without appearing in the official statistics. Some were diagnosed as malingerers and others shot by order of courts martial. Many more severe cases were misdiagnosed—for example, as "V.D.H."—or were left undiagnosed and labelled according to some presenting physical symptom.

The only statistics of any value are not of incidence but of more or less long-term disability. It is an incontrovertible fact that 103,257 pensions were given for psychoneurotic disability after the last war, and that well over a quarter were still being paid last year. In other words, one man out of every thirty on the day-to-day "strength" in the last war was considered sufficiently incapacitated by psychoneurosis to be given a pension, and one man out of every 103 on the day-to-day "strength" was considered sufficiently incapacitated *twenty years after the war* to merit continuance of that pension. These appallingly high figures are those of severe incapacity only. The figures of actual incidence must be much higher. Whether this war-time incidence is higher or lower than that in peace time is anybody's guess; but if Wing Commander Gillespie's guess is right it shows not that more facilities for treatment are unnecessary in war time but that our peace-time facilities are seriously inadequate. He is concerned lest the provision of treatment should breed psychoneuroses. Many of his colleagues are concerned about a much more real danger—namely, that such a cavalier attitude towards the problem of psychoneuroses may lead, as it did in the last war, to widespread personal distress and military inefficiency, with a bill of ten million pounds per annum for psychoneurotic pensions to follow. Dr. T. A. Ross's letters, and other evidence, suggest that our concern is justified.

The War Office committee of 1922 made recommendations to avoid the difficulty, which Dr. Ross mentions, of diagnosing potential psychoneurotics at a single short interview. It recommended that depot medical officers should be skilled in the diagnosis of such personalities, and that the depot non-commissioned officers should be instructed in the behaviour characteristics for which they should refer recruits to the medical officer. In this way such recruits could be gradually eliminated during the period at the depot. The experience of the American Expeditionary Force teaches the same lesson. The attempt to reject potential psychoneurotics at the initial examination was abandoned in favour of observation and specialist examination during training. The 1922 committee's recommendation for early specialist treatment within the divisional area, or, for more serious cases, at special hospitals at the army base, to avoid evacuation to England, were equally well founded on medical evidence.

Dr. Ross's cases, and others of which I know personally, make it clear that the committee's recommendations for prophylaxis and treatment of psychological illness in the Army are not being implemented. If they had been many of the psychoneurotic soldiers who, in this present war, have already been evacuated to England would never have reached France in the first place, and, in the second place, having fallen sick, would not have reached the general hospitals in England.—I am, etc.,

London, N.W.3, Dec. 4. G. Ronald Hargreaves.

Genito-urinary Injuries in War

Sir,—Will you allow me a belated comment on Mr. G. E. Neligan's valuable article on injuries to the genito-urinary tract, recently republished in *War Wounds and Air Raid Casualties*. As certain chapters of this book are likely to be used as a textbook by many young surgeons without previous war experience the advice given must be very exact.

First may I stress the importance of Mr. Neligan's advice that suprapubic drainage, with an indwelling de Pezzer or Malecot catheter, be provided for all wounds of the bladder and urethra, and also (at least under field conditions) for all cases of paraplegia. The prophylactic value of this simple procedure is as great as that of colostomy or caecostomy for wounds of the rectum and colon, and should never in any circumstances be omitted.

Secondly, I venture to question Mr. Neligan's statement that partial amputation of the penis may be necessary in cases of severe laceration. The question of whether the urethra is or is not reparable is of course entirely irrelevant. All that matters is that one of the arteries should be intact. I have seen several cases of very severe penile laceration heal well, leaving an organ diminished in size and tied up with scar tissue, but still capable of erection and inviting plastic repair. The best treatment is certainly immediate and careful repair, to the extent to which this may be possible. But even if the surgeon in the casualty clearing station should feel that to attempt repair is hopeless, I would suggest that he should never go further than to trim the wound, ensure haemostasis, suture the skin so far as he can with nothing coarser than horsehair, wrap the organ, or what remains of it, in dry gauze (if completely sutured) or in cod-liver oil gauze (if the wound is wholly or partly open; if cod-liver oil, which is antiseptic, is not available, then in vaseline gauze), and splint the organ in the upright position, at right angles to the abdominal wall, to provide elevation and immobilization. This can be done with two pieces of pliable wire such as is used for a Böhler finger splint. One piece is bent as for a finger splint, well padded, and the penis fixed to it with strapping. The other forms an arch padded at each end and secured to the skin just above each inguinal ligament with strapping, and to which the penile splint is tied. The arch is then itself tied to a cradle placed over the patient. Suprapubic drainage of the bladder is of course provided, and the patient can be sent straight on to a plastic surgeon at the base.

There is, at the worst, nothing to be lost by such conservatism. The blood supply to the penis is such that it will survive as astonishingly as does the scalp. One need not be a psychologist to realize what it means to a man to retain the possibility of a normal sexual life.—I am obliged to sign myself

A Former Surgeon to the International Brigades.

Anaesthesia in War Time

Sir,—In your issue of November 25 (p. 1057) Dr. Priestman expresses a wish that all who teach anaesthetics should put certain "N.B.s." The first one interested me very much: "'Remember the significance of and difference between conjunctival and corneal reflexes.'" Surely the day is long past when anaesthetists take either of these reflexes. Sticking fingers into patients' eyes seems to me to savour of barbarism. In the *Journal* many years ago a paper was written by an ophthalmic surgeon who said: "The man who takes the corneal reflex shows the hall-mark of an incompetent anaesthetist." I have never seen that statement challenged.

I teach my students that all patients are blind; therefore there are no corneal reflex to obtain and no eyes to damage. The corneal and conjunctival reflexes are very superficial at the best, and I do not think surgeons would be overjoyed at having to operate in the presence of either of these. The eye is much too delicate a structure to use for anaesthetic signs, and with present-day premedication it is of very little value as a sign. During anaesthesia the eye should be kept covered and carefully guarded from outside irritation, such as ether vapour, bright light, and corneal attacks by anaesthetists. The most common cause of the condition known as "anaesthetic eye" is corneal damage by irritation and not, as formerly supposed, by ether or chloroform being spilled into it.—I am, etc.,

J. B. H. Holroyd, D.A.,
Anaesthetist, Sheffield Royal Infirmary; Instructor in Anaesthetics, Sheffield University.

Sheffield, Nov. 25.

Sir,—Your leading article on anaesthesia in war time (*Journal*, November 11, p. 958) stimulates me to send one more contribution on this important subject. It is one which specially concerns the general practitioner, and for the past ten years I have been trying to improve my technique with, I believe, some success. As you rightly say, ether will be the anaesthetic most commonly used, but though relatively safe it has various drawbacks, which I have tried, within the limits of general practice, to eliminate.

I think that anyone who has used morphine and atropine before anaesthesia cannot deny the benefit they confer, but unfortunately their use completely upsets the action of the pupil so that its size can no longer be used as a reliable guide to the depth of anaesthesia, as it could before morphine and atropine were used. With the inexperienced anaesthetist the depth of anaesthesia is the thing he is most bothered about, and nervousness on this point is perhaps the greatest cause of poor administration. Basal anaesthesia is also a great comfort to the patient, but to those not accustomed to it it adds other complications, and, furthermore, the technique of administration is not always possible in war conditions.

Just about the time that avertin was becoming popular, but before it was safe enough to be used in cottage hospitals, I stumbled on a combination of drugs which proved to give me practically all the advantages that avertin offered, together with relief from the two difficulties mentioned above. I have since used it, sometimes as surgeon and more often as anaesthetist, in over 300 major operations of various types in persons varying from 18 to 85 years of age, and although the dosage may seem heavy it has proved remarkably safe. About an hour before the operation the patient receives a subcutaneous injection of morphine hydrobromide 1/4 grain, hyoscine hydrobromide 1/100 grain, and atropine hydrobromide 1/200 grain (Tab. Hyoscinae Co., P. D. and Co.) and an intragluteal injection of somnifaine 2 c.cm. The latter has had a chequered career as an anaesthetic which I need not detail, but it has the valuable property that it is slightly mydriatic, with the result that the combined action of these drugs is found to leave the pupil practically normal, so that the size of the pupil proves once again a useful guide to the depth of the chloroform or ether anaesthesia. The amount of ether required is about half that which would be required without the addition of somnifaine, post-anaesthetic vomiting is greatly reduced, and amnesia is complete in about 90 per cent. of cases and usually continues for about twenty-four hours. There is a long post-anaesthetic sleep, usually about six hours, and though to some this may seem dangerous it has not proved so in practice, and it has the great advantage for war work that the useful time during which this combination works for anaesthesia is from three-quarters of an hour to three hours after administration, the ideal being between one and one and a half hours after. Where operations cannot be timed to the minute this is a considerable advantage for a basal anaesthetic. Actually it is my usual practice shortly after the patient has begun to recover from the anaesthetic, and been made comfortable from the nursing point of view, to give another 1/4 grain of morphine if he is at all restless, and this usually suffices for eighteen to twenty-four hours. The next night I follow this with a tablet of dial, which seems to act better than the other barbiturates on this night, unless there is much pain, in which case more morphine may be required, or a tablet of veramon with the dial. Occasionally two sonalgin tablets will succeed very well. With this scheme of dosage it is usually found that about three weeks after the operation the patient will have no clear memory, or complete amnesia, of the events of the first three or four days after the anaesthetic, and in the stress and horror of war work this ought to go a long way in reducing the number of psychological casualties among the injured.

One unexpected virtue of this combination is that under it the patient is noticeably free from shock. Pulling on the peritoneum and removal of a large organ or tumour, which in the ordinary way would be liable to cause marked shock under the anaesthetic, with this technique seem to affect the patient very little. This is not to excuse rough surgery, but it does help the anaesthetist by diminishing the trouble which an inexpert surgeon can cause him, and as the anaesthetic is a rather slow-moving one there is little chance of the patient suddenly collapsing or coming round at an awkward moment, and this diminishes the trouble an inexpert anaesthetist can cause the surgeon. There is usually a slight fall of blood pressure, 10 to 20 mm. Hg, but, as I say, shock seems much less than normal. However, should an analeptic be required there is none which, in my experience, can compare with cardiazol-ephedrine when this technique has been employed. I might add that the more I use oxygen the more am I pleased with its results, though it is by no means essential.

There remain the undoubted facts that post-operative shock is more marked after chloroform and ether than after nitrous oxide, etc., and also that both ether and chloroform are protoplasmic poisons which act specially deleteriously on the liver. This also has engaged my attention, and, though my observations are purely clinical and the deductions pure hypothesis, I believe that I have found out something of real help here too. When working with injections of concentrated solutions of vitamins A and D (now known as dekadexolin) I noticed that post-operative shock—as distinct from the shock during anaesthesia mentioned above—was practically absent if an injection of dekadexolin was given at the time of the operation. This observation has been so constantly repeated during the past eight years that I think it is indisputable. It has led me to suppose that some at least of the shock and poisoning action of the volatile anaesthetics is due to the fact that they are both powerful fat solvents and so, *a priori*, liable to interfere with the proper functioning of the fat-soluble vitamins stored in the liver. Whether this is so or not there is no doubt that when these patients are followed back into the wards they remain clinically in a much better condition than those who have not been so treated, and it is very rarely that any of them require even a rectal saline. Where relatively untrained nurses may have to be employed this also is a considerable advantage.

I am well aware that such a bald outline as can be given in a letter lays me and my methods open to many criticisms, but I also know that valid criticism can only come after a personal trial, which I trust that any would-be critics will hasten to make. After the experiment I believe that they will agree with me that, where conditions are not ideal or skilled team work is impossible, these three easily administered injections do in fact procure for patient, surgeon, and anaesthetist an ease and safety in ether anaesthesia unattainable by any other method. And with this it has advantages for war surgery which I have tried briefly to indicate.—I am, etc.,

Winsford, Cheshire, Nov. 23. W. N. LEAK, M.D.

Gas Injuries to the Eye

SIR,—I have been very interested in the letters which have appeared in the *Journal* on the subject of gas injuries to the eye, and note the comments of Colonel L. T. Poole and Professor J. H. Burn. I have had a fair amount of experience of these cases and have tried every therapeutic measure available. For more than two years I have confined my treatment to cod-liver oil and liquid paraffin. No other therapeutic measure has given a satisfactory result. Contact glasses may even do harm, as two of my cases have had the cornea perforated by this means. Colonel Poole, in his letter of November 25, stresses the instantaneous action of mustard gas, and when one notes this point it will be seen that the first-aid treatment is the same as the later treatment. Atropine will relieve the photophobia, but cod-liver oil is the essential. Dr. N. Pines mentions protein shock, but my own experience shows that this is useless, and also, be it noted, should be supplanted in the treatment of gonococcal ophthalmia by M & B 693.—I am, etc.,

Wolverhampton, Nov. 25. H. CAMPBELL ORR.

Blood Group Distribution in England

SIR,—As a consequence of the present emergency the blood group of a large number of persons has been determined in this laboratory. The distribution among the first 5,000 is recorded here. In every case the blood was taken from the finger into 3.8 per cent. citrate solution and tested with anti-A and anti-B sera of a titre not less than 128. Lately we have used serum supplied by the Medical Research Council through the Galton Laboratory Serum Unit, Cambridge, which we have found to be excellent. The tube method described by Thomas and Hewitt (*J. ment. Sci.*, 1939, **85**, 667) was used, except that the reactions were read by eye after two hours at room temperature and that the tubes were put up in specially designed racks of twenty-five rows. From a preliminary series of parallel tests we came to the conclusion that this method was superior to all others from the points of view of speed, accuracy, and convenience, and that it is the only one suitable for mass grouping. Naked-eye reading was made necessary by the large number of tests which were set up at one time, and which on occasion ran into many hundreds. All the tests were made by one or more of a team of three people, and it is with possibly pardonable pride that we can record the taking of 134 blood samples in twelve minutes. The rate at which the tests can be set up depends upon individual experience, but 300 an hour is not excessive for one person.

The observed proportions among this sample were:

Group	O	A	B	AB	Total
f	2233	2162	444	161	5000
p	0.44660	0.43240	0.08880	0.03220	1.00000
σ_p	± 0.00703	0.00700	0.00402	0.00249	

The gene frequencies calculated from this data and corrected for the initial observed value of D (Bernstein, O., *Z. Indukt. Abstamm. Vererb.*, 1930, **56**, 233) are:

$$\begin{aligned} p' &= 0.26842 \\ q' &= 0.06248 \\ r' &= \underline{0.66911} \\ & \quad 1.00001 \end{aligned}$$

The observed values are in good agreement with the theoretical sum of unity (D′ = 0.00001). The D/σ_D test gives $\sigma_D = 0.000025$ and $D/\sigma_D = 0.4$, so that the statistical fit for the series is also excellent.

This and our subsequent data will be fully treated in a future publication. The present figures have been communicated to the Galton Laboratory Serum Unit in response to the appeal of Professor Fisher and Dr. Taylor for inclusion in their national data.—I am, etc.,

JOHN C. THOMAS,
Major R.A.M.C.

Military Hospital, Shenley,
Herts, Nov. 23.

Bipp

Sir,—While the times are surgically quiet I should like to draw the attention of all who are connected with war surgery to a paste which was used with marked success during the war of 1914-18, the so-called bipp. I saw this used myself with unfailing regularity and almost never-failing success. One of the leading consultant Army surgeons during that war gave to me the opinion that of all the antiseptics used at home or in France none had so great a value.

The process, briefly, is: (1) a clean dissection of the damaged and infected tissues; (2) a liberal smearing or filling up with bipp. The wound granulates from below upwards and needs no further dressing, thus saving an immense amount of pain and nursing labour.

We must learn from the lessons of the past; a substance whose value proved so remarkable after four years of unprecedented surgical experience must come again into the field of operative surgery. For the sake of those who would put to the test this pain-saving invention I submit the formula given to me; the formula in which 25 per cent. paraffin was used as a basis was not so successful.

Bismuth subgallate	4 ounces
Iodoform	8 „
Liquid glucose .. .. or q.s.	3½ „
Balsam of Peru	4 drachms

Fiat pasta.

I trust that this method of dealing with wounds will be given a thorough trial during this war.—I am, etc.,

Folkestone, Nov. 27. Austin Priestman.

Injection Treatment of Hernia

Sir,—Mr. A. Simpson-Smith (*Journal*, November 18, p. 990) remarks that the difficulties of injection treatment of inguinal hernia have compelled many surgeons to give up this procedure. That in skilled hands it can be entirely satisfactory I have had ample confirmation. I have seen many cases treated by Surgeon Commander St. G. B. D. Gray, R.N.V.R. (now on active service). The results were excellent. There is no doubt in my mind which form of treatment I would plump for if I had a hernia.—I am, etc.,

London, W.1, Nov. 28. A. Ernest Sawday.

Treatment of Varicose Ulcers

Sir,—Being in charge of a very large varicose vein and ulcer clinic I was naturally interested in the letter from Dr. J. R. A. Davies appearing in your issue of November 25 (p. 1060). I should like to make the following comments.

In my experience true varicose ulcers are seldom multiple and are never associated with deep abscesses that need opening. Dr. Davies (in the one case he describes) attributes the spread of the *Staph. aureus* infection (to parts of the body remote from the legs) to "the damming-up of foul stinking septic discharges." After a careful study of his report it would appear that there is nothing upon which one could base his assertion of the spread of the infection from the legs to other parts of the body; it would appear at least equally probable that the boils and abscesses broke out everywhere (axillae, groins, and legs) as a manifestation of the one general infection, and that it was this infection that caused the temperature and general illness and not the occlusive dressings.

In such a case as is described Dr. Davies obviously adopted the correct treatment. I do, however, most seriously join issue with him when he condemns the modern miraculously successful treatment of varicose ulceration (by the tight binding up of the whole foot, ulcer, and leg with elastic adhesive bandages) merely because this treatment had been applied unsuccessfully to one isolated case which, on the face of it, was not one of true varicose ulceration, but one of multiple body abscesses, including the legs.

Every ulcer seen on a leg is not necessarily varicose. A Wassermann is often helpful (even in real varicose ulceration); and, when indicated, concomitant anti-syphilitic treatment is instituted. Even, however, in cases of syphilitic ulcers the elastoplast treatment is a valuable adjuvant. At my own clinic the tight "occlusive" bandaging up of ulcerated legs leads to regular cure. Large ulcers can be "expedited" by the placing over them of pieces of specially prepared sponge rubber. It is frequently our practice first of all to put cod-liver oil into the ulcer cavity under the sponge rubber. In other cases, if there be much purulent discharge, the ulcer is first filled with calomel powder or T.C.P. powder.

I write this "answer" to Dr. Davies in no sense of carping criticism, but merely because one cannot allow to pass unchallenged destructive criticism of a treatment that has brought rapid cure of untold pain and suffering to countless thousands throughout this country. After all, this "occlusive" tight bandaging treatment is on the same lines as the most successful "occlusive" method of treating compound fractures by the Winnett-Orr method.—I am, etc.,

Liverpool, 1, Nov. 30. Stuart McAusland, M.D.

Virtues of Brown Bread

Sir,—A very few years ago a letter advocating whole-meal bread would have provoked a lively and somewhat acrid discussion on the respective merits of white and whole-meal. This is no longer the case. Professor Geoffrey Taylor's letter (November 18, p. 1022) has so far been allowed to pass without comment. Your own annotation of August 5 (p. 289) was a masterly presentation of the large mass of experimental evidence that you had accumulated, proving the great superiority of whole-meal over white judged by every criterion. Your exposition aroused no response whatever apart from my own letter, which you were good enough to publish on August 19 (p. 426). The reason must, I think, be that the superiority of whole-meal is no longer in dispute. Why then are we still a white-bread-eating nation? And why do thousands of medical men themselves eat white bread although they know it to be inferior to whole-meal?

The remedy I suggested in my letter was for all medical men (*a*) to advise their patients to eat whole-meal bread, and (*b*) to insist on being supplied with whole-meal for their own use. Professor Geoffrey Taylor's suggestion is that the British Medical Association should urge the Government to legislate to encourage, if not to compel, the universal eating of whole-meal instead of white bread. This would be an ideal plan, but it might take some time to mature; meanwhile I would plead with the medical profession to adopt my suggestion, which, of course, is an obvious and not a new one.—I am, etc.,

London, W.1, Nov. 25. Alfred C. Jordan.

Sir,—With all the prominence given to food and its rationing it is surprising that so little attention has been accorded to brown bread in the dietary. It is an important source of the accessory food principle vitamin B_1, so advantageous for the healthy functioning of nervous and unstriped muscle tissue, while for many persons it has an actual relish not obtaining in white bread.

In Italy since the beginning of totalitarianism brown bread is compulsorily supplied by the bakeries, for it is recognized there that not only is the quality enhanced but the quantity is also increased—seven loaves in place of six for the same quantity of grain. In England a "colour prejudice" is apparently extended to food, especially among the poor and uninformed.—I am, etc.,

Netley, Nov. 26. Arthur King.

Oestrogens: Natural and Synthetic

Sir,—Your statement in the *Journal* of November 25 (p. 1048) that no differences have been observed between the actions of the natural oestrogenic hormones and the synthetic product (stilboestrol) fails to take into account the recently published findings of two Dutch workers (Duyvené de Wit, J. J., and Bretschneider, L. H., *Klin. Wschr.*, 1939, 18, 1423), who describe an absolute qualitative difference in the actions of the natural and synthetic oestrogens. They found that while oestradiol, oestrone, and oestriol were definitely active in the Bitterling test, stilboestrol caused no reaction in doses one hundred times those of the natural oestrogens.

Quantitative differences are, of course, numerous.—I am, etc.,

Horsham, Nov. 25. N. HOWARD JONES.

A Testicular Tumour

SIR,—In view of the rarity of tumours of the testicle and of their apparent association with the undescended organ, I send you the following account of a case which you may like to record.

An African patient aged about 40 was admitted to hospital recently under my care. He had a history of a lump coming and going in the region of the left inguinal ring, for an unknown but considerable length of time; recently this had been increasing in size and becoming painful, and had remained at the external ring. On examination the lump resembled a hen's egg sitting on the external ring; it felt rubbery and was painful; there was only one testicle in the scrotum. At operation, kindly performed for me in my absence by Dr. Billington, there was degenerating grumous material in the centre of the mass, which appeared to be the testicle undergoing malignant change. The tumour was removed locally, as a more extensive operation did not seem justifiable. But the wound has already broken down and oedema of the scrotum and feet has developed.

The pathologist's report is as follows: Dense stroma and epithelial cells and lymphoid tissues in haphazard arrangement; congestion and some inflammatory reaction. The condition appears to be a teratoid tumour of an undescended testicle. It contains some rapidly proliferating cells and is probably malignant.

With regard to the frequency of testicular tumours in England, I find that the majority of figures approximate to that of 0.06 per cent. from an investigation of a series of 110,000 male cases admitted to a general hospital. Of this series, 16 per cent. are recorded as occurring in the undescended testicle (other series show 11 per cent. and 12 per cent.). I regret I cannot find strictly comparable figures for the incidence of undescended testicle, but it is recorded that 0.45 per cent. of a series of 2,000 public schoolboys had this abnormality. If these two sets of figures were comparable it would suggest that 2 per cent. of undescended testicles become malignant. I have no significant figures for the incidence of these conditions in this country, but I have seen nothing to suggest that they would be very different from those in England.—I am, etc.,

R. B. LEECH, M.B., B.Ch.Cantab.

Mengo Hospital, Kampala,
Uganda, Oct. 6.

Sigmund Freud

SIR,—Having just returned to my desk from a prolonged summer stay, I find your issue of September 30, 1939, awaiting me. I have read with much interest the obituary notice of Sigmund Freud and am presuming to compliment you upon its accuracy, its completeness, and, above all, its understanding. The *British Medical Journal* has for many years stood high in my estimation for its outstanding service to medicine and the medical profession. This fair-minded and sympathetic obituary has served to increase my admiration for the many high qualities of the *British Medical Journal*.

Freud himself tells us he spent but six months with Charcot and not a year as stated, but this slight error is of little significance. Furthermore, also of minimal importance, was not his contact with Breuer earlier than 1884? Also " cancer " should read " sarcoma " if one wished to be exact pathologically, but as the distinction is not known to many physicians the broad term " cancer " will suffice.—I am, etc.,

New York, Nov. 16. SMITH ELY JELLIFFE.

Obituary

SIR WILLIAM PROUT, K.C.M.G., M.B.

Lieutenant-Colonel Sir William Prout, K.C.M.G., late Colonial Medical Service, died at the Manor House, Lingfield, Surrey, on November 18, aged 77. He was born in 1862, the son of William Prout of Mauritius, and educated at Edinburgh, where he graduated as M.B. and C.M. in 1884. He entered the Colonial Service in 1885 as assistant poor law medical officer in Mauritius, but in 1888 was transferred to West Africa, where he spent the rest of his service, first as assistant colonial surgeon of the Gold Coast; in 1895 he was appointed colonial surgeon of Sierra Leone, medical officer of health of Freetown, and Official Member of the Legislative Council, with the rank of principal surgeon, which he held till his retirement in 1906 after thirty years' service. He then settled in Liverpool, where he was a lecturer in the Liverpool School of Tropical Medicine, and in 1912 was appointed medical officer to the Colonial Office. During the war of 1914–18 he served in Egypt as a lieutenant-colonel in the R.A.M.C., and was twice mentioned in dispatches. After the war, in 1919 he was appointed senior medical officer to the Colonial Office and in 1927 senior consulting physician for that office, resigning in 1929. He was made C.M.G. in 1905, O.B.E. in 1919, knighted in 1924, and created K.C.M.G. in 1928. He had been a member of the British Medical Association since 1898; at the Annual Meeting in 1910 he was honorary secretary, and in 1912 vice-president, of the Section of Tropical Diseases. In 1888 he married Mary, daughter of John Mackenzie of Montrose, and had one son and one daughter; the son was killed in the war of 1914–18.

NAUGHTON DUNN

Mr. T. P. McMurray writes:

The death of Naughton Dunn at the early age of 54 years has deprived the British Orthopaedic Association of its president, a post he had held during 1938 and 1939. His association with orthopaedic surgery began before the last war, when he became house-surgeon to the late Sir Robert Jones in the year 1911. His holding of this post was the beginning of an unbroken association and friendship between the two men, which lasted until Sir Robert's death. Leaving Liverpool in 1913, he became connected with the problem of the cripple in Birmingham and district when he was appointed surgeon to the Birmingham Cripples Union, the forerunner of the present Royal Cripples Hospital in Birmingham. In 1915 the formation of military orthopaedic centres was found to be necessary, and Robert Jones, who had been given complete charge of its organization, called on Dunn as one of the few men who were adequately trained to carry out the work. Dunn's work during the strenuous war period was magnificent, and earned for him a great reputation among his colleagues and assistants. Returning to Birmingham after the war, he continued his work at the Royal Cripples Hospital and at the Robert Jones and Agnes Hunt Orthopaedic Hospital at Oswestry, an institution in which he played a particularly vital part. His reputation was world-wide as a sound progressive orthopaedic surgeon who had added much to our knowledge, particularly in regard to the surgery of deformities of the feet. He received many honours, but of them all probably the one he treasured most was the honorary LL.D. which was conferred upon him by his own University of Aberdeen. He was connected with many hospitals in the Midlands, both in an active and in an advisory capacity, and held the very important post of lecturer in orthopaedic surgery to the University of Birmingham.

WILFRED TROTTER

Dr. C. Wynn Wirgman writes:

In your noble tribute to Wilfred Trotter his friends and pupils will feel that justice has been done to one who was certainly among the great men of the age. None ever sought counsel of him but they felt that he spoke as one of the oracles of God. I was intimately associated with him for years, and I cannot remember an occasion or opinion where he was at fault. No doubt he was wrong sometimes, but personally I never found him so. All knowledge seemed his province, and his teaching to those who were fortunate enough to sit at his feet was complete and final. His opinion on a medical case was as reliable as that on a surgical one. Simplicity, modesty, and altruism were the keynotes of his character. His loss makes the world poorer and adds a name to the list of the world's great dead.

"G. H. S." writes:

Your biographer has rightly stressed Mr. Wilfred Trotter's awe-inspiring mental calibre, which was liable to produce an oaf-complex in his disciples if it did not already exist, and has relegated his operative skill to second place. But what was secondary in him was as the brightness of Sirius in relation to his contemporary surgical "stars." Of how many others could it be said, as was true of him, that it was a perfect joy to watch him remove a simple appendix: the knife handled as Vermeer must have wielded his brush, the needle with the finesse of an embroidress, and above all the surpassing gentleness of manipulation? Alas, that we so rarely encounter such a complete surgical artist, in the best sense of both words, in whom an outstanding intellect is happily wedded to true art, but so frequently find surgeons possessing these qualities in the single state.

With the death of **Benjamin Sumner**, M.D., M.Ch., on November 3, at his residence in Warren Road, Blundellsands, at the age of 76 years, Liverpool and its northern suburbs have lost one of their best known and highly esteemed practitioners, who had been a member of the British Medical Association for fifty-three years. Dr. Sumner studied medicine at the Liverpool Royal Infirmary and University College, London, qualifying in 1885. During his studentship he was awarded the Lyon-Jones Scholarship at the Liverpool Royal Infirmary. In 1889 he was appointed honorary physician to the Bootle General Hospital (then the Bootle Borough Hospital). Having interested himself in gynaecology, which was becoming a special subject, he was in 1908 appointed honorary gynaecological surgeon to the hospital, resigning the post of honorary physician. He remained gynaecologist to the hospital until he retired from the active staff in 1923, when he was appointed consulting gynaecological surgeon. For many years Dr. Sumner had been vice-president and also vice-chairman of the general committee of his old hospital. "W. R. R." writes: By Dr. Sumner's death his fellow practitioners, and especially his younger colleagues, have lost a great friend who was only too glad to help them with his knowledge, gained from his vast experience. His familiar figure riding his pet horse will be greatly missed by the residents of Crosby. He died in harness as was his wish, having done his usual work up to three days before the end, though owing to a serious cardiac lesion work during the last few months must have required great endurance.

Dr. **Frederick Richard Brefks Atkinson**, who died suddenly in London on November 18 in his 73rd year, was educated at King's School, Canterbury, and Edinburgh University, where he graduated M.B., C.M. in 1891 and proceeded to the M.D. in 1896. After two years at sea as ship surgeon he took up the work of a general practitioner first at Dulwich and then at Chertsey, but he early devoted himself to the study of tuberculosis. On the establishment of the national health insurance scheme he was appointed tuberculosis medical officer by the Middlesex County Council and spent the rest of his working life in this post. In his leisure time Dr. Atkinson translated for the New Sydenham Society Sternberg's monograph on acromegaly and other foreign medical works, and himself wrote a book on acromegaly which appeared in 1932.

Dr. **William Cecil Whiteside** of Fazeley died on November 18 at the age of 69 years. He was a son of the Rev. Stephen Whiteside, vicar of Shap, Westmorland. A student at Trinity College, Dublin, and at the University and Royal College of Surgeons, Edinburgh, he obtained the degrees of M.B., Ch.B.Ed. in 1909. In 1912 he went as assistant to Dr. Thomas Buxton at Fazeley, and on the latter's death in 1916 succeeded to the practice. He also took over the appointments of medical officer and public vaccinator for the Fazeley district and Wilnecote and Middleton, which he held until his retirement from the profession just over a year ago. For many years he had been honorary surgeon to the Wilnecote Division of the St. John Ambulance Brigade, a movement in which he was keenly interested. Dr. Whiteside is survived by his widow and one daughter.

Dr. **G. T. Eccles** died at Worthing on November 25 aged 73. He studied medicine at Cambridge and St. Bartholomew's Hospital, and graduated B.A. in 1887, M.B., B.Ch. in 1892, and M.A. in 1918. Before taking up practice at Hove he had been house-surgeon and house-physician at the West London Hospital and assistant medical officer in the electrical department at St. Bartholomew's. "J. H. C." writes: Dr. George Tolcher Eccles practised in Hove and was the borough police surgeon for nearly forty years, and his memory will long be kept alive in the town by the very many kindnesses he did for so many people. His generosity was only one of his many excellencies. He had a dominant personality, and in any gathering he was outstanding. He was one of a medical family, and he was himself typical of his generation of trusted family doctors. Of late years his chief interest was in fly-fishing. He was also a prominent Freemason and president of the Devonian Society in Brighton and Hove for three successive years.

Dr. **Harold Everett Pace** died at his home in Goring-by-Sea, Worthing, on November 26 at the age of 71. Six years ago he retired from general practice in Leyton, E.10, where he had practised for over a generation. A Londoner by birth, Dr. Pace studied medicine at the London Hospital, qualifying in 1893. He held posts at "the London" as house-surgeon and house-physician, and took his M.B. degree in 1897. He served as civil surgeon with the African Field Force during the South African War. Apart from that his whole career was spent in general practice in Leyton, where his familiar figure was known to two generations of Leytonians. "D. S." writes: Dr. Pace was one of the finest types of men to be found in the profession, much liked and trusted by his patients and highly esteemed by his fellow practitioners. He was district medical officer to the Essex County Council and public vaccinator. He retired from practice on reaching the age limit and went to live at West Worthing. During the great war his house in Leyton was completely destroyed by a Zeppelin bomb, and it was marvellous how any of the family escaped alive. A few years ago he lost a son in the Royal Air Force. Dr. Pace bore these trials bravely, but there is no doubt they adversely affected his health. He leaves a widow and a son and daughter. He had been a member of the British Medical Association for twenty-four years.

The death is announced of Dr. **Edmund Herbert Corder** of Worcester, aged 76. He was educated at Queen's College, Birmingham, and qualified in 1886 as L.R.C.P., L.R.C.S.Ed. and L.R.F.P.S.Glas. After holding the post of resident surgical assistant at the Queen's Hospital, Birmingham, Dr. Corder began practice at Worcester, and for over twenty-seven years was poor law medical officer for No. 2 District; he was also appointed honorary surgeon to the Worcester Dispensary and for a time acted as anaesthetist at the Worcester General Infirmary. He was a most popular medical officer and had a large private practice. For six years he served on the city council and during the last war devoted much time to the local medical board. He retired from active work about four years ago because of failing health. Dr. Corder first joined the British Medical Association in 1887.

The following well-known foreign medical men have died: Dr. Heinrich Neumann, formerly professor of oto-rhino-laryngology in Vienna, in New York, aged 66; Dr. D. G. Stiefler, extraordinary professor of neurology at Innsbruck, aged 62; Dr. Auguste Pettit, professor at the Pasteur Institute of Paris, member of the Academy of Medicine, and author of works on anti-poliomyelitis serum and spirochaetosis ictero-haemorrhagica, aged 70; and Dr. Carl Gustaf Santesson, emeritus professor at the Karolinska Institute, Stockholm, and editor of *Skandinavisches Archiv für Physiologie*, aged 77.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Faculty Board of Medicine gives notice that as from October 1, 1939, it has withdrawn approval of courses in pharmacology held at institutions outside Cambridge, but students who on October 1, 1939, had gone out of residence without attending the course in Cambridge may make application to the secretary of the Faculty Board for leave to attend courses given elsewhere.

UNIVERSITY OF WALES

Welsh National School of Medicine

The following candidates for the degrees of M.B., B.Ch. have satisfied the examiners in the examinations indicated.

Pathology and Bacteriology.—J. D. P. David, A. A. Edwards, W. M. Jones, J. Lewis, Monica Parry-Morton, D. K. W. Picken, K. M. Wheeler, J. Williams, O. Williams, G. A. Wright.

Obstetrics and Gynaecology.—*Beryl Badham, T. C. H. Davies, D. I. Harries, Marguerite J. Hennelly, D. D. Howell, O. Howell, G. A. Jones, Anne N. M. Llewhelin, J. E. Lloyd, R. M Marshall, D. G. Morris, H. V. Roberts, Glenys J. Wade.

Pharmacology.—J. D. P. David, Sadie M. Davies, *N. E. France, W. S. Hill, E. H. Horton, Margaret W. Hughes, Morfudd E. Humphreys, R. T. James, E. R. Jones, D. K. W. Picken, Erica M. G. H. Roberts, Huw D. Walters, O. Williams.

Surgery.—H. R. Hudd, M. Lewis, Mair Llewelyn, Silvia M. D. Mehta, D. G. Morris, R. E. Packer, J. L. Rees.

* With distinction.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

Surgery.—J. B. Gurney-Smith, A. M. McCall, M. F. Smith, K. Talboys.

Medicine.—G. O. C. Davies-Webb, R. M. J. Franks, E. A. Griffiths, W. C. Heunis, J. N. Hunt, J. A. Sutton.

Forensic Medicine.—G. O. C. Davies-Webb, R. M. J. Franks, E. A. Griffiths, W. C. Heunis, J. N. Hunt, J A. Sutton.

Midwifery.—C. E. S. Myers, J. P. Rochford.

The diploma of the Society has been granted to W. C. Heunis and J. A. Sutton.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At the annual meeting of the Royal College of Physicians of Edinburgh, held on November 30, Dr. Alexander Goodall was re-elected President, and the following were elected to form the Council for the ensuing year: Dr. Edwin Bramwell, Dr. Charles McNeil, Dr. A. Fergus Hewat, Dr. D. M. Lyon, Dr. W. D. D. Small, and Dr. A. Graham Ritchie. Dr. McNeil was nominated Vice-President.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow held on December 4, with Dr. J. Souttar McKendrick, President, in the chair, the following were admitted Fellows of Faculty: James Paton Orr Erskine, M.B., Ch.B. (Glasgow), Alexander Slessor, M.B., Ch.B. (Motherwell).

Medico-Legal

DISSOCIATED PERSONALITY

The tragic case in which Dr. L. P. Lockhart was found guilty of the murder of his wife but insane[1] showed very clearly the application of established legal principles to a somewhat unusual set of facts. The doctor had been badly shocked in the last war, and there was plenty of evidence of his emotional instability before the act. He was proved to have written a notice, "Keep out; gas (study). Fetch police," to have given his wife an injection of sodium evipan, to have placed her and himself on the floor by a gas fire, and to have turned on the gas. The defence sought to prove that he had done these things unconsciously in a condition in which his personality was suppressed and the automatic powers of the body took charge. Serjeant A. M. Sullivan, K.C., pointed out that this was not an insanity defence but that, as the doctor had committed the act during unconsciousness, he should simply be found not guilty. Eminent psychiatrists agreed that the facts, if true, showed a genuine state of dissociation, and that in such a state a series of highly complicated and apparently rational acts could be performed automatically and not remembered.

In order to set up an insanity defence it is necessary to prove that the accused person, owing to mental disorder, either did not know what he was doing or did not know that it was wrong. If, however, a person kills another in a state of unconsciousness the obvious inference is that he was labouring under mental disorder. In his summing-up the learned judge indicated some disagreement with the suggestion that Dr. Lockhart really was quite unconscious of his acts, but said there was evidence on which the jury could find that he had been insane and not responsible for them; the jury found this evidence convincing. Even if the unconsciousness had been proved beyond any doubt, it was manifestly due to disorder of the mind; the unfortunate patient was shown to be a danger to himself and others; and it was necessary in his interests as well as those of the community that he should come under the care of the State and be suitably treated. Incidentally, it is interesting and encouraging to observe the progress the courts are making in their recognition of dissociated states in which the offender is not responsible for his actions and is hardly, if at all, conscious of them. They do not yet, however, recognize the state, sometimes called "irresistible impulse," in which the action is just as dissociated and automatic but the offender is conscious of it and of its illegality. Nor does the law of England permit a verdict of "Not guilty on the ground of insanity," preferring the illogical formula "Guilty but insane." One of His Majesty's judges a short time ago directed the jury in a similar case that they might find the accused guilty of the act charged but by reason of disease of the mind not responsible at law. Such a formula is more merciful as well as more logical. Moreover, those who desire to see a verdict of "not guilty" follow a successful insanity defence must remember that no legislation is likely to take away the prerogative right of the Crown to take care of an insane person who has committed a crime until he can safely be allowed to re-enter the community.

---

[1] *British Medical Journal*, November 25, p. 1063.

"*Surgical Addiction*."—In an excellent paper is described the unfortunately familiar type of patient whose psychological state becomes successively worse with each of the many operations which he or she has successfully induced surgeons to perform. The phrase "surgical addiction" indicates the psychological homology between this and other types of addiction.—Surgical Addiction: Case Illustration. P. Greenacre. —*Psychosomatic Med.*, April, 1939, **1**, 325.

The Services

DEATHS IN THE SERVICES

Colonel Henry Halcro Johnston, C.B., C.B.E., late R.A.M.C., died on October 18, aged 83. He was born at Orphir House, Orkney, on September 13, 1856, the fifth son of James Johnston, eleventh Laird of Coubister, Orkney, and was educated at Dollar Academy, at the long-defunct Collegiate School of Edinburgh, and at the University of Edinburgh, where he graduated M.B., C.M. in 1880. He proceeded M.D. in 1893 and in the same year took the B.Sc., proceeding D.Sc. (Public Health) in 1894. He entered the army as surgeon on July 30, 1881, attained the rank of colonel on February 16, 1911, and retired on September 13, 1913. In his young days he was a noted rugby footballer, having played as full-back for Scotland against both Ireland and England in 1877. He did not again receive an international cap, but for three years he played as a forward in the Edinburgh University fifteen. He had a fine list of war service: Sudan, 1885, at Suakin, medal with clasp and Khedive's Star; North-West Frontier of India, 1897–8, in charge of British No. 1 Field Hospital, operations in the Malakand, in Bajaur, in the Mahmund country, and in Buner, including the action at Laudakai and the attack and capture of the Tanga Pass, mentioned in dispatches, April 22, 1898, medal with clasp; South Africa, 1899–1902, operations in Natal, mentioned in dispatches, February 2, 1901, and July 29, 1902, Queen's medal with clasp and King's medal with two clasps, and the C.B. After retirement he rejoined for service in the war of 1914–18, when he served as Assistant Director of Medical Services at Glasgow and at York, and as Deputy Director of Medical Services at Gibraltar, and received the C.B.E. He was the author of numerous contributions to scientific journals. After retirement he settled at Orphir, in his native island of Orkney, where he was a deputy lieutenant of the county. He was unmarried.

The Bibby liner *Yorkshire* was torpedoed and sunk by a German submarine with much loss of life. She had on board a total of 278, of whom 160 were ship's complement, the remainder passengers, chiefly officers and soldiers with their families on the way home from the East. The company reports that 33 passengers were missing, chiefly women and children. Among those lost was Lieutenant-Colonel William Leonard Eliot Reynolds, M.C., R.A.M.C. He was born on April 4, 1889, was educated at Guy's Hospital, and took the M.R.C.S., L.R.C.P. in 1915. He at once entered the Royal Army Medical Corps, Special Reserve, as a temporary lieutenant, took a commission as lieutenant and temporary captain on January 1, 1917, became captain on August 1, 1918, and major on February 2, 1927, and was promoted to lieutenant-colonel in August this year. He served throughout the war of 1914–18, in which he gained the Military Cross. He had been a member of the British Medical Association since 1927. He was Deputy Assistant Director-General, Army Medical Services, War Office.

Lieutenant-Colonel Charles Henry Straton, R.A.M.C. (ret.), died at Exmouth on November 1, aged 63. He was born on May 16, 1876, was educated at St. Mary's Hospital, and took the M.R.C.S., L.R.C.P. in 1898, and subsequently the D.P.H. of the Colleges in 1911. After serving as house-surgeon at St. Mary's Hospital and clinical assistant at the Great Ormond Street Hospital for Sick Children and at the Central London Ophthalmic Hospital, he entered the Royal Army Medical Corps as lieutenant on April 25, 1900, became lieutenant-colonel on December 26, 1917, and retired on August 20, 1921. He served throughout the war of 1914–18, chiefly in the Mediterranean, where he acted as Assistant Director of Medical Services in Egypt. He received the Order of St. Sava of Serbia (4th Class), as well as the war medals. After his retirement he settled in Devonshire, where he was school medical inspector to the Devon County Council at Honiton. He was a member of the British Medical Association for thirty-eight years.

Lieutenant-Colonel George Fowler, Indian Medical Service (retired), died suddenly at Keynsham, near Bristol, on November 13, aged 65. He was born on April 29, 1874, and educated at Madras and Charing Cross Hospitals. He took the Scottish triple qualification in 1895, after gaining the L.M.S.Madras in 1894. He also took the D.P.H. of the London Colleges in 1899, and the D.T.M.Lond. and D.T.M. and H.Cantab. in 1908. Entering the I.M.S. as lieutenant on June 27, 1901, he became lieutenant-colonel on December 27, 1920, and retired on April 29, 1929. He was appointed a Civil Surgeon in the Central Provinces in May, 1914, but reverted to military employ during the war from January, 1915, to October, 1919. He had been a member of the British Medical Association for thirty-eight years.

Major George Baillie, R.A.M.C. (ret.), died suddenly at West Runton on October 26, aged 66. He was born on March 1, 1873, the youngest son of the late Dean Baillie of Letterkenny, Co. Donegal, and was educated at Trinity College, Dublin, where he graduated M.B., B.Ch., B.A.O. in 1900. He entered the Army as lieutenant in the Royal Army Medical Corps on January 21, 1900, became major on June 21, 1912, and retired on August 1, 1920. He served in the war of 1914–18.

Major Pierce Morgan Brett, R.A.M.C. (ret.), died at Salisbury on November 26, aged 54. He was born on May 23, 1885, was educated in Ireland, and graduated M.B., B.Ch., B.A.O. of the Royal University of Ireland in 1909. He entered the Royal Army Medical Corps as lieutenant on January 27, 1911, became major on November 25, 1927, and retired immediately afterwards but continued to be employed at Salisbury in the Reserve of Officers after retirement. He joined the British Medical Association in 1926 and served as honorary secretary of the Salisbury Division in 1936–8. He leaves a widow.

Medical Notes in Parliament

In the House of Commons on December 5, during the debate on the address, Dr. Elliot said that he had that morning received from Lord Nuffield the offer of a million ordinary share units of Morris Motors Limited, equivalent to perhaps £1¼ million, as the nucleus of a central fund for the co-ordination of hospital finance and policy in the provinces, which he had accepted forthwith (see p. 1148).

The debate on the address continued during the week and was largely concerned with supplies for the fighting Services. In the House of Lords Lord Halifax spoke on British war aims.

The Postponement of Enactments (Miscellaneous Provisions) Bill was down for second reading in the House of Commons on December 6. It proposes to postpone the operation of the House-to-house Collections Act to a date to be fixed by Order in Council.

Hospital Accommodation in Scotland

In the House of Commons on November 21 a discussion took place on hospital problems in Scotland. Colonel Colville said that they had secured some 12,000 beds in existing hospitals for the treatment of casualties, and this number could be increased at short notice to 14,500. Adaptation of mental hospitals and three large hotels should give them, in a few months, some 5,100 additional beds, and hutted hospitals and annexes now being built 10,000 more. In all the programme would give them some 31,000 beds. The needs of the ordinary sick and of military cases were not being overlooked. Hospitals included in the scheme were expected to admit all persons who might fairly be said to be in urgent need of institutional treatment. Arrangements were being made under which the additional hospital accommodation would be available for the ordinary sick if they could not obtain treatment elsewhere. He was issuing a small brochure on the hospital services which would give the information in some detail.

Army personnel in urgent need of institutional treatment were admitted to hospitals in the Emergency Service in the same way as civilian patients. Arrangements had also been made at the request of the Deputy Director of Medical Services, Scottish Command, whereby accommodation was being made available for 500 Army sick who required light hospital treatment which could not be afforded in hospitals controlled by the military authorities. The patients were being admitted, in the main, to base hospitals on the understanding that they would be evacuated as rapidly as possible if the hospital beds were required for the purposes of the Emergency Service. An extension of this arrangement, to cover some several hundred additional patients, was under consideration.

First-aid Posts

On November 21 Sir JOHN ANDERSON, in reply to Mr. Denville, said that the attention of public authorities had already been drawn to the importance of providing direction boards to first-aid posts, but he was informed by Dr. Elliot that it was not generally considered necessary to provide direction boards to hospitals; ambulance drivers learnt the routes as part of their training. The police had already been in consultation with the hospital authorities about traffic arrangements with a view to securing that ambulances should arrive and depart in the shortest possible time.

On November 21 Dr. ELLIOT told Mr. Denville that he was not aware that at certain aid posts the access to those parts set aside for the decontamination of gas casualties was so restricted by sandbags that a stretcher case could not be admitted, but he would look into any case of which Mr. Denville forwarded particulars.

Dr. ELLIOT also informed Mr. Denville that supplies of the antiseptic called azochloramid had already been distributed so as to be available at first-aid posts.

Medical Board Examinations

In reply to Dr. Howitt on November 23, Mr. ERNEST BROWN said his information did not confirm a statement by the former that many men passed fit by medical boards had soon been found to be unfit for service. He was carefully examining the position. Dr. HOWITT asked Mr. Brown to ensure that all such mistakes were at once reported to the medical board which passed the man as fit so as to prevent recurrence of such mistakes. Mr. BROWN replied that he would consider this suggestion. A few cases had been brought to his notice, and in these he had always arranged for a re-examination.

Dr. HOWITT asked whether it would be possible for the boards to have power to refer doubtful cases to specialists before the men were passed. Mr. BROWN stated that he was examining suggestions of the kind. Each medical board consisted of a chairman and four other medical men.

Women in Industry and Infant Mortality

Mr. DAVID ADAMS asked Sir John Anderson on November 30 whether, in view of the severe increase in infantile mortality during the last war, special observations were being made for the protection of the health of women in industry; and in what circumstances the Government's permission must be sought with regard to the working of overtime by women, and upon what principle this permission was granted. Sir JOHN ANDERSON recalled that the War Cabinet Committee on Women in Industry reported in 1919 that the influence of employment upon the infant mortality rate was not altogether clear, but observed that the rates were low in 1916 and 1917, when a continually increasing number of married women were being employed. He said that special observation would be kept, in consultation with the Industrial Health Research Board, on the working conditions of women and others in factories during the present war. As regards women's hours of work, the hours authorized, while varying according to circumstances, were far shorter than those which were commonly worked in the last war. They were being kept under review.

Social Services to be Expanded

In the House of Commons on December 5 Dr. ELLIOT said that when we were planning for a three-years war and spending at the rate of £2,400,000,000 a year in the process we still contemplated some expansion in our social services. The money invested in these had provided an excellent return. We had now a lower infant mortality and a lower maternal mortality than Germany. Before the outbreak of war the national service of midwives set up by the Midwives Act, 1936, was settling down to full-time work. The first steps had been taken to set up the comprehensive arrangements for the treatment of cancer, for which provision was made in the Cancer Act. Over 4,000,000 houses had been built since the last war and we had entered upon the fifth million. The President of the Board of Education and he hoped shortly to complete arrangements for a far greater concentration of medical effort on the school children than ever before. The process which had added inches in height and nearly a stone in weight to school children was still going on. During the war the aim must be to keep in working order this vast machine, improving it from time to time as conditions permitted. He hoped it would be possible to complete the bulk of the houses started by local authorities before the war, to complete all those which were being built for factory workers and agricultural workers, and, subject to the financial position, eventually to enable local authorities and private enterprise to build new houses for such workers.

Payment of Medical Boards

On December 5 Mr. GROVES asked the Minister of Labour and National Service what fees were payable to members of civilian medical boards for the examination of recruits, having regard to the notification to doctors by the British Medical Association confirming the appointment containing the statement that an appropriate fee, to be settled in consultation with the Association, would be paid for each session. Mr. ERNEST BROWN replied that members of medical boards were paid at the rate of two guineas a session for the first five sessions in a week, and 1½ guineas for any subsequent sessions in the week, an additional half-guinea being paid to the chairman. These rates applied uniformly to all medical boards.

Functions and Inspection of First-aid Posts

On December 5 Mr. GROVES asked the Minister of Health how he reconciled the instructions that the seriously injured were to be taken direct to hospitals and not to first-aid posts with the terms of E.M.S. Memorandum No. 4 issued by his Department. Dr. ELLIOT said that although the first-aid posts were intended primarily for the lightly injured it was recognized that some of the more serious cases might require early treatment at first-aid posts in certain circumstances—for example, if the nearest casualty receiving hospital was much further away than the first-aid post and the patient appeared to require immediate treatment. This was indicated in the opening paragraph of E.M.S. Memorandum No. 4.

Dr. ELLIOT also informed Mr. Groves on December 5 that the medical officers of his Department who inspected first-aid posts were specially experienced in the organization of casualty services. In making their inspections they adopted such procedure as in their judgment was best suited to the circumstances of the area. Any changes or adjustments were normally settled by them on the spot, in agreement with the medical officers of health, who were assisted by the medical officers appointed to each post; but if necessary they were the subject of communications between the responsible local authority and himself.

Central Medical War Committee

On December 5 Mr. GROVES asked the Minister of Health whether the Central Medical War Committee was the same as the Central Emergency Committee of the British Medical Association, having regard to the answer on November 16 and the statements made in the British Medical Association circular D.17/1939–40. Dr. ELLIOT said that the Central Emergency Committee assumed the functions of the Central Medical War Committee shortly after the outbreak of war.

Equipment at First-aid Posts.—Mr. GROVES asserted on November 30 that the official equipment of first-aid posts contained no provision for the accommodation of recumbent cases, whether adults or children. Dr. ELLIOT replied that stretcher cases would normally be taken to hospitals and not to first-aid posts. Adequate provision was made under the official scheme for recumbent cases at first-aid posts by stretchers and blankets issued to each scheme-making authority and by trestles which could be purchased out of the furniture allowance of £15 per post

Medical Officers for A.R.P.—Dr. ELLIOT told Mr. Groves on November 30 that he would not be justified in advising local authorities that medical officers of an age which made them likely to be called upon for military service and without practical experience of war wounds should not be employed as deputy medical officers of health for air raid precautions purposes or placed in charge of first-aid posts. Local authorities, guided by the advice of their medical officers of health, were employing suitable medical officers in these services.

Approved Societies' Additional Benefit.—Dr. ELLIOT states that some modification of the normal procedure for dealing with approved societies' schemes of additional benefits has been made in the present exceptional circumstances with the object of saving work on the part of societies and of the seriously depleted staffs of the Department and the Government Actuary. Under the new procedure a suitable scheme of benefits, so far as possible identical with that at present in force, is recommended to the society for adoption. If any society desires to submit alternative proposals consideration is always given to any representations which they may make. This procedure does not differ in any material respect from that adopted by the Department of Health for Scotland.

Notes in Brief

No women doctors are serving in the Women's Auxiliary Air Force, but the appointment of a limited number of women doctors primarily for duty with that Force is receiving consideration.

In a statement on November 22 about the British troops in France Mr. HORE-BELISHA said their health was exceptionally good, the sickness rate being lower than the peace-time rate at home.

Medical News

In September last it was decided, in consequence of the war, to postpone the Chadwick Public Lectures which were to have been delivered this autumn. The Trustees have now resolved to resume the lectures, if national conditions permit. The first lecture is to be delivered on Tuesday, December 12, at 2.30 p.m., at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W.1, when Sir William Savage, M.D., will discuss "The Health Aspects of Canned Foods." Admission is free.

As Patron of St. Bartholomew's Hospital the King has accepted a specially bound copy of *Rose Window*, the book published by Heinemann's in aid of St. Bartholomew's Hospital. As President of the Hospital His Royal Highness the Duke of Gloucester has accepted a similar copy, and has expressed the hope that the volume will bring in a good sum. The book (illustrated by Anna Zinkeisen) consists of twenty-five hitherto unpublished contributions by famous authors. It costs 7s. 6d.

The 1939 Nobel Prize for Chemistry has been divided between Professor A. Butenandt, director of the Kaiser-Wilhelm Institute for Biochemistry, Berlin, for his work on sex hormones, and Professor L. Ruzicka, of the University of Technology, Zurich, for his work on polymetylenes and higher terpene compounds. The reserved 1938 Prize for Chemistry has been awarded to Professor R. Kuhn, Heidelberg, director of the Kaiser-Wilhelm Institute for Medical Research, for his work on carotinoids and vitamins. The Nobel Foundation has decided not to hold the usual festivities in connexion with the distribution of the prizes this year.

The secretary of the London Lock Hospital informs us that the out-patient departments for both sexes at Dean Street remain open as usual, and the Lock should therefore have been included in the list of London hospitals out-patient departments appearing last week at page 1105. The out-patient department of the Metropolitan Ear, Nose, and Throat Hospital (Fitzroy Square, W.) is now open every weekday from 10 a.m. to 11.30 a.m.

The name of the National Baby Week Council is now changed to National Baby *Welfare* Council, this name being more commensurate with the increased scope of work falling to the Council's lot under war conditions. The address of the National Baby Welfare Council is 29, Gordon Square, London, W.C.1.

On October 24 a meeting was held at the St. Louis Medical Society in honour of Dr. William Washington Graves, professor of neuropsychiatry, St. Louis University School of Medicine, and Dr. Graves was awarded a certificate of merit and a gold medal for scientific accomplishment for his classification of scapulae and other inherited characters, and for his discovery of "the age-incidence principle of investigation." The St. Louis Medical Society has given this certificate of merit for scientific accomplishment on two previous occasions: in 1927 to Dr. Evarts A. Graham and his associates, Drs. Glover H. Copher, Warren H. Cole, and Sherwood Moore, for their work in cholecystography; and in 1935 to Dr. Edward A. Doisy for his achievements in hormone chemistry and physiology.

Professor R. T. Leiper, Professor H. S. Raper, and Professor W. W. C. Topley have been elected members of the Council of the Royal Society for the ensuing year.

Dr. A. Douglas Cowburn retired on November 18 from the post of H.M. Coroner for the Southern District of the County of London.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

The rise in the prevalence of diphtheria and scarlet fever in England and Wales referred to last week has not been maintained. The increase in pneumonia (influenzal and primary) continues, but the extent is negligible, and deaths from influenza are well below last week's figure, although they exceed that of the corresponding week of last year. There has been a tendency for the incidence of cerebrospinal fever to increase in the last few weeks, but in no locality have the numbers recorded amounted to more than minor outbreaks. The total 37 cases recorded in England and Wales were distributed over as many as seventeen administrative counties, and in only three were there more than 3 cases—namely, Denbigh 6 (all in Wrexham M.B.); Glamorgan 5 (Rhondda 2, Caerphilly, Cardiff C.B., Merthyr Tydfil, 1 each); Lancaster 5 (Swinton and Pendlebury 3, Liverpool 1, Rochdale 1). Acute poliomyelitis has fallen to less than one-third of last year's level. Among the twelve counties involved Somerset only had more than a single case: 1 each in the rural districts of Wincanton and Yeovil. The urban districts were more frequently affected than rural districts.

Notifications of both measles and whooping-cough show an increase of more than 50 per cent. over those recorded last week. In all probability some part of the increase is attributed to more complete notification. In some localities measles has already attained epidemic proportions. For instance, of 414 cases in Glamorgan 214 were in Caerphilly and 101 in Rhondda U.D.; of 166 cases in the West Riding of Yorks 95 were in Thorne R.D. and 26 in Skipton R.D., compared with 5 in Sheffield. Other striking examples of unusual prevalence in certain areas are: Cumberland 105 (33 in Ennerdale); Warwick 119 (81 in Leamington); Gloucester 68 (29 in Cheltenham). On the other hand, there were only 2 cases in Leicester County (none in Leicester itself), 6 in Middlesex, and 13 in London. In six counties in England and four in Wales no case of measles was recorded during the week—namely, Berks, Isle of Ely, Norfolk, Soke of Peterborough, Rutland, West Suffolk, Carmarthen, Montgomery, Pembroke, and Radnor. It is evident that the expected measles epidemic is beginning in rural and urban areas rather than in the large towns, to which it will doubtless spread in the next month or so. How far this is due to the abnormal distribution of non-immunes consequent upon evacuation and how far it is a natural phenomenon cannot be determined with certainty as comparable figures for previous epidemics are not available.

No. 46

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 18, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)

† Death from puerperal sepsis.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The Telephone Number of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The Telegraphic Addresses are
EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*
SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Doctúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Income Tax

Change in Employment

"M. T." ceased his employment in 1938–9 and accepted another appointment for 1939–40 at a higher salary. On what basis should he be assessed?

⁎⁎ The correct legal basis is that adopted by the inspector of taxes—that is, to regard the first source of income as having ceased and consequently the present employment as a new one, carrying the liability to assessment for the first year on the actual earnings of that year. We understand, however, that where the two employments are substantially similar and continuous the authorities are willing to disregard the change and continue to apply the previous year's basis. If the income of 1939–40 should fall short of the anticipated (and therefore the assessed) amount redress can be obtained before the second instalment of tax falls due for payment next July. Another reply in this issue covers "M. T.'s" question with regard to expenses; in any case private removal expenses are not allowable.

War Work—Travelling Expenses

"M.," a retired practitioner, receives 30s. a day for full-time work at a military reception centre. He has to motor eleven miles a day between home and the centre, and also has to incur mess expenses. What can he deduct?

⁎⁎ The remuneration is chargeable under Schedule E, and the relative rules as judicially interpreted do not permit the deduction of such expenses. Consequently we have to advise "M." that he has no claim.

LETTERS, NOTES, ETC.

Economy in the Kitchen

The Food Education Society, 29, Gordon Square, London, W.C.1, has published a leaflet, prepared at the instance of the St. Pancras Council of Social Welfare, entitled "Help and Health for Housewives." The hints given are as follows:

> Save your baker's bill by buying whole-meal bread. It is far more nourishing than white bread and you need less of it.
>
> Save your stale bread. Cut it in thin slices and dry in a slow oven to make "scrunch," which children love. It is good for teeth and digestion.
>
> Save your cabbage and other vegetable water. It is a splendid drink: a good medicine and a favourite with children. Use it also for soup and gravy.
>
> Save time and money by cooking potatoes in their skins. This will give you the highest food value and the best flavour.
>
> Save your butcher's bill by eating more herrings and cheese. Whole-meal bread, margarine, cheese, and apple make a perfect meal.
>
> Save fuel and labour by sometimes giving children, instead of puddings, apples, oranges, dates, and figs, which contain natural sugar.
>
> Save labour and firing by eating more raw salad, such as watercress, tomatoes, celery, finely chopped raw heart of cabbage, grated carrot, or onion, etc.
>
> Save by spending less on vinegar, sauces, pickles, and salt. Good cooking is spoilt by these additions.
>
> Save by avoiding ready-made food in packets. Why pay through the nose for breakfast cereals when whole-meal bread gives much better value?
>
> Save by using the stewing-pot more and the frying-pan less. This saves fuel and is better for the digestion.
>
> Save by chewing your food carefully and not drinking much at meals. Sip plenty of water on rising, in place of tea, and between meals. See that children get enough water to drink.
>
> Save both health and tea bill by avoiding strong or stewed tea. It plays havoc with digestion, nerves, and sleep. Never give tea to children. Milk or milk and hot water is excellent.

We are asked to add that the leaflet may be had in quantities at reduced rates—50 for 2s. 6d., 100 for 4s. 6d., 1,000 for £2.

Administration of A.R.P. Casualty Services

"C." writes: Dr. H. Mainwaring Holt, in his letter in the *Journal* of November 18 (p. 1021), uses the phrase, "Mobile units sound very attractive." They are lavishly equipped and staffed. There is one objection, however (there are others), which should be stressed. This is delay—long delay—before they are in a position to deal with their patients. During a recent exercise the "all clear" signal was given at 5 p.m., and the mobile unit arrived on the scene at 5.55 p.m. Casualties may have occurred at a time considerably earlier than 5 p.m.; say, 4.30 p.m. Presumably the injured could not have been attended to at the earliest in much under half an hour. Allowing fifteen minutes for the return by ambulance to the A.R.P. first-aid station or hospital, it would appear that well over two hours elapse before casualties can reach surgical help of hospital standard. In my opinion the most sketchy first aid, if rendered within half an hour, is preferable to this.

Crataegus oxyacantha

Dr. A. E. Sawday (Crouch End Hill, N.8) writes: I am curious to know why Dr. Frank Bodman (*Journal*, November 18, p. 1022), who I understand is attached to a homoeopathic hospital, uses a dose of 1 to 5 minims of tincture of crataegus rather than a homoeopathic dose.

An International Congress Postponed

Professor H. Burger, president, and Dr. A. Marres, honorary secretary, write from Amsterdam: The committee of the fourth International Oto-rhino-laryngological Congress regret that they are obliged to give notice of their decision to postpone the congress for an indefinite time. Our first circular letter was ready to be forwarded in August to the 8,000 oto-rhino-laryngologists whose addresses were known. It contains the information that H.M. the Queen of the Netherlands had graciously accepted the patronage of the congress. Four Ministers, the Governor of the province of Noord-Holland, and the burgomaster of Amsterdam were to be honorary presidents; delegates of H.M. Government were to hold a reception for the congress in the Amsterdam National Gallery (Rijksmuseum), and the Netherlands Oto-rhino-laryngological Society invited all members to the closing banquet. We thankfully mention that for the three main subjects nine well-known colleagues had promised to deliver reports; besides over twenty oto-rhino-laryngologists from several countries had already announced papers. We hope that the present horror will give way to better times, and that at some future date it may be granted to us to send our invitation once more to the oto-rhino-laryngological world.

An Apology by "Picture Post" to Lord Horder

Lord Horder writes: I shall be grateful if you will give space to the enclosed apology, which will appear in the next issue of a magazine called *Picture Post*. The paragraph is self-explanatory.

"*Apology to Lord Horder*

> "A private photograph of Lord Horder was published in our issue of November 27 without his knowledge or consent. Lord Horder has further drawn our attention to the incorrect description of himself as 'the King's Physician' and as having acted as physician to the late King George V. We take this early opportunity of expressing our regret to Lord Horder for the inconvenience and annoyance that have been caused him."

CLINICAL PORPHYRINURIA

WITH REPORT OF A CASE OF THE ACUTE IDIOPATHIC TYPE

BY

F. G. CHANDLER, M.D., F.R.C.P.

G. A. HARRISON, M.D.

AND

C. RIMINGTON, M.A., Ph.D., B.Sc.

(*From St. Bartholomew's Hospital and the National Institute for Medical Research*)

Porphyrinuria of such a degree that the abnormal colour leads to examination of the urine is rare (see below). Study of cases, however, may be of considerable importance in furthering our knowledge of the building up of haemoglobin and of the metabolism of pigments in the human body. Similar studies are clearly indicated in lesser grades of porphyrinuria which are not suspected from the colour of the urine but which require for their recognition quantitative determinations of, or special qualitative tests for, the porphyrins. Indeed, the separation of "clinical" or "frank" porphyrinuria from the lesser grades is obviously arbitrary, but has clinical value in two respects: first, the urinary colour itself calls for special investigation; and, secondly, it seldom happens that the porphyrinuria is clinically of paramount importance unless the urine is abnormal in colour. For these reasons discussion is here limited to clinical porphyrinuria.

Probably relatively few physicians in this country are familiar with the brilliant work of Hans Fischer and his colleagues on the chemistry of the porphyrins. Since studies of porphyrinurics and all hypotheses of the causes of porphyrinuria must be subject to this knowledge, it is essential to give at least a brief summary of it. Owing to the almost complete absence of a reasonable account of acute idiopathic porphyrinuria from British textbooks, our clinical experience of the case reported below should be of value.

Nomenclature and Summary of Chemistry of Porphyrins

Haemoglobin belongs to the group of chromoproteins and consists of globin united with a complex pigment, haematin. Haematin is an iron derivative of porphyrin. The porphyrins themselves contain no iron and are not proteins. Haemin is the hydrochloride of haematin. It has been known for many years that when iron is removed from haemin by the action of acids a porphyrin is formed, called "haematoporphyrin" by Nencki, its discoverer. It was for long assumed that the porphyrins in urine were the same, hence the employment of the term "haematoporphyrinuria," which is even now sometimes seen in clinical literature. Later it was shown that only by the use of mild reagents such as acetic acid and hydrazine upon blood or haemin is it possible to separate the corresponding porphyrin without alteration. This natural porphyrin is designated "protoporphyrin" ($C_{34}H_{34}N_4O_4$). Haematoporphyrin ($C_{34}H_{38}N_4O_6$), which results when a drastic reagent such as concentrated sulphuric acid is used, is a chemical artefact and not a naturally occurring substance. Hans Fischer showed that the main porphyrin in the urine in congenital porphyrinuria was different from protoporphyrin, and called it "uroporphyrin." The chief porphyrin in the faeces in the same disease was different again, and Fischer called it "coproporphyrin" (*syn.*, stercoporphyrin).

It has long been known that even in health the urine contains minute traces of a porphyrin. By working up enormous volumes this has been isolated and shown to be coproporphyrin. Nowadays, therefore, the term "porphyrinuria" is employed to denote an excretion of urinary porphyrin in excess of the normal amounts, and the porphyrins present may be coproporphyrin or uroporphyrin, or both. Similarly, the faeces may contain a mixture of porphyrins, but in this excrement the list is extended; in addition to coproporphyrin and uroporphyrin there may be protoporphyrin (by degradation of haemoglobin ingested or from haemorrhage into the gut), deuteroporphyrin (by degradation of haemoglobin or myohaemoglobin), and others.

Hans Fischer has synthesized haemin, which is easily prepared from blood in crystalline form (Teichmann's crystals), and has shown that it is $C_{34}H_{32}N_4O_4FeCl$, with the following structural formula:

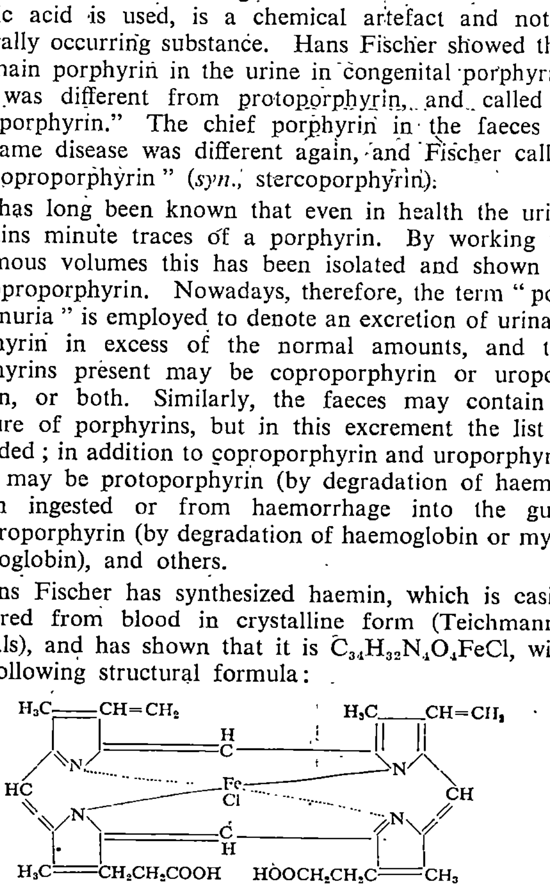

FIG. 1.—Structure of haemin.

Fischer and his colleagues have established the formulae of many of the porphyrins, some of which are given in the table below. The parent substance of them all is porphin, $C_{20}H_{14}N_4$ or $C_{20}H_6N_4.H_8$, with the following structure:

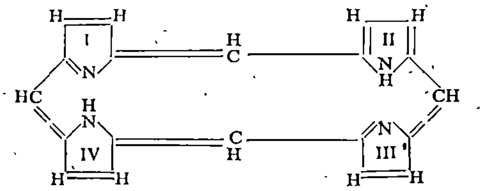

FIG. 2.—Structure of porphin.

The different porphyrins are obtained by substitution of different groups (methyl, ethyl, vinyl, acetic, propionic) for the hydrogens in the β, β' position in the four pyrrole rings of porphin. The corresponding haemins are obtained by attachment of Fe˙˙˙Cl to the nitrogens of the four pyrrole rings (see formula of protohaemin above). In the corresponding haematins (oxyhaematins) Fe˙˙˙OH, and in the reduced haematins Fe˙ (ferrous), is in the same position.

The following table summarizes the formulae of the substances which have been or are about to be mentioned:

Substance	Ring-structure	Side-chain Groups
Porphin	$C_{20}H_6N_4$	8H
Aetioporphyrin ..	$C_{20}H_6N_4$	$4(CH_3)$ and $4(C_2H_5)$
Protoporphyrin ..	$C_{20}H_6N_4$	$4(CH_3)$; $2(CH_2CH_2COOH)$ and $2(CH:CH_2)$
Haemin (protohaemin)	$C_{20}H_4FeClN_4$	$4(CH_3)$; $2(CH_2CH_2COOH)$ and $2(CH:CH_2)$
Coproporphyrin ..	$C_{20}H_6N_4$	$4(CH_3)$ and $4(CH_2CH_2COOH)$
Uroporphyrin ..	$C_{20}H_6N_4$	$4(CH_2COOH)$ and $4(CH_2CH_2COOH)$
Deuteroporphyrin ..	$C_{20}H_6N_4$	$4(CH_3)$, $2(CH_2CH_2COOH)$ and 2H
Bilirubin	Porphin ring opened	

This is complicated, but becomes more so when the fact is considered that numerous isomers of these compounds are possible, depending upon the order of arrangement of the substituent groups upon the pyrrole rings; Fischer *et al.* have synthesized many of these. There are fifteen possible isomers of protoporphyrin, but by suitable treatment a simpler porphyrin—aetioporphyrin—is obtained, of which there are only four possible isomers, designated, for convenience, aetioporphyrins I, II, III, and IV.

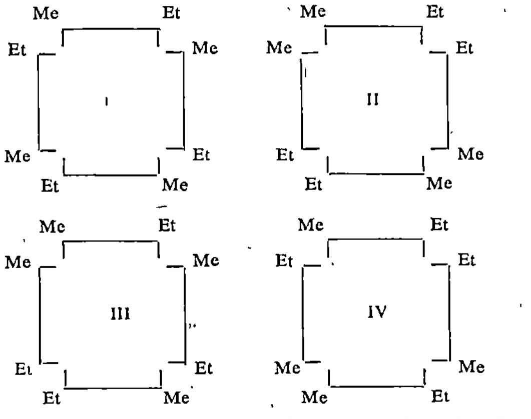

FIG. 3.—The four aetioporphyrins. Fischer's abbreviated formulae, showing positions of substituents in β, β' positions in pyrrole rings.

These may be regarded as the starting-point of four series of derived pigments, I, II, III, and IV. So far, in Nature porphyrins of the I and III series alone have been encountered, and the difference between these will be seen to lie only in the exchange of positions of two neighbouring groups in one of the rings. The structures of the naturally occurring coproporphyrins and uroporphyrins are reproduced in Figs. 4 to 7.

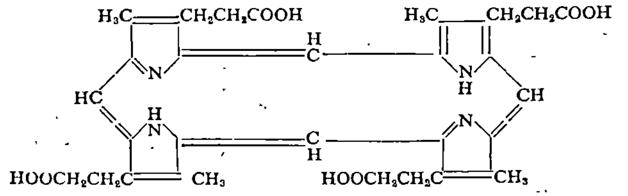

FIG. 4.—Coproporphyrin I: $C_{36}H_{38}N_4O_8$

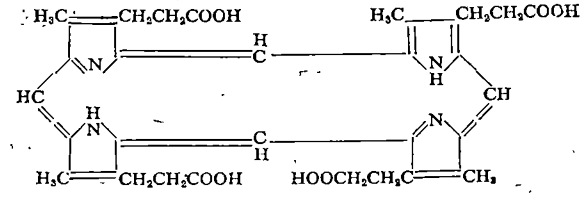

FIG. 5.—Coproporphyrin III.

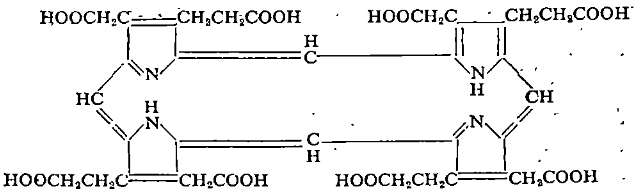

FIG. 6.—Uroporphyrin I: $C_{40}H_{38}N_1O_{16}$

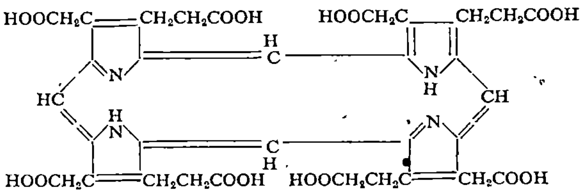

FIG. 7.—Uroporphyrin III.

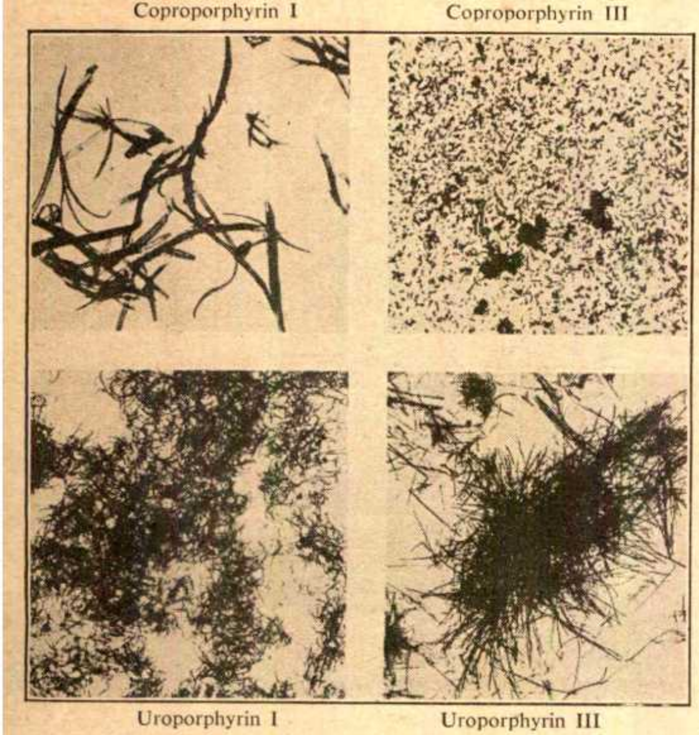
Fischer *et al.* showed that haemoglobin and chlorophyll belong to series III, whereas the porphyrins in the excreta in disease belong mainly to series I. This is important, because it excludes the possibility of the porphyrins excreted in disease being derived by breakdown from haemoglobin. Passage from series III to series I would necessitate breakdown into the constituent pyrrole units and rebuilding into the new configuration—a sufficiently unlikely occurrence.

In addition to deciding whether the porphyrins in urine are coproporphyrin or uroporphyrin, or both, it is now necessary to show whether they belong to series I or III, or both, if data are to be obtained on which sound hypotheses can be built as to their origin.

In the methods employed in this work advantage is taken, as usual, of differences in solubility, crystalline form, melting-point, mixed melting-point, spectroscopic properties, etc. Since the free porphyrins do not possess sharp melting-points, they are converted into their crystalline methyl esters, which have well-defined melting-points for identification. So far as possible the investigations are carried out quantitatively; but they are laborious, and require considerable experience owing to the small amounts of the porphyrins and the complexity of biological fluids and tissues.

The melting-points of the methyl esters are: coproporphyrin I, 252° C.; coproporphyrin III, 145° C. (remelt 172° C.); uroporphyrin I, 302° C.; uroporphyrin III, 261° C.



Coproporphyrin I Coproporphyrin III

Uroporphyrin I Uroporphyrin III

FIG. 8.—Crystalline porphyrin esters. The uroporphyrin I ester was from bones (Rimington (1936), Fig. 13), the other three esters from the urine of our case of acute idiopathic porphyrinuria.

Wave-lengths (mμ) of Absorption Bands of Porphyrins

Acid Spectra (25 per cent. HCl):

Copro- .. 618 .... 569 .... 539 504
Uro- .. 612 .... 561 .... 539 504

Neutral Spectra (in ether):

Proto- .. 633 585 .... 576 .... 537 502
Copro- .. 624 .... 597 .... 578 .... 568 .... 529 498
Uro- .. Insoluble in ether.

Classification, Frequency, and Literature of Clinical Porphyrinuria

Adhering to the definition already given, there are three types of clinical porphyrinuria: (1) congenital (less than thirty cases published); (2) due to drugs, such as sulphonal, trional, etc. (about 100 cases published); (3) acute idiopathic, of unknown cause—about fifty cases recorded in the older literature; recently 103 from Sweden by Waldenström (1937). Several schemes of classification have been proposed, but need not be considered in detail here. Waldenström (1937) has recently made the suggestion that the term "porphyry" should be reserved to embrace conditions 1 and 3, in which the constitutional element predominates, while all other types of increased porphyrin excretion should be grouped under the heading "porphyrinuria."

The literature dealing with porphyrins and porphyrinuria is enormous, and in this brief summary only a few reviews and long articles can be mentioned, from which, however, the reader will have no difficulty in obtaining an introduction to it. Congenital porphyrinuria is dealt with by the late Sir Archibald Garrod (1923) in his *Inborn Errors of Metabolism*. Reference should also be made to Mackey and Garrod (1922, 1926) and to Garrod (1936). For the German work on the case of Petry, see Fischer, Hilmer, Lindner, and Pützer (1925) and Borst and Königsdörffer (1929). For congenital porphyrinuria in cattle, see Fourie (1936), Rimington (1936), and Fourie and Rimington (1938). Porphyrinuria due to drugs is reviewed by Günther (1922). Papers by Garrod and Hopkins (1894–6) and Drigalski (1937) contain interesting points. Increased porphyrin excretion in pellagra has been dealt with by Beckh, Ellinger, and Spies (1937). Acute idiopathic porphyrinuria is reviewed by Günther (1922). See also Mason, Courville, and Ziskind (1933), Waldenström (1934, 1939), Mertens (1937), Turner (1938), and Geissler (1939). For general reviews consult Fischer and Zerweck (1924), Fischer (1930), Carrié (1936), Vannotti (1937), Waldenström (1937), Hernando (1938), and Watson (1938).

Chief Signs and Symptoms of Clinical Porphyrinuria

Only the salient features are summarized in the following table. Further details concerning the acute idiopathic form are given below.

Type of Porphyrinuria	Congenital	Due to Drugs	Acute Idiopathic
Red urine	From birth	After much drug	Usually in adult life
Photosensitivity ..	Severe	Absent	Absent or very mild
Pigmentation of bones and teeth	Present	Absent	Absent
History of drugs ..	No	Yes	No
Abdominal and other toxic symptoms	None	Present	Present
Sex incidence.. ..	Mostly males	Usually females	Mostly females

A Case of Acute Idiopathic Porphyrinuria

The patient was a male insurance clerk aged 28, and was referred to St. Bartholomew's Hospital by Dr. K. R. Bali on September 19, 1938. He was under the care of one of us, complaining of severe abdominal pain, constipation, vomiting, loss of weight, occasional frontal headache, and insomnia.

HISTORY OF PATIENT

He had had measles and scarlet fever in childhood. In 1929 or 1930 he had pain over the whole abdomen, in occasional attacks, usually coming on ten to thirty minutes after a meal and frequently relieved by an alkaline powder. These attacks, each lasting about a fortnight, were separated by intervals of three or four weeks and became slowly more severe, until in 1937 he started to vomit. In 1937 his appendix was removed at Old Church Hospital, Romford; it was said to be chronically inflamed. Following this he had pneumonia and a left-sided pleural effusion. He left Romford much improved, but was admitted to St. Bartholomew's Hospital because the pleural effusion persisted. A skiagram of the chest revealed some dense calcareous foci in the right upper lobe, and the erythrocyte sedimentation rate was 49 mm. in the first hour. He was sent to Ventnor Sanatorium for six months, at the end of which period he was free from symptoms. There was never any specific evidence of tuberculosis, and never any haematemesis or melaena.

The patient believed it was in 1935 that he first noticed that his urine would sometimes darken on standing; darkening of the urine was not observed at Ventnor. In March, 1938, he had a bad attack of abdominal pain and vomiting, and his urine was red. There was no history of drug-taking, apart from the alkalis mentioned above, and six Dr. Cassell's tablets just before his final admission on September 19, 1938. His father suffered from disease of the kidneys, and passed urine the colour of blood. Two sisters and three brothers are living, but there is no history of any of them passing abnormally coloured urine. One sister died from pulmonary tuberculosis. There is no consanguinity between the parents.

The final attack started two weeks before his admission to St. Bartholomew's Hospital. He had been unable to keep anything down, and had no desire for food. He had lost a stone in weight in three weeks. On examination he was thin and sallow-looking. His whole body was a little brown, and this was most noticeable on his face, on which a few pigmented spots were present, but no scars. There was no patchy bronzing and no hypertrichosis. On the front of both knees there were six or seven round scars 1/4 to 1/2 inch in diameter, believed to be due to falls as a boy, but there were none on the elbows; he had a few septic spots on the trunk, each about 3 mm. in diameter. There was no definite evidence of photosensitivity. The eyes were normal, the tongue was furred, the teeth sound and not stained, and the mucous membranes were normal in colour. The temperature was occasionally 99°, but generally normal; the pulse was about 100, and the respiration rate normal.

EXAMINATION

Nothing abnormal was detected in the heart, and the blood pressure was 120/96. There were no physical signs in the chest, but a skiagram again showed the calcareous foci mentioned above; tubercle bacilli were not found in the sputum, which yielded a mixed growth of organisms in which pneumococci predominated. The erythrocyte sedimentation rate was 5 mm. in the first hour (September 21), and the Wassermann and sigma reactions were negative. There was generalized tenderness over the abdomen, but no mass was felt at first, and the liver and spleen were not enlarged. A barium meal on September 22 revealed nothing abnormal, and another on September 28 showed that though evacuation took a considerable time there was no evidence of obstruction. Tests for occult blood in the faeces were negative. Apart from brisk reflexes, nothing unusual was found in the nervous system.

The urine was normal in colour immediately after it was passed, but rapidly darkened, becoming deep brown or reddish brown in a few hours. Thus a sample received in the laboratory on September 21 was of a deep port-wine colour and acid in reaction; spectroscopically there were two absorption bands in the green very much like those of oxyhaemoglobin, and a band at the junction of the green and blue. Microscopically there were no red cells. Chemically there was a minute trace of protein, but the pyramidon test for blood was negative; Schlesinger's test for urobilin was strongly positive. By means of the tests given later it was shown without any doubt that the oxyhaemoglobin-like spectrum was due to a metallo-porphyrin. Subsequently many samples of urine were examined by two of us, and all showed the same behaviour, though of course the concentration of metallo-porphyrin and of urobilin varied. The effect of heat was as described under "Urinary Tests." One of us (for preliminary communication see Rimington, 1938a) separated the porphyrins from the urine and faeces by the methods outlined later.

The serum calcium was 9.3 mg. (October 24), the blood urea 52 mg. per 100 c.cm. (October 4), and no abnormal pigments were detected spectroscopically in the plasma or in the laked red cells (October 24).

CLINICAL HISTORY

The abdominal symptoms became worse, and occasionally the patient complained of pain in the arms, legs, and neck. By October 2 the cramp-like abdominal pain was so severe and the vomiting so frequent and distressing that he begged for something to be done. At this time a hard mass was felt in the epigastrium, which was slightly movable. A surgeon was called in, and agreed to operate, though very reluctantly, on the grounds that the lump was probably a malignant mass and the case hopeless. In spite of the fact that we knew there is intense spasm of the intestinal tract in acute idiopathic porphyrinuria, the one of us who was responsible for the patient's welfare urged operation because of the pain, the mass in the abdomen, and the fact that in many books porphyrinuria is described as associated with certain diseases of the stomach. It is possible that the last clinical point is not sound, and that there is no conclusive evidence of the association of organic disease of the stomach with clinical porphyrinuria; in that case the statement repeated in one textbook after another should be deleted.

A laparotomy was performed on October 12. The stomach was in extreme contraction, suggesting at first a leather-bottle stomach, this producing the apparent tumour. Otherwise nothing abnormal was found. The patient recovered quickly, and for some unknown reason was entirely free from symptoms for several days, and there was much less porphyrin in his urine. On October 17 the pain returned, and thereafter the porphyrinuria increased.

On October 19 Dr. Denny-Brown kindly made a neurological examination. He found no definite sensory changes, no convincing focal wasting, and only a general weakness. All the reflexes were brisk; there was no tenderness of muscles and no loss of vibration or position sense. He did not think there was a true peripheral neuritis, and felt certain that the pains were not neuritic.

The patient's condition rapidly deteriorated, and he begged for more and more opium. There is little doubt that he suffered acute and intolerable pain, and it would have been kinder to increase the dose of omnopon, which was kept within reasonable limits in the hope of recovery. Not obtaining the complete relief from pain for which he asked, the patient wished to be discharged, and on October 24 was transferred to the care of his own doctor. On October 25 he was unable to use his arms, and there was great weakness in the hands and legs. On October 27 his temperature was still normal, but he developed a cough. Increasing asthenia led to his death on October 28. A necropsy was performed, but unfortunately the pathologist was not aware of the findings in hospital, so there was no special study of the bones or central nervous system and no material was kept for chemical investigation. We do not consider, therefore, that a report of the findings would be of any value. (For post-mortem histology, cf. Geissler, 1939.)

During the patient's stay in hospital vigorous symptomatic treatment was instituted, which need not be detailed. Eight intravenous injections, each of 10 c.cm. of 10 per cent. calcium gluconate, were given, but afforded no relief.

Simple Urinary Tests in Porphyrinuria

The colour of the urine varies from brown to red, and is often described as "port-wine." Sometimes the fresh urine is more or less normal in colour, but slowly darkens so that in a few hours it is obviously abnormal, and ultimately may become deep reddish brown or almost black. This is due to the excretion of porphyrinogens and other chromogens of unknown constitution which are slowly changed in light and air to the corresponding porphyrins and pigments. It has been recognized for many years that the pigmentation is due mainly to the unknown pigments. To produce the change rapidly the urine may be heated at 100° C. for half an hour; the darkening starts in a few minutes and, so far as our limited experience goes, is complete in half an hour. Potassium permanganate and other oxidizing agents have been recommended to produce the change, but in our hands, though they might cause darkening, they did not produce porphyrins judging from spectroscopic examination. We therefore recommend that in routine examinations the urine be heated at 100° C. for half an hour before it is concluded that there is no gross porphyrinuria.

It is, of course, the examination with the spectroscope that establishes the diagnosis of porphyrinuria. In a typical case the four-banded spectrum of alkaline porphyrin is seen when the urine is examined in an ordinary boiling-tube (about 1 inch in diameter). The alkaline spectrum is seen at all natural reactions of urine; the acid spectrum is produced only by the addition of a mineral acid. Obviously the concentration of porphyrins varies, and it is necessary to have a working rule as to how thick a layer of urine shall be viewed before declaring a negative result. We suggest that clinical porphyrinuria can safely be excluded if a 4-inch or 5-inch layer* of urine does not show the absorption bands (compare Günther, 1922.) The effect of heat should, however, be tried as mentioned above; in highly pigmented urines it is impossible to see through so thick a layer, and the simple extraction method given below must be tried before concluding that there is no porphyrin.

A second important point in the spectroscopic examination is that occasionally the porphyrin is excreted as a metal complex, and the urine shows two absorption bands in almost the same positions as the bands of oxyhaemoglobin, instead of the typical four-banded spectrum. Careful observation reveals the fact that the β band is the more intense, whereas with oxyhaemoglobin it is the α band which is the darker. Wave-length measurements may be used to differentiate, but to make this conclusive it is necessary to use a reversion spectroscope (see later). Since the porphyrins contain no iron and are not proteins, negative chemical catalytic tests for blood (guaiac, pyramidon, reduced phenolphthalein, etc.), and negative tests for proteins, rule out haemoglobin; but, naturally, positive tests do not exclude a metallo-porphyrin. Confirmation of the presence of a porphyrin or metallo-porphyrin is easily obtained by adding a few drops of concentrated HCl or H_2SO_4 to about 10 c.cm. of urine, when the acid spectrum is obtained.

---

* For a convenient method of varying the thickness, see *Biochem. J.*, 1938, **32**, 933.

As mentioned above, when the porphyrins are dilute or the urine is highly pigmented it is necessary to extract them for certain recognition. A simple method is to acidify about 15 c.cm. of urine with a few drops of glacial acetic acid and then to add about 5 c.cm. of ethyl acetate or of amyl alcohol. After shaking thoroughly, the mixture is centrifuged and the upper layer is transferred to another tube and examined spectroscopically, if necessary in a thick layer (cf. previous footnote). Shaking the extract with one drop of HCl produces the acid spectrum. This method does not give positive results with normal urines, but will detect slight increases in porphyrin excretion.

Some Special Investigations of the Urine and Faeces

By spectroscopic means it is impossible to differentiate between the series I and the series III isomers of the same porphyrin; indeed, the data already given show that careful measurements of wave-lengths are required to distinguish between the uroporphyrins and coproporphyrins, for the maximum difference between corresponding absorption bands is only of the same order as that between the bands of oxyhaemoglobin and of carboxyhaemoglobin respectively (about 60 A.U.). A differential estimation of the isomers, therefore, necessitates first a separation of the porphyrins from the urine.

Several methods have been proposed for this purpose. Nebelthau (1899) found that the addition of acetic acid to urines containing much porphyrin caused the formation of a slowly settling precipitate in which nearly all the porphyrin was included. To Garrod (1894–5) we owe one of the earliest procedures of a roughly quantitative nature. To 100 c.cm. of urine was added 20 c.cm. of a 10 per cent. solution of sodium hydroxide. This produced a precipitate of the earthy phosphates, upon which much of the porphyrin was adsorbed. After filtration the precipitate was washed off the filter paper by water and sufficient acid and alcohol added to dissolve it completely. The solution then showed the acid porphyrin spectrum. A calcium precipitate was used to carry down the bulk of the porphyrin as an adsorbate by both Salkowski (1890–1) and Dobriner (1936). Barium precipitates have been used for a similar purpose, and were also investigated by Salkowski. In our own case four volumes of 10 per cent. barium chloride added to ten volumes of urine produced a precipitate containing almost all the porphyrin, but it is probable that irregularities would be observed were this method to be tried upon a number of different urines (see below). Fink (1937), in his work on the isolation of the normal urinary coproporphyrin, employed with success a thick layer of paper pulp to adsorb porphyrin from the large bulk of urine acidified with acetic acid, and Grotepass (1938) similarly filtered large quantities of urine through infusorial earth in order to obtain enough pigment for chemical identification.

By far the most convenient and reliable technique, however, is that of chromatographic adsorption, using the Tswett column, and first applied to the particular case of the extraction of porphyrins from urine by Waldenström (1935); this is the method we have employed in the investigation of the present case and is described below in full.

As has already been pointed out, pathological urines may contain both uroporphyrins and coproporphyrins. A fundamental difference in physical properties exists between these two pigments—namely, the coproporphyrins may be extracted by ether from an aqueous solution solidified with acetic acid, while the uroporphyrins do not pass up into the ether phase under these conditions. A preliminary separation may thus easily be effected. A further difference exists between uroporphyrins I and III, in that the latter, as discovered by Waldenström, Fink, and Hoerburger (1935), may be removed from a carefully acidified solution by repeated extraction with ethyl acetate. Uroporphyrin III was thus obtained in pure form for the first time from the urine of acute idiopathic porphyrinurics. Fischer's (1926) method for the isolation of the coproporphyrins from urine, faeces, serum, etc., is based upon the acetic acid–ether solubility discovered by Saillet (1896); a similar technique has been used by Schumm. Briefly, the material is strongly acidified by acetic acid and then shaken with successive quantities of ether until all the porphyrin is extracted. The combined ether extracts are washed with water to remove most of the acetic acid, and the porphyrins recovered by shaking with dilute hydrochloric acid. According to the concentrations of acid used, a further separation may be achieved of the different ether-soluble porphyrins present, since, for example, coproporphyrin can be extracted completely by 0.5 per cent. HCl but protoporphyrin not until an acid concentration of 3 or 4 per cent. is used.

In the following description of the methods by which we isolated the individual porphyrins from the urine and faeces of our patient these methods find illustration.

Preliminary Tests upon the Urine

When viewed by a direct-vision spectroscope the red-brown urine voided by this patient exhibited two well-defined absorption bands at approximately 580 and 542 mμ. (Using the same instrument, the readings for oxyhaemoglobin were 577; 540 mμ.) The addition of a reducing agent caused no change, but upon acidification with a few drops of concentrated hydrochloric acid an immediate shift was seen to approximately 600 and 556 mμ. There was strong continuous absorption in the blue end of the spectrum and also in the far red region. The two-banded spectrum is closely similar to that of the zinc complex of uroporphyrin.

Isolation of Coproporphyrins and Chromatographic Separation applied to the Urine Residue

Two litres of urine (collected October 4 to 10) were acidified with 100 c.cm. of glacial acetic acid and shaken twice with 1-litre portions of ether. The ether phase was washed well with water and the porphyrin then removed by shaking into 1 per cent. hydrochloric acid. This solution showed absorption bands at 595 and 549 mμ. Spectrophotometric comparison with a standard coproporphyrin solution gave the yield as 0.306 mg. By addition of potassium acetate and shaking with ether the porphyrin was transferred back again to the organic solvent, which exhibited the neutral four-banded spectrum of coproporphyrin 625, 570, 532, 498. The solution was evaporated to dryness, esterified by methyl alcoholic hydrochloric acid, and the dry ester treated with anhydrous ether, in which coproporphyrin III ester is soluble but coproporphyrin I ester insoluble. All dissolved except a small unweighable quantity, which was, however, crystallized from hot chloroform-methyl alcohol and obtained in the form typical of coproporphyrin I methyl ester, melting-point 230° to 240° C. (Fig. 8). The ether solution was concentrated to low volume in a weighed tube and then stoppered and set aside in the ice-chest. The crystals which formed were washed sparingly with dry ether and then with petrol: weight, 0.3 mg.; melting-point, 172° to 174° C. (Fig. 8). The coproporphyrin fraction of the urine thus consists principally of coproporphyrin III (0.15 mg. per litre), together with a trace of coproporphyrin I.

The residual urine, after removal of the ether-soluble porphyrins, was allowed to filter slowly under gentle suction through a column of alumina (Merck's "nach Brockmann") in a vertical glass tube measuring 2 × 30 cm. The first filtrate was yellow, but a brownish-red pigment followed which showed no absorption bands in the red or green, but the broad band of urobilin in the blue region of the spectrum. When all the urine had passed through the column, the chromatogram was washed by percolation with 1 litre of 5 per cent. acetic acid, which extracted the last of the reddish-brown pigment. Glacial acetic acid now removed a small quantity of pigment, migrating as a narrow zone and emerging as a mahogany-red solution with two faint bands at 580–555 and 530. On standing in the ice-chest the liquid deposited the substance responsible for this spectrum, which proved to be uroporphyrin metal complex.

After washing out the acetic acid from the column with water, dilute ammonia (50 c.cm. of specific gravity 0.88 to 200 c.cm. of water) removed the porphyrins. First came a deeply coloured zone emerging as a dark red solution consisting mainly of the metal complex (two-band spectrum), and following this the main bulk of the material in a bright red solution in which the four bands of the alkaline spectrum of uroporphyrin were very sharply defined. Since any metal in complex combination with the porphyrin is eliminated by the strong acid used during the process of esterification, the above solution and the fraction consisting mainly of metal complex (which was put once more through the chromatographic process to remove some accompanying brown material) were combined and acidified by acid to *p*H 3.7. On standing, the porphyrin material was precipitated completely. It was centrifuged off, washed with acetate buffer solution of *p*H 3.7, and dried *in vacuo*, then esterified and the ester crystallized from hot chloroform-methyl alcohol. It separated in the form of very fine hair-like needles usually in aggregates (Fig. 8) and having a melting-point of 258° C., not depressed by admixture with uroporphyrin III methyl ester. The total yield was 42 mg., corresponding to 21 mg. per litre of urine. Uroporphyrin I could not be detected.

	Yields of Methyl Esters (mg. from 2,000 c.cm.)	Melting-points of Methyl Esters
Coproporphyrin I	minute trace	230° to 240° C.
Coproporphyrin III	0.3	172° to 174° C.
Uroporphyrin I	*nil*	—
Uroporphyrin III	42.0	258° C.

Identification of the Metal Present in Complex Combination

Using a calibrated reversion spectroscope the wave-lengths of the bands due to the metallo-porphyrin were 5,782; 5,406 A.U. (oxyhaemoglobin in the same instrument was 5,769; 5,389). Messrs. Adam Hilger, Ltd., kindly took spectrograms of the materials absorbed on a barium precipitate of the patient's urine and of a normal urine, and concluded that no doubt there was a greater concentration of zinc in the patient's sample.

The acid liquids from the esterification process, containing the metal which had been removed from its combination with the porphyrin, were evaporated to dryness, taken up in a little water, and filtered. Spot tests applied to this solution were positive for Zn, Fe, and Cu. It is thus possible that more than one porphyrin metal complex was present, although the observed absorption spectrum corresponded most nearly to that of uroporphyrin zinc complex, for which Mertens (1937) gives 571.5; 536 mμ. (For the coproporphyrin zinc complex Kapp (1939) gives 575; 539. Kapp and Coburn (1936), however, mention that higher dilutions gave 578; 541.) Zinc in complex combination with porphyrins has been observed by other workers, among whom may be mentioned Turner (1938) and Derrien and Cristol (1930). There is no doubt that the metal complex was present in the urine as voided, since a specimen obtained immediately after micturition still exhibited the characteristic two-banded spectrum. On the other hand the chromatographic results make it quite clear, also, that some of the uroporphyrin was not so combined. All the urine was collected in porcelain or glass, and never came into contact with metal.

Isolation and Identification of Porphyrins from the Stools

There was available 275 grammes of material (October 14 to 18) having a moisture content of 64.9 per cent. The mass was ground up with about 1 litre of acetone and, after standing for some time, this solvent was filtered off and replaced by a further 1 litre of acetone. The defatted residue was then ground with 100 c.cm. of glacial acetic acid, 1 litre of ether added, and the mixture shaken in a stoppered jar for one and a half hours. After decantation the extraction of the residue was repeated, using 50 c.cm. of acetic acid and 1 litre of ether. The combined ether extracts were filtered through a sintered glass filter-funnel into a large separating funnel and washed several times with water. Shaking with six 100-c.cm. portions of 5 per cent. HCl removed the porphyrins. Since there was some emulsification, the extract was cautiously warmed on a water bath and stirred until the ether had been removed. There remained a clear deep red liquid containing only a little suspended matter which could be easily filtered off. The porphyrin was returned to ether with the aid of potassium acetate, and the ether solution, after washing, extracted first with 0.5 per cent. (coproporphyrin fraction) and then with 5 per cent. hydrochloric acid (protoporphyrin fraction).

The 0.5 per cent. acid extract was freed from some urobilin, etc., by shaking with chloroform, and the quantity of porphyrin determined spectrophotometrically: yield 2 mg. The protoporphyrin fraction (5 per cent. acid), after a little further purification, gave a solution containing 2.4 mg. of porphyrin. The total yield thus corresponded to 4.56 mg. per 100 grammes of dried faeces, or 1.6 mg. per 100 grammes of undried stool, and approximately half was coproporphyrin.

By esterification and separation with anhydrous ether as described above it was shown that there was only a trace of material crystallizing like coproporphyrin III, the main fraction (1 mg. from 1.1 mg. of crude esters) being identified as coproporphyrin I with ester melting-point 245° to 247° C. Examination of the stool residue for uroporphyrin failed to reveal any trace of this pigment.

Recovery and Purification of Urinary Porphyrin from a Barium Chloride Precipitate

The chromatographic process can be relied upon, but demands much time and attention. Our results with barium chloride precipitation followed by certain innovations are considered, therefore, to be worthy of record, because pure uroporphyrin ester was readily obtained in good yield. To 7.3 litres of urine was added 2.2 litres of 12 per cent. barium chloride solution, and the fine precipitate collected upon a large Buchner funnel, washed by water and then by methyl alcohol. It was then suspended in methyl alcohol containing 2 per cent. by weight of sulphuric acid and the mixture refluxed on the water bath for some hours. After filtering off the deeply coloured liquid by suction, the residue was boiled with a fresh lot of this mixture, the process being repeated yet a third time. The three extracts were combined and placed in a large separating funnel with about 300 c.cm. of chloroform. Much water was then added and, after shaking, the chloroform layer was run off. Extraction with further smaller quantities of chloroform removed all the porphyrin ester from the acid aqueous layer. This crude chloroform solution was brownish red in colour and quite clearly contained much pigment in addition to porphyrin ester. To it was added twice the volume of petroleum ether, and the mixture was shaken repeatedly with 1 per cent. hydrochloric acid until no further brown material was either extracted or precipitated at the interface. This amorphous brown impurity was filtered off, and the remaining chloroform solution shaken repeatedly with 10 per cent. hydrochloric acid, which removed the porphyrin quantitatively, affording a clear deep red solution (1.25 litres). It was allowed to stand overnight at room temperature for complete hydrolysis to take place. 100 c.cm. of 50 per cent. sodium hydroxide was added and enough saturated potassium acetate solution (150 c.cm.) to bring the *p*H to about 3.7, when there was an immediate precipitation of the free porphyrin. This was centrifuged off, washed by acetate buffer solution of *p*H 3.7, then with water, and dried *in vacuo*. Re-esterification and crystallization from hot chloroform-methyl alcohol gave 64.5 mg. of well-crystallized uroporphyrin III methyl ester, melting sharply at 260° C.—that is, approximately 9 mg. per litre of urine.

Discussion

Acute idiopathic porphyrinuria is clearly recognized in Germany and elsewhere on the Continent; it is being increasingly reported in America, but even to-day it is scarcely mentioned in British literature. Yet some of the early cases were published in this country, under such titles as "Haematoporphyrinuria not due to Sulphonal"—

for example, Calvert and Garrod (1901), Garrod (1904), Brown and Williams (1909). Possibly the negative form of title was partly responsible for lack of interest; or perhaps the fact that it was noted that not all cases of porphyrinuria were accompanied by grave symptoms led to the conclusion that the porphyrinuria was incidental and of little importance clinically; then again, sulphonal had just been recognized as a cause of porphyrinuria, and it was not always certain that the patient had not taken this or a similar drug; also, several patients were diagnosed as suffering from abdominal diseases and the porphyrinuria was regarded as secondary.

The modern attitude is that, if a patient has abdominal pain, constipation, and vomiting, with a brown or red urine containing porphyrin which can be detected without special methods of separation and concentration, the possibility of "acute idiopathic porphyrinuria" should be considered. A difficulty is that in certain patients the symptoms and porphyrinuria may not be striking at first —hence some authors would make a fourth group of "chronic porphyrinuria"—and there may be several mild attacks before one which is grave establishes the diagnosis. None the less, there can be no doubt of the existence of a separate clinical group of porphyrinurics of the acute idiopathic form. The diagnosis is important in practice because it prevents unnecessary operations: in our patient there was no clear-cut history of the urine being red at the time of the appendicectomy in 1937; but the laparotomy in 1938 was unnecessary, as now we all agree, although, as noted previously, he was temporarily better after it. The decision whether to operate or not will remain difficult in future cases, for no physician wishes to be responsible for stopping an operation which could have done good. In the presence of grave abdominal symptoms it is the significance attached to the porphyrinuria which settles the issue: we repeat that, if the urine is brown or red and contains porphyrins that can be detected without special methods of separation and concentration, the diagnosis of acute idiopathic porphyrinuria may be made. But the responsible physician may still hesitate, for he knows that the condition is rare, and justifiably may refuse to be guided largely by a laboratory report. He will be influenced much more if the tests for porphyrins are quantitative: in acute porphyrinuria several milligrammes are excreted in the twenty-four hours' urine, whereas in health 0 to 50 µg. (1 µg. or 1γ = 1/1000 mg.) and in the lesser grades (see below) of porphyrinuria only fractions of a milligramme are present.

It is interesting that there are important differences chemically as well as clinically between the three types of porphyrinuria. In the acute idiopathic form the urinary porphyrins belong mainly to series III, whereas in congenital porphyrinuria they are largely series I compounds.

	Copro I	Copro III	Uro I	Uro III
Health	Very slight trace	Very slight trace	Nil	Nil
Congenital porphyrinuria	+	Trace	+++	Trace
Drug porphyrinuria (sulphonal, etc.)	+	? Trace	+++	? Trace
Acute idiopathic	Very slight trace	+	Nil	+++
Lead poisoning	? Slight trace	+	Nil	Nil

Congenital porphyrinuria is distinctive in several respects; there are marked photosensitization and pigmentation of bones and teeth, neither of which is present in the other types (see under heading "Chief Signs").

Were it not that series I porphyrins apparently predominate in sulphonal porphyrinuria too (Fischer and Duesberg, 1932; Fischer and Libowitzky, 1936), it might have been suggested that the distinctive features of the congenital form were due to the series I isomers, which are known to be more active as photosensitizers. It is curious that in sulphonal porphyrinuria uroporphyrin I, whereas in the acute idiopathic form uroporphyrin III, predominates, according to Fischer and his collaborators, for otherwise the two groups have almost everything in common; indeed, they are often classified as subgroups of the same "toxic" group. In contradistinction to the congenital form, both show in the advanced stages similar abdominal and nervous symptoms.

One point emerges quite clearly, however, as indicated in our section on the chemistry of the porphyrins. It is inconceivable that the excreted series I porphyrins can be derived from the *breakdown* of haemoglobin or other series III compounds. It is possible that where series III isomers are excreted these may have had such an origin, although in modern literature the tendency is to assume that it is at some stage in the *building up* of haemoglobin, etc., that an error or toxic effect has occurred which causes an excessive excretion of these porphyrins also. Experiments by one of us at present in progress may help to throw light upon the origin of the series III porphyrins in various pathological conditions (cf. Rimington, 1938, b; 1939).

Summary

"Clinical porphyrinuria" is defined; it includes the congenital form, that due to drugs such as sulphonal, and the acute idiopathic type, of which a case is described because it is not well recognized in British literature.

A summary is given of the chemistry of the porphyrins, for upon that depend not only the simple tests used in clinical laboratories but also the special investigations being made at several centres in the hope of throwing light on the synthesis of haemoglobin and the metabolism of related pigments.

The urine may contain uroporphyrin or coproporphyrin or both, and two isomers of each (I and III) have to be considered; methods for the separation and identification of these are described; in our case of acute idiopathic porphyrinuria, uroporphyrin III accounted for about 99 per cent. of the total urinary porphyrins.

CAUSES OF POST-PARTUM HAEMORRHAGE*

BY

FARQUHAR MURRAY, M.D., F.R.C.S., F.R.C.O.G.
Professor of Midwifery and Gynaecology, University of Durham College of Medicine

The causes of post-partum haemorrhage can be divided into two main groups. The first and larger consists of cases where an otherwise normal uterus has been treated unkindly by Nature or other agencies; the second includes cases in which there is some pathology or possibly a misplaced placental site.

Group I: The Normal Uterus

Many primiparae after a spontaneous delivery have cervical lacerations, a few of which extend above the level of the vaginal vault or have some degree of perineal laceration. It is a rarity for such cervical or perineal lacerations to give rise to alarming or dangerous bleeding. If, however, an incompletely dilated os is forcibly stretched by the premature application of forceps or an injection of pituitary extract, or by an accelerated breech delivery, the cervical lacerations are considerably increased, and indeed may assume the nature of a minor degree of rupture of the uterus. Too rapid stretching of the perineum by forceps or pituitary extract or by imperfect control of the head during a spontaneous delivery also results in severe trauma. It is surprising how seldom severe bleeding occurs even in these cases, although there may be considerable shock.

The most important bleeding point is the placental site. Prolonged or obstructed labours exhaust the uterine muscle and predispose to an imperfect third stage as regards the mechanism and control of bleeding. Mismanagement of an otherwise perfectly normal third stage is a prolific cause of difficulty and bleeding at this time. The uterus if well treated performs its work satisfactorily. At the Tarnier Clinic in Paris I noted that the women were delivered on their backs, and the resident doctor left them alone after delivery during the third stage. He returned from time to time to palpate the uterus. This procedure struck me as somewhat casual, and as different from what is the general rule in this country, where the patient is usually delivered on her left side and may remain in this position for some time before she is turned on her back to await the separation of the placenta, and where massage of the uterus is often performed.

A study of some hundreds of cases of incomplete B.B.A.s on the hospital district, where the baby had been born but the placenta had not come away by the time the nurse arrived, showed that in only one instance was a slight post-partum haemorrhage reported. These women had no skilled attention before the arrival of the nurse or district doctor.

A series of cases injected with 1 c.cm. of pituitary extract immediately after the delivery of the baby, with a view to studying the effect on the third stage and the amount of blood loss, revealed that the only cases in which there was any trouble were those which had been allowed to remain unduly long on their side after the injection was given or in which the uterus had been massaged. It is well known that a uterus which is kept out of the pelvis either at laparotomy or by means of a full bladder tends to bleed. If a patient lies for long on her side before the placenta comes away the uterus tends to fall up into the abdomen, with disturbance of its neuro-muscular mechanism.

With the rarest possible exceptions I deliver patients in the lithotomy and cross-bed position aided by a Clover's crutch. Unless there has been a long labour and much anaesthetic has been used I do not allow anyone to touch the uterus, but proceed to repair any laceration or episiotomy wound which may be present and merely lightly palpate the fundus from time to time to determine if the placenta has separated. The third stage is uniformly most satisfactory, and there is a minimum of blood loss. The time factor is a most important one, especially at night. The time of delivery should be noted, and at least ten to fifteen minutes allowed to elapse—unless there is bleeding—before deciding whether the placenta is ready for expulsion or not.

Occasionally one meets with post-partum haemorrhage of an insidious nature if the placental separation is not going according to plan. This is most likely to be found if the patient is nervous or has had a long and tiring labour or a lot of anaesthetic. The placenta in these cases has left the fundus but has not yet been completely detached from the lower part of its site. The physical signs are misleading. An attempt at expression fails to deliver the placenta, but a mass of blood clot the size of a small orange is squeezed out. There is no active continuous bleeding, but merely expulsion of a mass of blood clot each time an attempt is made to express the placenta. Each clot represents several ounces of blood and the patient slowly deteriorates. It is a sound rule to remove these placentae manually while the patient's condition is good.

I have never seen sepsis arise where a manual removal of the placenta followed by an intra-uterine antiseptic douche was done while the patient was in fairly good condition. Delay in doing this owing to a dread of causing sepsis or because the blood loss is intermittent and slight, and not continuous and severe, is responsible for many bad results.

Group II: The Pathological Uterus

In the other group of cases there is some intrinsic mischief in the uterus. One such, a multipara, was referred to me as her two previous confinements had been followed by a most profuse haemorrhage after the third stage was complete. I made a point of personally attending her in the maternity ward. After the labour and the third stage, which were perfectly normal, she suddenly started to bleed profusely from the placental site, which was checked only by prolonged bimanual compression and the injection of pituitary extract.

---

* Contribution to a discussion in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

The explanation of such a case is extremely difficult, as the course of labour, and also the third stage, on each occasion appeared normal. This in my opinion would rule out disease and also deficient retraction. There was no suggestion of placenta praevia. I think it may be explained by an experience I had when curetting a patient who had been bleeding for many weeks following a miscarriage at the fourth month. The curetting was done with a sharp curette as there were no retained fragments. Following the curetting she bled so profusely and so persistently in spite of treatment that a vaginal hysterectomy was performed. Section of the uterus showed a large vessel the size of the normal uterine artery passing through the musculature to the placental site.

I suggest that some of those rare and unaccountable haemorrhages from an apparently normal and empty uterus may be due to the presence of some unusually large arterial trunks in close proximity to the placental site. Occasionally cases which have been treated for ante-partum haemorrhage of the accidental type have a serious post-partum haemorrhage. Fortunately, the more serious cases of this condition, especially where the bleeding is concealed, are operated on, and this enables the operator to estimate the extent of the damage to the musculature, and whether or not it is safe to conserve the uterus without risking a severe and fatal post-partum haemorrhage. Many of these cases, however, are dealt with by domestic measures and have a spontaneous delivery or one aided by forceps, and there is no way of assessing the condition of the uterus. In one such case where there had been some concealed haemorrhage the third stage concluded with a most profuse and continuous haemorrhage. It was quite impossible to perform bimanual compression, as the empty uterus lay relaxed and flaccid in the abdomen and no mass of muscle substance could be squeezed. She died before a laparotomy could be performed. All cases of accidental haemorrhage, especially of the concealed type, should, if possible, be dealt with in a nursing home or hospital.

In cases of placenta praevia there is always the risk of a severe post-partum haemorrhage, but fortunately it is a rarity. I have met only one such case which failed to respond to any of the usual routine procedures, including bimanual compression. In this connexion it must be borne in mind that the rapid extraction of a breech baby in such a case may very readily cause a tear of the cervix and lower uterine segment and result in profound and even fatal haemorrhage.

Conclusion

As regards the problem of post-partum haemorrhage in general, with the exception of the rarer conditions, if the uterus is handled properly it will very rarely give rise to anxiety on account of bleeding, and with the rarest possible exceptions an empty uterus will not bleed except from a cervical laceration. I am against packing a uterus. The rule is to empty the uterus if the bleeding is to be stopped. The pathological uterus which is deficient in contractile and retractile power is less likely to respond if it is distended. I never repair cervical lacerations, and would perform bimanual compression followed by a hot douche in preference to packing if faced with serious bleeding from such a lesion. My experience of cases sent into hospital with the vagina reported to have been packed before admission would in itself make me opposed to advocating deeper tamponage.

I consider that many of the cases at present treated by blood transfusions would do equally well if they were given gum- or glucose-saline.

OPHTHALMIC INJURIES FROM MUSTARD GAS (D.E.S.)

BY

JOHN FOSTER, M.B., F.R.C.S.

Ophthalmic Surgeon to the General Infirmary at Leeds

Recent letters in the *Journal* are evidence of the interest taken in ophthalmic lesions due to mustard gas. I felt, in the circumstances, that certain information on this subject collected by me in the last few years might be acceptable to others. The table below is compiled mainly from figures in the *Medical History of the Great War*, already quoted in part by Sorsby. Thuillier (1939), while giving the total number of British mustard gas casualties as not fewer than 150,000, states that the total number of eye casualties is unknown. In the *Official History of the War: Medical Services* (1923), however, it is stated that "the great majority of D.E.S. casualties had eye burns." Yet out of this large number only ten had persistent impairment of vision after the war—this number rising from recurrent corneal trouble to thirty-four in 1937.

Reagent Mustard	Grading	%	Onset	Physical Signs	Symptoms	Treatment	Incapacity
Vapour <1/10,000,000	Mild	75	2–48 hrs.	Conjunctival congestion	Irritation and photophobia	2% $NaHCO_3$; paroleine; paper shade	1–4 weeks
Stronger vapour 1/20,000	Intermediate	15	2–48 hrs.	Ditto + chemosis	Ditto more severe	Ditto + 1% ung. atrop.	4–6 weeks
Concentrated vapour and liquid	Severe	10	May be almost immediate	Ditto + blistered lids and white band across cornea	Ditto	Ditto + treatment for infected ulcers and symblepharon	8–16 weeks

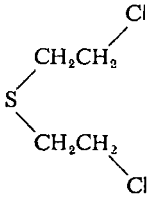
The burn is divided into three stages by Bonnefon (1939): the period of impregnation, the established burn, and the period of decrescence. It is the period of impregnation which is most interesting therapeutically, as once the burn is established there appear to be very few curative possibilities other than the treatment tabulated above. The difficulties in countering D.E.S. in the period of impregnation are as follows:

1. *Liposolubility.*—The gas is even more readily absorbed by the cornea than by the skin, and Sorsby (1939) has stated that if "drops" of liquid D.E.S. are placed experimentally on both corneae of a rabbit, and one eye is irrigated, the lesions are identical in both next day.

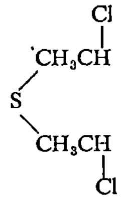
2. D.E.S. is relatively insoluble in water.

3. Except for its peculiar and specific intracellular reaction it is not an active substance chemically. Dichlormethyl sulphide and $\alpha\alpha$-dichlorethyl sulphide are equally liposoluble,

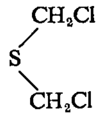
very similar in constitution, and just as easily broken up into hydrochloric acid under conditions resembling the intracellular, but are non-vesicant.



D.E.S.



αα-Dichlorethyl sulphide



Dichlormethyl sulphide

4. The eye will only tolerate in low concentrations reagents active enough to attack D.E.S.

As we may have an opportunity in the near future to try the effect of different remedies on the human subject, for those who may become dissatisfied with the accepted treatment I have included in the second half of this paper some notes on the chemical possibilities.

For the Established Burn

I find that Hederer and Istin (1935) have suggested the following applications, which I have not seen quoted elsewhere. These may be helpful in unsatisfactory cases which have not responded to the regular treatment. I have no other evidence as to their efficacy, however, than their quotation in the volume mentioned, and their recommendation by René Onfray in a personal communication in 1936. (1) For photophobia: 2 per cent. pilocarpine drops. (2) For pain and chemosis, ophthalmic ointment Z-1:

	Grammes
Orthoforme (benzocain)	5
Ichthosulphol	2
Sodium ichthosulphol	1
Thigenol	1
Sodium bicarbonate	1.5
Borax	1
Sodium sulphate	0.25
Magnesium sulphate	0.25
Excipient	ad 100

The benzocain does not produce corneal desquamation.

For the period of decrescence after the main infection has subsided they have suggested the use of ophthalmic ointment Z-2:

	Grammes	
Medicinal scarlet red, insoluble	2	
Methylene-blue, purified	0.5	
Bismuth subgallate	1.5	
Liquid paraffin, neutral	20	q.s., ad 100 gm.
White vaselin, neutral	20	
Anhydrous lanolin	60	

Period of Impregnation: Antidotes

MECHANICAL REMOVAL

Oil, grease, and soapy solutions which remove the liquid from the skin have been shown to reduce the effects up to ten minutes after exposure, while, again, oily substances on the skin have a definite temporary prophylactic effect, clearly demonstrated experimentally (Sollman, 1919). I know of no experiments in which oily substances are used as a prophylactic in the eyes, and the skin experiments are not directly applicable, as the grease was removed after a time. The prophylactic effect may merely represent the partition coefficient of mustard gas between grease and human skin. While the vesicant effect of the tears in the earliest stages, custom, and the incidence of secondary infection suggest that ocular irrigation reduces the severity of the burn, the efficacy initially, owing to the rapidity of absorption of D.E.S., is open to doubt.

ADDITION COMPOUNDS OF D.E.S.

These are formed by *p*-toluene-sodium-sulphochloramide and toluene-sulphodichloramide (monochloramine-T and dichloramine-T). The end-product isolated by Mann and Pope (1922), ββ-dichlorodiethyl-sulphide-para-toluene-sulphonylimine, is in spite of its imposing name relatively inert. Dichloramine-T also breaks up lewisite into harmless oxidation products. Monochloramine-T has a solubility of 1 in 7 in water, and has been used as an antiseptic on mucous membranes in a 0.25 to 2 per cent. solution. It has also been employed as a 1.5 per cent. ointment and as a 1 in 500 aqueous solution for bi-daily irrigation in cases of trachoma.

Dichloramine-T.—A 0.5 per cent. solution in chlorcosane (chlorinated medicinal paraffin) has been used in trachoma. This solution is stable for three days only and should not be employed if there is a precipitate. Warthin *et al.* (1918) claim that it has a definite prophylactic and therapeutic effect on rabbits' eyes when exposed to D.E.S. and that its effect on human eyes burnt by D.E.S. is beneficial. I can, however, find very little information elsewhere about its use.

OXIDATION OF D.E.S.

Oxidation of D.E.S. produces the less irritant tetrachlorodiethyl sulphoxide and the non-irritant sulphone. The eye, however, will not tolerate concentrations of reagents which leave the skin unaffected. Among possible applications are:

(*a*) 1 in 10,000 potassium permanganate.

(*b*) Diluted eusol solution as used by St. Margaret's on cases of ophthalmia neonatorum, and which I have employed on hypopyon ulcers for some time: it is equivalent to a 1 in 10 strength ordinary eusol solution. The prescription of ophthalmic eusol (J. D. M. Cardell, personal communication, 1936) is as follows. Two ounces of boric crystals and 2 oz. of chlorinated lime are dissolved in half a gallon of water. The solution is allowed to stand for twenty-four hours. It is then filtered and diluted with an equal quantity of water. This is kept as a stock solution. For use in the eyes nine parts of water are added to one part of stock solution, a further filtration being sometimes necessary. Unfortunately, I found only recently, the composition of the final aqueous solution is: hypochlorous acid, 0.027 per cent.; calcium borate, 0.128 per cent.; calcium chloride, 0.017 per cent. Some might object to the application of a solution containing calcium to a lesion in which punctate keratitis develops and extends after the first ten minutes.

(*c*) *Milton.*—This is a proprietary preparation of sodium hypochlorite, 1.01 per cent.; sodium chloride, 16.8 per cent.; with traces of sodium sulphate, sodium chlorate, sodium carbonate, and calcium chloride. It also is open to the objection that it contains calcium. According to the directions supplied with the bottle ten drops are to be placed in half a glass of cold water, as stronger solutions irritate the eye. If an eight-ounce tumbler is assumed, then this is a dilution of 1 in 152.

The free chlorine available in the latter two solutions and in Daufresne's solution is: eusol, 0.4 per cent.; Milton, 0.47 per cent.; Daufresne's solution, 0.45 per cent. This would suggest that it would be possible to utilize a much stronger solution of Milton than advised on the bottle if one were anxious to introduce more free chlorine, and that Daufresne's solution (liq. sod. chlorinat. $\bar{c}$ sod. bicarb.) can be used in a slightly greater dilution than eusol, and with the advantage that it would be less likely to contain calcium. All these solutions contain hypochlorites and are unstable to a varying extent.

HYDROLYSIS OF D.E.S.

Although sodium bicarbonate solution was probably suggested originally as an eye-wash in the hope of producing hydrolysis, and irrigation by saturated boric acid followed by sodium bicarbonate ointment (Kinttof, 1939) is still the German first-aid treatment, it is doubtful if hydrolysis of mustard gas in the conjunctival sac plays much part in reducing the severity of the lesion, for the following reasons:

(*a*) At 10° C. mustard gas has a solubility of only 0.07 per cent. in water. At body temperature 25 per cent. of the mustard gas in such a solution is hydrolysed in three minutes, but this reaction is not accelerated by alkalis (Peters and Walker, 1923).

(*b*) The tears, except in the earliest stages of the burn, have no vesicant effect on the conjunctiva of rabbits (Warthin). (Bonnefon dissents from this, stating that tears are vesicant for two to five days.)

(*c*) If mustard gas is applied to skin covered by a paste of sodium bicarbonate and water the resultant burn is worse than if it is applied directly to the skin (Warthin).

Consideration of these facts suggests that if sodium bicarbonate solution has any effect on eye burns it is simply by virtue of the irrigant effect of the aqueous vehicle. Saturated boric acid acts in the same way, but has the disadvantage that it dissolves slowly and that solutions must be prepared in quantity in advance.

Hypertonic Withdrawal

Bonnefon has advocated the use of hypertonic solutions on the grounds that a freer flow of lymph is produced in the already oedematous conjunctiva, and that D.E.S. is withdrawn through the conjunctiva by the osmotic effect of the solution—as shown by the fact that the fluid in the eye-bath used for application becomes caustic after a few minutes. The solution suggested is 800 grammes of saturated sodium sulphate + 200 grammes of saturated sugar syrup. It is extremely difficult to accept this scientifically, as he quotes no statistics of clinical results and the scientific basis for his claims is incorrect. He states that a porcelain-like burn of the cornea occurs only in the horse and the rabbit because they have no lacrimal glands. This porcelain-like burn is recorded in the *Medical History of the Great War* in the 10 per cent. of severe cases in human beings, and the horse and the rabbit have lacrimal glands—the lacrimal bones are notched for the duct (E. A. Spaul, personal communication).

Bonnefon also suggests, earlier in his paper that the tears remain caustic for a few days in any case. A hypertonic solution in the ordinary way would withdraw water only through the living semi-permeable membrane. It is possible, therefore, that his hypertonic solutions merely act in the same way as sodium bicarbonate—that is, as a mechanical irrigant. Nevertheless as he makes strong claims for the clinical results it would be interesting to analyse the washings of eyes burnt by D.E.S.—one group being irrigated with sodium bicarbonate and the other treated by hypertonic solutions. This might give us a clue as to the relative value of the two methods, since it is doubtful if the mere production of further oedema will do very much good. The induction of conjunctival oedema is, I think, disappearing as a treatment from the armoury of most ophthalmic surgeons these days.

Summary

The tolerance of the eye to certain reagents capable of neutralizing mustard gas under various conditions is discussed.

Animal research on the following lines is suggested: (1) The effect of the application of the reagents discussed above to eyes exposed to low concentrations of mustard gas. (2) The comparison of the washings of such eyes of the first few days for total chlorides, after treatment by (*a*) alkaline lavage; (*b*) hypertonic solutions, as suggested by Bonnefon.

The results thus obtained might indicate further clinical trial of some of these reagents in the event of gas warfare.

I am obliged for information from Professors Spaul and Challenger of Leeds University and Mr. B. Wood, senior dispenser of the General Infirmary at Leeds.

A RAPID PRESUMPTIVE SEROLOGICAL TEST FOR WEIL'S DISEASE

BY

H. C. BROWN, C.I.E., M.B., D.T.M. & H.

(*From the Wellcome Bureau of Scientific Research, London*)

The macroscopic agglutination of bacterial suspensions in the presence of homologous sera on a slide, which is gently rocked to and fro about a longitudinal axis, has been known for more than thirty years as a rough-and-ready method for the determination of the nature of a bacterium. Garrow (1917) elaborated the procedure in the form of his clockwork agglutinometer. It is claimed that the readings are on the average within one dilution of that found by the full macroscopic method, but, as the Medical Research Council's Report No. 51 points out, this represents a possible 100 per cent. error, and concludes that the field of usefulness of this apparatus lies where rapid work is required under stress of circumstances. It is exactly under such stress that the test described below is intended for use.

In the first place brief reference must be made to the standard agglutination technique devised by Professor Schüffner. This consists in making varying dilutions of the patient's serum, to which are added equal volumes of a formolized suspension of leptospira: after incubation, droplets are examined microscopically by dark-field illumination with a 2/3-inch objective and a high eyepiece; no coverslip is used. I have personally for several years been in the habit of examining for agglutination after the mixture of leptospira and diluted serum has been allowed to interact overnight at room temperature; other observers incubate for varying periods at different temperatures.

From time to time a macroscopic technique has been advocated similar to that used when studying bacterial agglutination, the results being read either by the naked eye or with a hand lens. Pot (1936), in describing a macroscopic test for Weil's disease, advocated the use of an antigen grown in Korthof's medium and incubated at 52° C. for two hours, the results being read with a hand lens against a black background. In discussing this technique Brown and Broom (1939) gave it as their opinion that the test was not so sensitive as the microscopical test and that certain sera of low titres, such as those met with about the sixth day of the disease, might be overlooked when employing the macroscopic test. Brown and Broom also pointed out that human strains of *Leptospira icterohaemorrhagiae* isolated in England showed considerable differences in their agglutinability when using Schüffner's technique.

These observers also drew attention to the occasional occurrence of false positive reactions met with in the case of certain sera; these would cause difficulty in reading the macroscopic test. It is interesting to note that on the rare occasions upon which this false agglutination has been encountered a temporary false Wassermann reaction has also occurred. Even taking this and variations of agglutinability of different strains into account, the following rapid presumptive test would seem to be a useful diagnostic aid.

Technique of the Test

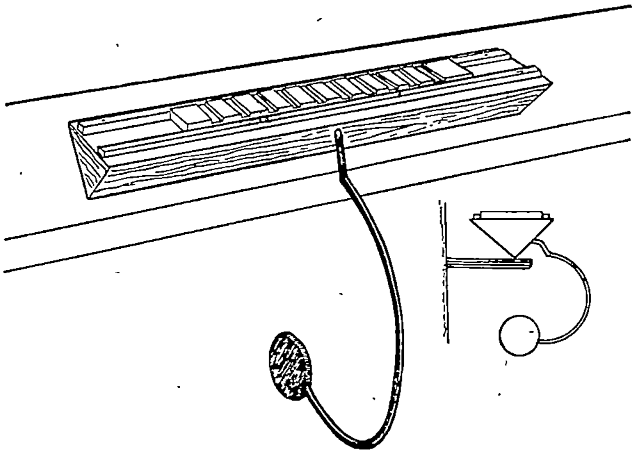
The test essentially consists in rocking to and fro on a slide for ten minutes small quantities of varying dilutions of the patient's serum in presence of a heavy suspension of *L. icterohaemorrhagiae*; this saline suspension is formolized to a concentration of 0.2 per cent. The preparation of a suitably concentrated antigen for this test is not a simple matter, as leptospira cannot be easily thrown down by means of a centrifuge from the fluid medium in which it is grown. Centrifuging a culture of leptospira in Fletcher's broth at 5,800 revolutions per minute for half an hour does not cause any obvious clearing of the supernatant fluid.

There are numerous references in the literature to spinning down leptospira from fluid media, but in my experience it is not a practical proposition unless some reagent is added which will facilitate the sedimentation of leptospira from the medium when it is centrifuged. This can conveniently be done by adding to the fluid medium saponin up to a total concentration of 1 in 1,000. The addition may be made after the culture has been formolized, which makes the procedure free from any risk of infection, although the strain, like the one employed, may have been subcultured at fortnightly intervals for five years and be no longer pathogenic.

Reference has already been made to the variation in agglutinability of various strains of leptospira which have been isolated from human cases during the last few years. Four human strains were compared as regards their agglutinability, both when put up in a water-bath for three hours at 56° C. and on the rocking slide. The same serum was used in each case. Both procedures gave exactly the same titres, but the titres varied according to the strain used. One strain was agglutinated up to 1 in 1,000, one only to 1 in 30, and the two other strains up to 1 in 100.

It is thus evident that the strain to be used as antigen in serological tests must be carefully chosen. The massed culture, about 500 c.cm., after the addition of formalin and saponin, is centrifuged at high speed and the deposit collected; this is suspended in saline until the opacity approximates that of a No. 1 Wellcome opacity tube used for the standardization of vaccines. The concentration required to get a suitable antigen from a well-grown culture for the rocking-slide method is approximately tenfold, so that 50 c.cm. of antigen can be obtained from half a litre of culture. This antigen is then centrifuged at approximately 3,000 revolutions per minute for ten minutes in order to get rid of any clumps of leptospira, and the supernatant fluid is bottled for future use.

The dilutions of the serum are made in the depressions of a painter's palette as in Schüffner's method. They are then mixed with an equal volume of antigen and placed on the slide shown in the diagram. This is made to rock for ten minutes, and the result is read by means of a hand lens against a dark background. Numerous sera have been tested by this method, and by the macroscopic method after incubation for three hours in a water-bath at 56° C. The results have been compared with those obtained with Schüffner's technique, incubation having taken place at room temperature for approximately eighteen hours.



Results

The results of the rocking-slide method and the macroscopic have been consistently identical, but in every instance Schüffner's technique has given a titre three times higher than that obtained by either of the other methods. In order to test the sensitivity of the rocking-slide method two rabbits were immunized with 2 c.cm. of a broth culture of leptospira administered intravenously. Four days later the sera of these animals were tested by all three methods. The macroscopic and rocking-slide gave a titre of 1 in 10, whereas Schüffner's method gave 1 in 30. On the seventh day the two former readings were 1 in 100 and Schüffner's method 1 in 300, and on the tenth day 1 in 1,000 and 1 in 3,000 respectively.

It is claimed that the rocking-slide method, given a suitable antigen, will produce a result within fifteen minutes of the receipt of the serum, and that it is reliable enough to justify the administration of curative serum.

I should like to thank my assistant, Mr. R. J. Reed, for his skill and care in maintaining the cultures of leptospira.

Histology of Mongolism.—Ten cases are described in which histological examination of the brain revealed widespread proliferation of the fibrous glia, which in several cases was not accompanied by corresponding changes in the myelin and in the cells. The pathogenesis of these changes is discussed, and it is suggested that the findings are not likely to represent the pathological substrate underlying mongolism. They do throw light, however, on the interpretation of certain previous findings.—Histological Changes in the Brain in Mongolism. A. Meyer and T. B. Jones.—*J. ment. Sci.*, March, 1939, **85**, 206.

EFFECT OF HEAT AND COLD ON HAEMORRHAGE

BY

S. BRANDON STOKER, F.R.C.S.Ed.

Assistant Honorary Surgeon, Dewsbury Infirmary

At the present time, when ambulance classes are being held all over the country, one feels that some notice ought to be taken of the effect of heat and cold on the control of haemorrhage. Although a surgeon or an obstetrician will try to control bleeding into a cavity by washing it out with a hot solution, it does not appear to be generally understood why this is done, and it is set out in the St. John Ambulance handbook that bleeding ought to be controlled by the application of cold.

By a series of experiments, performed as a preliminary to other work on blood-coagulation time, it was shown that heat shortened bleeding time but cold greatly prolonged it. It is known that the coagulation time of blood is affected by changes of temperature, but the duration of bleeding time appears to be altered more by the effect of temperature on the tissues than on the blood itself. In the two experiments illustrated below the first specimens of blood coagulated in approximately the same time whether the tissues were hot or cold. It is on the subsequent specimens, flowing through the same punctures, that the effect of temperature is seen.

In these experiments the blood was obtained through a small stab puncture above the terminal joint of a finger, a slight congestion being first produced. The rate at which the blood flowed could be controlled by altering this congestion. A bowl of water was used to warm or cool the hands, but the temperature of this was never excessive. The principle of the coagulometer used was that of Cannon and Mendenhall. Into a standard glass tube containing the blood a wire dips every half-minute until a clot forms. This limits the excursion of the wire. The instrument works automatically once the specimen is in position, and it allows the clotting time of ten specimens to be measured at the same period. When blood flows through a wound the subsequent specimens obtained have a gradually shortening clotting time. This shortening is considerable when the tissues are warm, but much less so when they are cold. It seems that a blood-coagulating substance is formed in increasing quantity by the tissues after a wound is made and that heat accelerates its production. If the rate of flow of a single blood specimen is increased less of the coagulant will be mixed with it, and we see that it has a longer clotting time than the specimens taken before and after it. A decrease in the rate of flow shortens the clotting time. It is to be noted that the rate of flow of first specimens taken from wounds does not affect the clotting time. Similarly, when tissues are cold and less of the coagulant is being formed, specimens are little affected by the rate of flow. The effect of heat and cold on bleeding time corresponds to that on clotting time. In the subjects used for these experiments the bleeding time was always greatly prolonged by the application of cold.

As bleeding is controlled by plugging the damaged vessels with blood clot, the aim of treatment ought to be directed to this end. Heat is obviously the means to attain this rather than cold, which merely narrows the vessels without accelerating the plugging process. It is noticed by many men, when it is pointed out to them, that they bleed from a shaving cut much longer on a cold winter day than on a warm summer day.

Experiment 52

HAND COLD No. of Blood Specimen (*a*)	Clotting Time in Minutes	HAND WARM No. of Blood Specimen (*a*)	Clotting Time in Minutes
1	9½	1	8½
2	7½	2	5
3	5	3	5
4	4	4	1
5	3½	No further flow.	
6	4		
7	4½		
8	—		
9	4½		
10	4		
11	3½		
Blood continued flowing.			

Experiment 69

HAND COLD No. of Blood Specimen (*a*)	Clotting Time in Minutes	HAND WARM No. of Blood Specimen (*a*)	Clotting Time in Minutes
1	7½	1	7½
2	6½	2	6½
3	8½	3	4½
4	7	4	2½ slow (*b*)
5	6½	5	4 quick (*b*)
6	7	6	3½ quick (*b*)
7	5½ quick (*b*)	No further flow.	
8	4½ quick (*b*)		
9	4½ slow (*b*)		
10	5½ quick (*b*)		
Blood continued to flow.			

Notes.—(*a*) Specimens were taken at 1-minute intervals and through the same puncture. (*b*) Denotes that the rate of flow was made quick or slow by altering the capillary congestion.

Summary

It is shown that heat accelerates the production of a blood-coagulating substance in damaged tissues and cold retards it.

It is suggested that heat and not cold ought to be used to control haemorrhage.

Clinical Memoranda

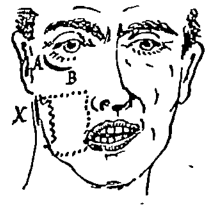
An Unusual Case of Facial Paralysis and a New Operation

Cases of facial paralysis due to various causes are fairly common, but such as I am about to describe I have never experienced before in civil or war practice. Before perusing the following description I would ask the reader to look into the nearest looking-glass, draw the right lower eyelid well down, push the tip of the nose over to the left, then screw up the facial muscles of the left side, and a very good idea of the case can be conceived. In May, 1939, the patient came into my hands, and the results obtained by my operation being considered satisfactory by all parties concerned I submit these brief notes.

Case.—A man aged 45 with right-sided facial paralysis; and the history was that forceps had been used at birth and in later life he had a motor accident. The lower right eyelid was everted, with epiphora and some discharge. The nose pointed to the left side, the right ala being collapsed. The mouth was drawn to the left side. When his face was not passive the patient grimaced hideously.

The Problem.—Obviously none of the classic operations such as nerve grafting or Gillies's temporal muscle transfer would be of any use even if the patient would have agreed to the time necessary for it. The everted lid and epiphora alone necessitated operative procedure. The nasal stenosis also caused distress; for the rest a cheery personality and congenial outdoor occupation led him to make light of his condition. After much thought I conceived the idea that if the facial tissues could be drawn across and firmly anchored the result should be satisfactory.

The Operation.—Excision two inches below pinna and behind angle of jaw; forceps entered at X and opened until the entire skin area represented by the dotted line on the diagrammatic sketch was separated from the tissues beneath, great care being taken not to injure any structures such as the duct. By keeping the finger within the buccal cavity Mr. Wilson safeguarded any penetration of the same. The whole skin tissues were then forcibly dragged over to X, a large semicircular portion of tissue was excised (see wavy line), and under considerable tension the parts were brought together at X and secured between two parallel knitting needles. The eyelid condition was much improved by a common plastic practice—incision at AB and stitching in the opposite direction. The patient can now breathe through his right nostril. A further considerable improvement is due to the fact that the right angle of the mouth is now normal at rest and in action, in contradistinction to the very ugly effect due to the fact that in the course of years the orbicular muscle had contracted so much that the angle had disappeared and the orifice resembled a pear with stalk pointing to the left.



In due course I hope to be able to present to the Library of the British Medical Association enlarged photographs of the patient before and after operation. I have to thank Mr. H. C. Wilson, F.R.C.S., for entrusting me with the case, and for his valuable assistance during the operation.

J. L. Aymard, M.R.C.S., L.R.C.P.,
Formerly Plastic Surgeon, Queen's Hospital for Facial Injuries, Sidcup, and the Cambridge Hospital, Aldershot.

Two Cases of Grease-gun Finger

These two cases, which have been termed "grease-gun finger," are the result of an unusual industrial accident. The condition has been described by Smith (1939). In a number of garages and omnibus depots a high-pressure grease gun is used which delivers through a very small nozzle grease at a pressure of between 200 and 1,000 lb. per square inch. The grease is ejected by the pressing of a trigger attached to the gun. The accident usually occurs when the garage hand is wiping the nozzle of the grease gun, which comes into contact with a finger, generally the index finger of the other hand. The grease is forced through the pulp on the palmar aspect of the finger into the digit, and in a moment balloons the whole of it out and fills the tissues.

Interesting features are that the accident is entirely painless; the patient notices that the finger has suddenly become three or four times its normal size, and that there is a small puncture wound where the grease has entered. The patient usually says that the finger has gone numb. On examination the digit is dead white in colour and considerably swollen, the swelling extending down to the junction with the palm of the hand. It resembles superficially a very bad whitlow, but is quite cool and quite painless, and the patient can move the finger freely. It is usually impossible to express any grease out of the puncture wound, for it has been spread uniformly and diffused over the whole of the subcutaneous and other tissues of the finger.

From this point the history is a very chronic one. There is no discharge; the finger is treated as potentially septic, and by the third or fourth day the skin on the palmar aspect of the distal part has become black and gangrenous, but there is still very little indication of inflammatory change. About the tenth or twelfth day signs of sepsis are usually apparent, and it becomes necessary to incise and remove gangrenous skin. The course of the disease is apyrexial from beginning to end. Extension beyond the finger does not appear to occur. Suppuration is local, usually with profuse granulation tissue, and ultimately there is a discharge of a flake of bone from the palmar aspect of the distal phalanx. The average duration of the condition from the time of the accident to the time of healing is six months. There is very little residual incapacity, and the patient retains free movements of the fingers.

Case I

A tecalemit operator aged 27 gave the history that on September 27, 1938, while working a high-pressure grease gun, he accidentally discharged the gun against the index finger of the left hand. He felt no pain, but noticed that the index finger became suddenly numb and swollen. He at once reported to the hospital, where all attempts to express any grease from the small puncture wound on the palmar aspect of the finger failed. He was put on expectant treatment, with rest, hot fomentations, and finally operative incision followed by baths. On February 20, 1939, a fair quantity of pus was discharging from the finger, and finally a small piece of sequestrum separated. On April 24 he was discharged as healed.

Case II

At 6 p.m. on May 5, 1939, a man aged 36, whilst operating a high-pressure grease gun, using yellow grease the consistency of petroleum jelly, accidentally pulled the trigger while the nozzle was against the first finger of the left hand. He said he did not realize anything had happened until the finger went numb, and he then saw it was dead white in colour, slightly swollen, and full of grease down to the middle joint. He came to hospital within half an hour of the accident. On examination the finger was slightly swollen and yellowish white in colour down to the proximal interphalangeal joint. A small puncture mark was visible on the palmar surface of the finger about a quarter of an inch from the distal end. There was no pain. An incision about half an inch long was made through the puncture mark. Very little grease appeared, even on firm pressure. A small strip of rubber glove was inserted as a drain and antiphlogistine applied. The antiphlogistine was repeated daily. There was a very slight discharge for twenty-four hours, then no more, as the grease seemed to have penetrated every tissue, rendering the finger avascular. After the fourth day the finger became indurated and black down to the terminal interphalangeal joint. About May 14 the finger suddenly doubled its size, the skin on the plantar and dorsal surface being separated from the underlying tissues by a watery fluid down to the mid-interphalangeal joint. On May 15 the raised skin was removed under nitrous oxide anaesthesia, and on the 16th radiant heat was given. Recovery occurred slowly.

Listeners on Christmas Eve will hear the first national wireless appeal on behalf of all voluntary hospitals throughout Great Britain and Northern Ireland. The B.B.C. has determined on this combined hospitals appeal in place of separate appeals on behalf of individual hospitals, and the detailed arrangements are being made by a special committee representing the British Hospitals Association and King Edward's Hospital Fund for London. Combined effort has already proved successful. In the past three years London hospitals have nearly doubled their street collections by doing away with the seventy-seven different flag days formerly held throughout the Metropolitan Police District which have been co-ordinated in one united effort.

Reviews

RECENT WORK IN BIOCHEMISTRY

Annual Review of Biochemistry. Vol. III. Editor, James Murray Luck; Associate Editor, James H. C. Smith. (Pp. 676; 1 figure. 27s. 6d., postage extra.) California: Stanford University; London: H. K. Lewis. 1939.

Once again the *Annual Review of Biochemistry* presents us with its comprehensive survey of the results of recent research in that science. The task of the editors tends to become no less formidable in that each year finds the prosecution of biochemical investigation continuing with ever-increasing vigour, but they and the reviewers, no matter what their difficulties, always manage to achieve their main objectives. In this eighth edition the quality of the work may be rightly gauged by reference to the names of some of the contributors—Linderström-Lang on proteolytic enzymes, Freudenberg on polysaccharides, Astbury on *x*-ray studies, Laqueur on hormones, Landsteiner on immunochemistry, to mention only a few. The literature under review, while it does not show that there have been many discoveries of a revolutionary nature, does clearly indicate marked and continuous progress. Much has been achieved in the way of extension and elaboration of highly important work, the basic features of which have already been fairly well established. Such is typically the case in the great strides made possible by the use of isotopes in labelling elements for metabolic studies. So wide has this application become that it enters into a number of different sections in this volume, but is most fully and interestingly presented in the chapter devoted to mineral metabolism. In particular, the fundamental principles governing the application of induced radio-active isotopes are here discussed, and followed up with an examination of the results so far achieved by this technique.

In the vitamin field, among the more important researches referred to are those concerned with the means of differentiating between vitamins A_1 and A_2, the further elucidation of the exact nature of the constituents of the B_2 complex, and the progressive steps culminating in the chemical synthesis of E. Certain clinical observations are included in the summary of the work on vitamin K, and afford ample evidence that there is distinctly more than mere academic interest in this anti-haemorrhagic factor. Due reference is also made to numerous chemical methods for the quantitative determination of vitamins, and their use in studies of human nutrition. The enormous volume of the current literature on the hormones presents unusual difficulty to those whose task it is to survey it adequately within reasonable space limits. In this book Laqueur and his collaborators succeed in presenting the gist of no fewer than 540 publications, and that in a readable form which is in no sense a mere cataloguing of papers. The most widely studied are seen to be the various anterior-pituitary, the sex, and the adrenocortical hormones. Of the first group, the diabetogenic and glycotrophic factors have come specially into the foreground in recent times, while the work on the nature of the urinary steroids is shown to have significant bearing upon each of the other two groups.

The proteins as a class have been subjected to intensive investigations from widely different points of view. Their chemistry and metabolism are each afforded separate chapters, while the *x*-ray studies that are reported penetrate deeply into the problems of their fundamental structure. Applied to fibrous proteins these *x*-ray investigations indicate that they all fall into two main groups—the keratin-myosin group and the collagen group. Myosin, the chief muscle protein, shows a quite remarkable similarity to the labile or "supercontracting" form of hair protein. Original distinctions between fibrous and globular proteins have now almost disappeared; thus it is that, to quote the reviewer, "we arrive at a conception of unity, a unity amongst all proteins. They are difficult in details, but not in principles."

The biochemically minded will study this volume from cover to cover; others who do not wish to delve into the more abstruse subject-matter, but merely desire to see where the science is making its most direct impress upon clinical medicine, will find it scarcely less valuable.

VARICOSE VEINS OF THE LOWER LIMB

Varicose Veins. By Alton Ochsner, B.A., M.D., D.Sc., F.A.C.S., and Howard Mahorner, B.A., M.D., M.S., F.A.C.S. (Pp. 147; 50 figures; 2 coloured plates. 12s. 6d. net.) London: Henry Kimpton. 1939.

This monograph on varicosities of the veins of the lower limb is, with some additions, a reprint of a paper by the two authors which appeared in *Annals of Surgery* last year. Varicose veins elsewhere than in the lower limb are not dealt with, and some indication of this might perhaps have been given in the title, since seekers for information concerning varicocele, haemorrhoids, oesophageal varices, or those found elsewhere in the body will be disappointed if the general title leads to the expectation that references to these conditions will be found in the book. Dedicated to Rudolph Matas, this volume on the leg veins, however, is a worthy addition to the important contributions to vascular surgery which have already come from the New Orleans School headed by Professor Matas. The treatment of varicose veins in the legs has passed from an almost purely surgical phase through a period of enthusiastic injection treatment to the present stage, when it is generally realized that most cases are best treated by a combination of surgery and injection. The internal saphenous vein forms the longest subcutaneous venous system in the body, and most cases of varicose veins involve the vein itself or its tributaries. The authors draw attention to Sir Benjamin Brodie's description in 1846 of a test to show incompetency in the valves of the great saphenous vein, and it was not until forty-five years later, in 1891, that Trendelenburg described the same test which is now usually known after him. It is pleasing to notice this test described by Ochsner and Mahorner as the Brodie-Trendelenburg test, and Professor Matas in an introduction describes this as a legitimate though tardy bit of historical justice.

A historical introduction is followed by considerations of the pathology, physiology, aetiology, and clinical aspects, and leads on to a description of the examination of the patient and the methods of treatment of the various veins themselves and of varicose ulcers when present. Where the Brodie-Trendelenburg test is positive Trendelenburg's operation should be performed. The importance of high ligation and transection of the saphenous vein, and, should the superficial external pudic, external superficial femoral, and superficial circumflex iliac veins empty into the saphenous above the site of the ligation, ligation of these tributaries also, is stressed. After transection the distal part of the saphena magna is injected with sclerosing solution. This is a highly successful form of treatment if attention is paid to details; in the past many relapses have been due to failure to pay such attention.

This monograph is a really excellent account of varicose veins in the lower limb and may be profitably consulted by all who are called upon to treat sufferers from the condition.

THE CRIMINAL AND HIS SETTING

The Criminal in Society. A Review of the Fundamentals of Criminology. By Henry T. F. Rhodes. (Pp. 280; illustrated. 7s. 6d. net.) London: Lindsay Drummond. 1939.

The contribution which Mr. Henry Rhodes has here made to the popular understanding of crime is to give a clear and condensed summary of the attitudes towards crime and the theories of its nature which have been held through the ages and more particularly in recent times. Until quite recently, as the notorious Calas case showed, the person accused of crime was accorded no rights at all, and even now men cling tenaciously to the idea that crime is a theological vice. Mr. Rhodes traces the advance to the psychological view of crime, which he regards as the most immediately important. He recognizes, however, that while we cannot escape from the study of the psychological situation which finally determines the criminal act, we cannot neglect the contributory factors of environment and social order. Society must take part of the responsibility for the crime; deficiencies are to be found in both the contributing factors. He therefore surveys the social background at various times, dealing with society itself as a problem, and gives particular attention to the economic factor, the neglect of which has been responsible for many fantastic opinions. He deals with criminal sociology, criminal responsibility, and the origin and significance of punishment, inferring that mere reform of penal methods can never be the final end of penology, which is deprived of all meaning and utility if no account is taken of the environmental factors. He closes the book with an acute analysis of crime in the authoritarian States, the democratic countries, and the socialist system of Soviet Russia, giving some account of the extraordinary progress reported to have been made in the U.S.S.R. by the application of constructive methods of reform. A student who requires a sound introduction to criminology could do no better than read this book, with its wealth of citation and reference and its moderate expression of opinion.

OCULAR APHASIA

Ocular Dominance in Relation to Developmental Aphasia. By M. Macmeeken, M.A., B.Ed. With appendix by Robert Sampson, F.R.C.S.Ed. (Pp. 60; 12 figures and 8 tables. 2s. net.) London: University of London Press, Ltd. 1939.

A quite remarkable piece of work has been done by Mr. M. Macmeeken, under the auspices of the Ross Foundation, for the study of prevention of blindness in Edinburgh. Children are brought to eye specialists in the hope that some defect of vision might be discovered that would account for the child's inability, total or partial, to learn to read. In some of these cases no such defect is found; the child is sent back to the difficulties of his educational outlook. There the matter is allowed to rest. Too often low mental capacity is adduced as the only alternative explanation, when in fact a high level of intelligence may be present. These cases, and others known as congenital word-blindness, were investigated by the Foundation.

In all 392 children were investigated—194 boys and 198 girls. They came from a good-class primary school of 900 pupils. The fathers were mostly engaged in industrial work. In examining the nature of the difficulties involved it was found that the recognized contributory causes to poor reading, such as absences from school, poor eyesight, and poor hearing, may and do produce bad reading capacity. But it was found that these were not sufficient to produce inability of such severe degree as to involve *disability*. The residual and serious disability is held to be due to aphasic characters. These children are "developmental aphasics" showing in varying degrees and as major aspects of the condition the two aphasic syndromes of word-recognition difficulty and the tendency to reverse letters or to distort letters or syllables within words. A significant relation was found between disability and left-eyedness as determined by sighting or directional tests of "eyedness." Every one of these "disability children" was found to be left-eyed.

This is a most interesting piece of research and well worthy of study. There is also an appendix giving the results of an investigation by Dr. Robert Sampson into the binocular vision of a series of children with reading disability.

A LITERARY TRIBUTE TO BART'S

Rose Window: A Tribute offered to St. Bartholomew's Hospital by Twenty-five Authors. With a foreword by the Lord Horder, G.C.V.O., M.D., F.R.C.P. (Pp. 386. 7s. 6d. net.) London and Toronto: William Heinemann. 1939.

St. Bartholomew's Hospital has good reason to be deeply grateful for a *Rose Window* constructed by twenty-five writers all of established position, who have been generous enough to give freely this work of theirs for its rebuilding fund. In this galaxy Marjorie Bowen paints a story of wistful charm in delicate colours, Ann Bridge draws a character study in forceful lines, J. B. Priestley tells us of some mad companions, G. B. Stern contributes a scene of skilful domestic diplomacy, while Noel Coward displays his contempt for theatreland, and Sir Hugh Walpole brings in a note of macabre horror according to his wont. In an age which produces more poets than real poetry Humbert Wolfe, Edmund Blunden, Walter de la Mare, Day Lewis, and others here prove that the authentic note has not faded into silence. Anna Zinkeisen has embellished the book with sprightly illustrations. With one exception every work is new and hitherto unpublished. The contributors have been so good as to make over all their royalties and in some cases the world copyright to the hospital—a gift obviously of great potential value. Clearly a most appropriate Christmas gift both for the recipient and for a famous hospital.

DIETARY STUDY OF AN AFRICAN TRIBE

Land, Labour and Diet in Northern Rhodesia: An Economic Study of the Bemba Tribe. By Audrey I. Richards, M.A., Ph.D. (Pp. 423; Illustrated. 30s. net.) London: Oxford University Press. 1939.

In former times any investigation into the diet of a primitive people would have been undertaken with a view to demonstrating how much better the feeding of savages in a state of nature was than that of a sophisticated European. To-day the study of the dietary of a primitive tribe or population has largely for its aim the practical improvement of that dietary in order to preserve the health and improve the nutrition of that people. Owing to the more intimate and ubiquitous contact of native tribes in Africa and elsewhere opportunities for inquiring into their habits of feeding and the production and quality of their food, as unaffected by such contact, are rapidly disappearing, and the importance of studying and recording facts in the field is now recognized by scientists and by Governments. Such a dietary study of the Bemba tribe has just been made by Dr. Audrey I. Richards, senior lecturer in social anthropology in the University of Witwatersrand, and published for the International Institute of African Languages and Cultures by the Oxford University Press. It is entitled *Land, Labour and Diet in Northern Rhodesia,* and it is an important book giving a careful and detailed account of the foodstuffs of the Bemba, the largest and most highly civilized tribe in Northern Rhodesia, the use the people put them to, their eating customs and prejudices, and their methods of growing, storing, and dividing food. It thus covers a wide field dealing not merely with dietary as such, but also with those economic, social, and magico-religious factors which arise in connexion with eating and drinking, and which, as the author remarks, "are social institutions in any country." The book is easy to read and is abundantly and appropriately illustrated. At the end are some useful maps and tables.

Notes on Books

Dr. F. M. B. Allen's useful *Handbook of Diseases of Infants and Children for Students and Practitioners* has been extensively revised for a second edition (London: Baillière, Tindall and Cox; 18s.). It is one of the best books of its size on paediatrics, essentially practical in outlook and clear in expression. The important advances of the last few years are faithfully incorporated, including the use of the sulphonamide compounds. Experience as physician in charge of infants at the Belfast Royal Maternity Hospital has enabled the author to revise the sections on the premature and newborn infant, which are now of great value.

In *Wild Foods of Britain* (A. and C. Black, 2s. 6d.) Mr. Jason Hill places the wild foods of this country into three categories: first there are a few delicacies which are well worth collecting however liberally stocked the garden and the larder may be; secondly, those which become worth special attention when supplies happen to be curtailed; thirdly there are many homely flavourings which have been unfairly ousted by the grocer's products. Here familiar names appear as unfamiliar foods—lady's smock for sandwiches, pig nuts such as Caliban dug with his finger-nails, sow thistle and shepherd's purse, tansy and sweet cicely, who in spite of her attractive name was the least appreciated by the Hill family. We are assured by the author that despite our mistrust there is only one lethal fungus in this country, appropriately named the death cap, which can always be recognized by its white gills. It is admitted that not many of the wild vegetable foods have a high nutritive value—if they had they would not be wild—but most are very rich in vitamins. Practically all the foods and recipes have been tried by the author and family, but it is regretfully stated that no method was discovered of making the fresh-water mussel edible; bargemen are reported to have eaten it, but their observations could not be recorded. Indeed, we gather that Milton was right, and that the services of a "neat-handed Phyllis" are essential to make a savoury dinner of these "herbs and other country messes"; otherwise L'Allegro's anticipations may be followed by sensations more appropriate to Il Penseroso.

In his work on *Medical Climatology* Dr. Clarence A. Mills, who is professor of experimental medicine in the University of Cincinnati, discusses, as the subtitle indicates, the effects of climatic and weather influences in health and disease. The subjects discussed include variations in fertility and sexual functions, world climates as they directly affect man, climate and disturbances of metabolism, infectious disease and body resistance, sclerosis and failure in the vascular system, mental function (suicide, homicide, mental instability and breakdown), dental caries, rheumatic fever and rheumatic heart disease, and tides in sickness and death rates. A bibliography of 119 references is appended. The work, which should form part of the library of every medical officer of health and epidemiologist, is published by Baillière, Tindall and Cox, price 25s.

Preparations and Appliances

CLOSED-CIRCUIT CO_2 ABSORPTION APPARATUS

Dr. H. Parry-Price, senior anaesthetist, Royal Berkshire Hospital, writes:

It seems that economy in gas and oxygen is going to be necessary during present hostilities. With this object in view I have devised a simple closed-circuit CO_2 absorption apparatus which will fit on to all machines such as McKesson, Boyle, and Walton.

As will be seen in the diagram, the gases pass through entrance A into a CO_2 filter. The basal oxygen supply comes in at inlet A at whatever pressure desired and from whatever gas-and-oxygen apparatus is being used. This entrance is guarded by a flap valve which prevents back-flow of gases during rebreathing. The collar A will jam on to the end of any apparatus—Boyle, McKesson, etc. The gases go out by pipe B, which has a McGill rebreathing bag on it, also a vinesthene drip-feed for deepening anaesthesia if required. They then pass by rubber tubing to the face-piece. At the face-piece there is an inlet guarded by a flap valve, C, and an exit guarded by flap valve D. There is an ordinary spring-guarded expiratory valve on top of the face-piece. Gases return along rubber tubing to the soda-lime tank and thus round the circuit again. The total cost of apparatus was just over £5. I have had it in use now for just over nine months with extraordinarily economical results.

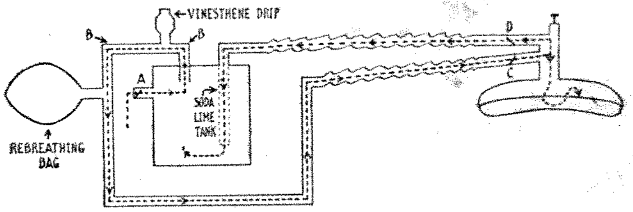

Fig. 1.—Diagrammatic drawing of closed-circuit CO_2 absorption apparatus.

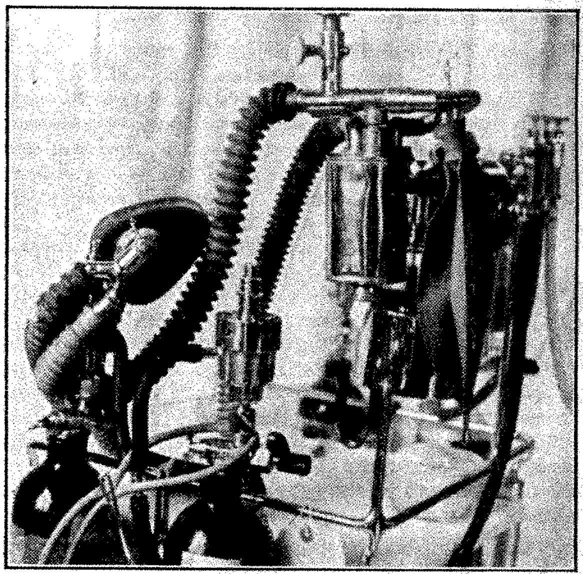

Fig. 2.—Apparatus attached to Boyle's machine, showing face-piece, inlet and outlet tubes, soda-lime tank, vinesthene drip-feed, and rebreathing bag.

CAPTAIN COOK, HYGIENIST

The Life and Achievements of Captain James Cook, R.N., F.R.S., Explorer, Navigator, Surveyor and Physician. By Surgeon Rear-Admiral John Reid Muir, M.B., F.R.C.S.Ed. (Pp. 310; illustrated. 10s. 6d. net.) London and Glasgow: Blackie and Son. 1939.

At first sight another life of the great circumnavigator James Cook may seem redundant. Ever since his tragic death at Hawaii in 1779 accounts have been published of his adventures and discoveries, as well as several lives of the explorer. Most of the last were written by distinguished sailors or naval historians. The volume before us is also written by a sailor, a distinguished naval surgeon, and herein lies the interest and value of his new book about James Cook.

None of the previous authors, whether sailor or landsman, failed to dwell upon the important and original measures which Cook took to preserve the health of his crews. Before his time it was the ordinary thing, in a long voyage of a year or more, for at least half, but usually more, of the ship's company to die before the completion of the voyage from disease, chiefly scurvy, but also from typhus and other fevers. Cook brought about a remarkable change for the better. It is true that a few earlier sea captains had interested themselves in this matter, particularly Admiral Sir John Hawkins, in the reign of Queen Elizabeth. But apart from the very few, no commander appears to have bothered himself over this vital problem, but to have looked upon the decimation of his crew as something unavoidable and all in the natural course of maritime events.

Surgeon Rear-Admiral Muir in his most readable biography has laid special stress on this side of Cook's genius, and for that reason, no doubt, refers in his subtitle to his hero as Physician, as well as Explorer, Navigator, and Surveyor. Although James Cook is, and will always be, remembered as one of our greatest English sailors, he is almost the only one who did not achieve his greatness by bloodshed. He was an Empire-builder who added colonies to the Empire by means of persuasion and not by force. He was essentially a humane man, both to those who served under him and to the natives of the various islands which he discovered. Cook began life with none of the advantages one associates with those who eventually become distinguished men of science. The son of a farm labourer, he became a shop assistant, and then signed on as a deck-hand on board a Newcastle coal vessel, a hard school in which, as the author remarks, "if the conditions of existence were severe the experience was essential in the work of transforming the grocer's assistant into the famous explorer."

No doubt the bad health of sailors was in part due to the low standard of efficiency among the members of the medical profession who were employed at sea. Even if they were not ignorant or lazy, their social status was so inferior that their opinions, even if sound, were little likely to carry any weight with their commanding officers. Overcrowding was always a fruitful cause of the spread of disease, coupled with the complete lack of separate accommodation for the sick, which meant that infections and contagious diseases were bound to spread with appalling rapidity; and it was not until the early years of the nineteenth century that the elementary precaution of isolating the sick was approved and the modern sick bay established. The only serious efforts made to deal with scurvy before Cook's time were those of Dr. James Lind, physician to the Haslar Hospital, 1758–94, who discovered lemon-juice to be a specific, although by a tragic misnomer it came to be called lime-juice, a far inferior anti-scorbutic, and it is lime-juice which is still issued instead of lemon-juice in the Royal Navy.

This interesting book is illustrated by seventeen plates and has a useful chart.

Philip Gosse.

JOHN HALL—SHAKESPEARE'S SON-IN-LAW

Many things, but not all, come to him who waits. For just over 300 years very little was known about John Hall, who married Susanna, the elder daughter of William Shakespeare, on June 5, 1607. It was known that she took after her father and that her husband was a skilful doctor who practised at Stratford-on-Avon and died there in 1635. He was well educated, had a sound knowledge of French, and was in some way connected with Acton, then a village six or seven miles from London. He was a Master of Arts of some university, and of his family nothing was known. The results of the search made by the Master of Jesus College, Cambridge—Mr. Arthur Gray—given in a little volume of twenty-two pages,[1] are most satisfactory and valuable. It now appears that he matriculated from Queens' College, Cambridge, in Michaelmas term, 1589, at the same time as his brother, Dive Hall, both being described as "of Bedfordshire." John Hall graduated B.A. in 1593–4, and took his M.A. in 1597. The father of the two sons was William Hall of Acton, Middlesex, gent., who made a will dated December 12, 1607. Mr. Gray gives a transcript of the will, which is a mine of information about the family. William Hall appears as a deeply religious Protestant with a rather disunited family. He seems to have practised medicine at Acton, perhaps as an extra-licentiate of the College of Physicians, and with such success that he had an assistant—called in the language of the day his servant. His leaning, therefore, was rather towards surgery, for a physician had no need for the services of an assistant. This assistant—Matthew Morris—may have been the Matthew Morris of Stratford-on-Avon who was a party to the transference of Shakespeare's house in Blackfriars to the use of Susanna Hall in 1618. The Hall family owned land near Harrold in Bedfordshire, so that Dive and John are properly described at their matriculation as of Bedfordshire, but their actual birthplace still remains to be discovered.

D'A. P.

AN OLD QUEBEC HOSPITAL

The issue of the *Revue des Deux Mondes* for August 1 contains an interesting account by Professor Emile Sergent of Paris of the Hôtel-Dieu de Québec, which recently celebrated the tercentenary of its foundation by the Duchess of Aiguillon, the niece of Cardinal Richelieu and patroness of Corneille. The noble lady arranged for the dispatch of some Ursuline Sisters from the Convent of St. Augustine in Dieppe to the recently founded French Colony of Quebec, where they succeeded in founding not only the Hôtel-Dieu but several other hospitals. At the present time the Hôtel-Dieu, which forms one of the principal centres for clinical instruction in Quebec, has more than seven thousand admissions a year, exclusive of the thousands of patients who throng its out-patient departments and dispensaries.

The "Penzance" medical manuscript, believed to be the oldest medical treatise written in England and ascribed to about A.D. 1250, which was described in the *British Medical Journal* of July 8 (p. 80), was sold by auction for £235, a distinctly moderate price in the circumstances. So far as is known it has not been acquired by any public institution or library. The two rare tracts, found together, described in the issue of July 29 (p. 242) were sold for £82.

A NATION IN GOOD HEALTH

Interesting and important as are the facts and figures presented in the Annual Report of the Chief Medical Officer of the Ministry of Health (reviewed in our last issue) its appearance makes us speculate rather on the story he will have to tell next year and the years after that. Will the downward tendency of the mortality and morbidity curves be reversed as a result of the war? Will the state of the public health reflect in increased sickness the state of the public mind, its anxieties and other emotional disturbances? Will it have to be recorded that the economy axe has fallen on this or that service, this or that control?

It is usual and understandable, but often fallacious, to go to the war of 1914–18 for parallels. If that can fairly be done in the field of public health the outlook is almost wholly encouraging. So far from public health having been retarded during the last war it took several leaps forward. The civilian death rate for the decade that included the war years was the lowest up to that time. Infant mortality fell markedly during the war—a rate of 108 per thousand births in 1913 had become 89 by 1919, and continued to decline, almost consistently year by year, to the present figure of 53. In 1917 the rate of maternal mortality was lower than it had been during the previous six years. Tuberculosis notably declined during the war. In 1913 the new cases of tuberculosis had numbered 117,000, but they never reached the six-figure level again, and in the first year after the war they were down to 77,000. Nor did the war interrupt the fall in incidence and lessening of virulence of various common infections. On the other side, the great influenza epidemic at the end of the war must be remembered. But on balance it would almost seem that a state of war—apart from its hideous toll of young male life—may have a hygienic value for a community. Or is it largely an illusion, and may the relatively low sickness level be explained by the fact that during war people do not so readily "give way" and in some respects live more hygienically?

On the other hand, the conditions of civil life were very different in the last war from what they are in the present. Twenty-five years ago war was not totalitarian. The possibility of occasional air raids on cities was a disagreeable anticipation (some people found it exhilarating) rather than a morbid obsession. Lights were dimmed, but there was no nightly "black-out" to endanger the traveller and lower the vitality of the whole community. Certain food shortages there were—people ate margarine instead of butter, saccharine instead of sugar, inferior bacon instead of butcher's meat—but these were not really felt until the war was more than half over. People as a whole were more busy, fewer had lost their jobs or failed to find others—and work which has to be done is a great prophylactic in times of public stress. Until the rise in prices, workers in civil life were for the most part better off than before; and income tax, slowly mounting from a small figure, never approached the catastrophic rate of 7s. 6d. in the £. There was no vast dislocation of hospital machinery and personnel with a partial paralysis of civilian medicine; and, above all, there was no large evacuation from cities. It is possible that organized civilian dispersal, which is only a precaution and not an act of war, may have effects more persistent for good or evil, or for both in different ways, than any direct action of the enemy, just as air raid precautions may number more casualties than air raids when damage to health and purse is reckoned in with damage to life and limb.

We must wait and see. For many of these effects we, or those who come after us, must wait for a very long time. It will be an interesting task for Sir Arthur MacNalty—we hope he will continue in office as long—to assess and chronicle the long-term reactions of a community like ours to a state of war. Meanwhile, the story he unfolds down to the very eve of war is so good that one feels anew the pity of it that the services should be interrupted or disorganized and that perhaps some territories where disease had been conquered should be retaken by that real enemy of mankind. Even the birth rate went up in 1938 to a figure which it had not reached for five years previously, and the death rate was lower than it had been for the last seven. The killing diseases mostly showed a lower incidence and a lower death rate. The one notable exception was cancer, which caused 1,665 deaths per million living in England and Wales. One interesting point is that while the crude rates imply that the mortality from cancer for each sex is increasing, the standardized rates—that is, with the differences solely due to the changed constitution of the population in regard to age and sex eliminated—show that the male death rate has steadily increased up to the present time, but the female rate since 1924 has been almost stationary with an irregular tendency to fall.

In his introduction to the report Sir Arthur MacNalty makes some philosophical reflections on progress. He points out that material progress, as exemplified by new inventions and economic prosperity, has always increased the difficulties of public health reform. To the superficial observer the industrial revolution of the early nineteenth century represented progress, with the

North of England studded with factories and national wealth increasing by leaps and bounds, but from the aspect of health it was not progress at all, and the clock of social welfare was put back. Progress is always two-edged. To-day the central nervous system is " dragged at the chariot wheels of modern progress." It is made to work, not necessarily more efficiently, but at a more rapid pace, and exposed to shocks and vicissitudes such as were never known in an earlier age. The penalty is nervous fatigue and breakdown. The mental health of the nation is of equal importance to its physical health. This Maginot Line is threatened, but we trust it will not be broken, by what is described as a " war of nerves." In any event it is reassuring to feel on the evidence of statistics, which here is indisputable, that this nation enters the war in much better health than it entered the last.

THE CONTROL OF PASTEURIZATION

The introduction by Kay and Graham in 1933 of the phosphatase test for controlling the efficiency of pasteurization constituted one of the most important steps of recent years towards the public health goal of providing the community with a safe milk supply. Already it has performed inestimable service, both in this country and on the other side of the Atlantic, where it has been adapted to the less stringent conditions of pasteurization in force in the United States and Canada. The original test has been modified considerably, and the effect of various factors on the result has been studied in some detail. The Imperial Bureau of Dairy Science, which was recently established at Shinfield, near Reading, could hardly, therefore, have chosen a better subject for its first technical communication[1] than the phosphatase test. The new monograph will be of particular value to chemists and technical workers who are called upon to use the test day by day. To the public health worker, however, it may prove a little disappointing by reason of its failure to answer one fundamental question—namely, What is the experimental error of the Kay-Graham test under practical conditions? Without this knowledge the exact interpretation of the result is impossible.

Milk is essentially a biological fluid, very complex in constitution, and never constant from one moment to the next. Every test, therefore, on milk is accompanied by an experimental error the magnitude of which varies greatly with the particular constituent under estimation. With regard to the phosphatase test, it is stated that the phosphatase activity of raw milk may vary considerably, depending to some extent on the stage of lactation, and that it is more closely associated with the fat than with the aqueous portion of the milk. It tends to be raised in milk coming from cows with mastitis. Experience has revealed the existence of differences in the buffer and in the Folin reagents used in different laboratories. The result of the test may be affected in addition by the use of carbolic soap on the hands or the glassware, by contamination of pipettes or of the milk with saliva, by the presence of tobacco smoke, by the use of bottle caps and stoppers containing phenolic resins or impurities, by the growth in the milk of phenol-producing bacteria or of bacteria capable of hydrolysing the substrate disodium phenyl phosphate, by the type of apparatus used for measuring the colour developed, and by sunlight on the bench. The test, moreover, requires great care in its performance and the possession of some technical skill. These are not objections to the test itself, which is undoubtedly an excellent one, but they must lead to the occurrence of an experimental error varying in size with different milks, different workers, and different laboratories. Until its range is known how is it possible to be certain that any colour exceeding 2.3 Lovibond units denotes imperfect pasteurization or contamination with raw milk?

There is a good deal of evidence already accumulated in the counties to suggest that many pasteurized milks are being unjustly condemned because a slightly greater depth of colour than the standard is obtained. When it is realized that the relation between the concentration of enzyme and of phenol liberated rises very steeply in the lower range of enzyme content, and that a difference of 0.5 Lovibond unit corresponds to a quite minute amount of residual phosphatase, it is surely important to know how often a difference of this degree can occur as the result of experimental error in titration. When it is further realized that the destruction of phosphatase in holder pasteurization occurs according to a monomolecular reaction, and that therefore the amount remaining after exposure to heat for a given time depends on the initial concentration present, there seems still further justification for wanting to know the nature of the frequency distribution of the results obtained under practical conditions. Would it not be possible to arrange for a comparative test to be carried out on an adequate number of milks between different workers (*a*) in the same laboratory and (*b*) in different laboratories? The recent international comparative trials of the Widal reaction brought to light surprising and unexpected differences between different laboratories in the accuracy of serum titration, and it seems not improbable that a similar trial, limited to this country alone, might well reveal more than minimal differences in the results of the phosphatase test. At any rate it is worth trying, and whatever the result the practical interpretation of the test will be placed on a much firmer footing.

---

A BACTERICIDAL BACTERIAL EXTRACT

When so many workers are preoccupied with the study of chemotherapy by means of sulphonamide compounds it is interesting to find that substances which will kill bacteria are also being looked for in quite another direction. An effort demanding exceptional patience and optimism which has nevertheless had astonishing success is described in a series of papers by R. J. Dubos.[1] He started with the assumption that bacteria may exist, which are capable of attacking Gram-positive cocci or some of their constituents, and employed in searching for them a method which has, in fact, already yielded micro-organisms capable of breaking down pneumococcal polysaccharide. A mixed sample of soil with certain mineral additions was maintained under suitable conditions of humidity and temperature until its decomposition was considered almost complete, and then fed for two years with suspensions of staphylococci, streptococci, and pneumococci. Since these bacteria furnished the only pabulum, only those soil organisms which could attack them would continue to proliferate, and presumably their capacity for doing so would be accentuated by adaptation during so long a period. At the end of it a sporing aerobic Gram-positive bacillus was isolated in culture from the soil which formed a substance capable of lysing staphylococci. This substance was liberated by the disintegration of the bacilli in ageing cultures, and could be obtained in a comparatively pure state by acidification, which precipitated it, and re-solution in a neutral medium. Although earlier preparations so obtained contained a protein, further purification yielded a highly active extract which was protein-free. The properties of this substance are quite unexampled. It attacks not only staphylococci but all Gram-positive cocci which have so far been tested; on the other hand, it is entirely without action on Gram-negative bacteria. Pneumococci, which are most susceptible to its action, are killed in a short period by a concentration of 0.002 mg. per c.cm., and their growth is inhibited by the presence of less than one-hundredth of this amount. The lysis which results from its action is regarded as secondary, death having been caused by an action the nature of which is uncertain, although there is evidence of interference with the dehydrogenase system of the bacterial cell. Not only is this bactericidal action exerted *in vitro*, but the substance protects mice against large multiples of a minimum lethal dose of pneumococcus culture, even when its administration is postponed for several hours after infection. This is, of course, a much more remarkable property than any *in vitro* action, and at once stultifies any comparison with the action of violet dyes, to which there is some resemblance in the fact that only Gram-positive bacteria are attacked. It is not too much to say that these observations open a new field in the study of bacterial metabolism. It has long been known that some bacteria form substances more or less antagonistic to the growth of others—pyocyanin is the most familiar and best authenticated example—but the vigour, scope, and specificity of the effect demonstrated by Dubos are something entirely new. It may well be that susceptibility to the products of other bacteria is confined to a few pathogenic species, fastidious in their growth requirements; on the other hand, who knows what further strange phenomena may be brought to light by patience and a few pots of soil?

CONSERVATIVE TREATMENT OF THE ENLARGED TONSIL

The indications for tonsillectomy are fewer now than when the doctrine of focal sepsis was more widely held, and recognition that the enlarged tonsil is not necessarily an infected one has also encouraged a more conservative attitude. There is still uncertainty, however, about the local measures to be adopted in conservative treatment, and reports on the value of x-ray therapy have been particularly conflicting. In a recent review of the literature[1] thirteen authors are cited who claim satisfactory results from x-ray treatment, among them Hickey, who claims to have sterilized 80 per cent. of diphtheria carriers by x rays. The conclusions of a further group of seven authors are entirely unfavourable. They find that the tonsillar infection is not influenced by x-ray treatment, and that cicatrization of the tonsil causes pus to become locked up in the crypts, while atrophy of the soft palate and lesions of the salivary, thyroid, and even the pituitary glands have apparently been observed as later sequels. Such lesions are, of course, the result of defective or too enthusiastic x-ray technique, but the objection that shrinkage of the tonsil does not often lead to resolution of the inflammation would be generally upheld. Opinion would thus favour the middle course of the eleven authors who restrict x-ray treatment to simple hypertrophy of the tonsils and uncomplicated tonsillitis. Stojakowski and Radzyminski consider that tonsillectomy is indicated when there is pus formation in the tonsil and when there are systemic effects such as arthritis, toxic myocarditis, etc., x-ray therapy being tried in such cases only if the general condition of the patient renders a surgical operation inadvisable. They are on more debatable ground when they state that a favourable result in these cases is due to the slight destructive effect of the rays producing an intense reaction in which the neutrophils, reticulo-endothelial phagocytes, and lymph-germ centres are all stimulated, so inciting the body to "autotherapy." The chief indication for x-ray therapy is undoubtedly the simple hypertrophy of Waldeyer's ring in young children, where the signs are those of mechanical obstruction in the nasopharynx. Destruction of lymphocytes and thrombosis of small blood vessels result in rapid and marked decrease in size of the tonsils and adenoids comparable to the effects of x rays on the thymic hypertrophy of infants. The authors do not discuss technique or dosage, although it is variations in these just as much as the wrong selection of cases which have resulted in so many contradictory reports on the value of x rays. A dose of 25 to 50 r at weekly intervals for four to six weeks should seldom be exceeded, and such a course may be repeated several times at six-monthly intervals with complete safety.

NOMENCLATURE OF SKIN DISEASE

The last International Congress of Dermatologists was held at Budapest in 1935 under the presidency of Professor Nekam, another is due at New York in 1940. Let us hope that the international storms with which we are now contending will clear away in time to permit it to assemble according to plan. As the principal object of the last congress Professor Nekam proposed a very definite task. It was nothing less than the standardization of the definitions and terminology employed by dermatologists all over the world. Although progress has been made in this direction by successive generations since Willan over a hundred years ago first put forward and defined the primary lesions of diseases of the skin, real uniformity is still unattained. Consequently with the help of no fewer than 568 collaborators of every nation and clime he has produced the *Corpus Iconum Morborum Cutaneorum* in three volumes[1] for the purpose of standardizing the nomenclature of dermatology. This work consists of three volumes, two of which consist of illustrations of all the manifestations of cutaneous disease known, while there is an initial introductory volume, the greater portion of which consists of descriptions of the plates; but there is also a most important section devoted to the terms employed and to classification. Professor Nekam postulates that all diseases should be defined in Latin in order to avoid ambiguity, and he provides translation of those Latin terms which, certainly not commonly used, may be employed in this work perhaps for the first time, into the four languages employed at international congresses —German, English, French, and Italian. The translation is undoubtedly necessary, for many of these words have been coined for this special purpose and will not be found in the Latin dictionary. It is possible to find fault with some of the English equivalents given. For example, the word "cladiosus" is translated as "branchy"; "branching" would certainly be better, and "short-stalky" might well be altered into "short-stalked." These mistakes are, however, unimportant. There is no doubt much to be said for the principle that the official nomenclature of all diseases should be in Latin terms and that all the Latin terms used should be listed and translated so that no ambiguity may be possible in their employment. Moreover, there is no department of medicine where it is so easy to get confusion as in dermatology, owing to the vast variety of conditions with which it deals. Professor Nekam has given to his specialty a most useful work of reference which, if properly used, will do much to avoid misunderstanding between dermatologists, especially among those who describe the rarer conditions. It will, however, do nothing to remove the popular reproach that dermatologists are inordinately fond of long names. Here is a good example: Histiocytoma xanthelasmaticum! The defence of course is that such names are really descriptive and, if trouble is taken to translate them, give a pretty clear idea of the nature of the disease or condition. On the other hand, if clarity be desirable, which it is, there is nothing to be said for the practice of calling a disease after the man (or woman) who first described it, even though the merit so acquired deserves to be remembered.

MUSCLE FLAPS IN VASCULAR SURGERY

Bleeding from a tumour bed in the brain or a wounded venous sinus may be arrested by applying a "postage stamp" consisting of a piece of muscle, usually part of the temporalis or one of the thigh muscles. It was Horsley[1] who in 1914 first drew attention to the rapid haemostatic effect of detached muscle fragments applied to cut surfaces, and he compared the thrombokinetic action of the muscle with an observation made by Wooldridge[2] in 1893 that the addition of tissue juices to blood accelerated its coagulation. T. de Martel of Paris in his neurosurgical work has employed pieces of pectoral muscle from recently killed pigeons in the belief that the muscle of birds is more effective than human muscle. A freely bleeding laceration in the liver has been effectively controlled by the insertion of a large piece of the rectus abdominis into its depths. Experimental work on pedicled muscle flaps wrapped around wounded arteries is reported by R. M. Isenberger and M. C. Carroll of Kansas City.[3] Incisions were made into either the femoral or carotid arteries of dogs, and it is stated that the procedure of using a still attached muscle flap is not difficult and results in immediate haemostasis, permanent healing, and the preservation of the normal patency of the vessel. Tissue juices exude from the raw muscle and within a few minutes precipitate fibrin along the plane of contact between the living muscle and the wall of the injured artery. Steady but gentle application by digital pressure is made between the freshly denuded muscle and the lacerated artery for from one to ten minutes, or the muscle flap is sutured in position around the artery, no sutures traversing the vessel itself. Subsequent examination of the wall of the vessel which remains patent shows that a layer of endothelial cells covers the muscle in relation to the rent in the artery. In any type of surgical repair of wounded blood vessels the most important consideration is perhaps the development of an occluding thrombosis, and Isenberger and Carroll's experiments suggest that thrombosis is more likely to follow the application of a detached than of a pedicled muscle flap which is still living. They conclude that living muscle tissue is well adapted mechanically as a plastic tampon for immediate haemostasis; thrombokinase is liberated from the raw muscle and sets in motion the train of clotting reactions by which fibrin is deposited on the opposing surfaces and so effectively seals them. They suggest that these pedicled muscle flaps may be employed apart from vascular surgery for the repair of a wounded common bile-duct or to reinforce a line of intestinal anastomosis. But these extensions of the work are of limited value in view of the fact that other and effective methods are available. In the field of vascular surgery, however, the pedicled muscle flap may have a future.

ENDOCRINOLOGY IN THE BEEHIVE

It is now known that the mammalian pituitary gland contains and secretes a principle which stimulates the sex glands to both increased growth and enhanced activity. Apart from this gonadotrophic principle of the pituitary gland itself, several other hormones having similar properties are now recognized and are finding a useful place in practical therapeutics. Of these, one is present in considerable amount in the serum of mares at one stage of pregnancy; another, with somewhat different properties, is abundant in the urine of pregnant women; and a third is found in the urine of women after the menopause. These gonadotrophic principles are mammalian in origin, and it is of interest, therefore, that evidence has recently been obtained of a gonadotrophic hormone from a different source—the bee. It is well known among bee-keepers that all new-born bee larvae receive during the first two or three days of life a special food known as royal jelly. But only those larvae which are destined to become queens continue to receive this food throughout the whole of their larval life. On this diet the larva grows rapidly to maturity, attaining twice the size of the adult worker bee but in a shorter time, and develops large ovaries and mature sex organs capable of laying eggs for several years. The worker bee, on the other hand, deprived of the continued benefit of royal jelly and fed on nectar and pollen, emerges from the larval stage with infantile sex organs incapable of function. That this development of a queen is solely due to a royal jelly diet and not to any constitutional cause would seem to be well established by an experiment, first recorded in 1791 and since abundantly confirmed, in which worker larvae substituted for the normal inhabitants of queen cells received the royal jelly intended for their predecessors and emerged as a result as full-size queen bees.[1] It was concluded by apiculturists that the jelly itself must contain some principle stimulating development of the sex organs. Definite evidence that this is so has recently been obtained by Heyl.[2] Samples of royal jelly were extracted by the same methods which are known to provide active extracts of mammalian pituitaries. The extracts were tested by the usual methods for detecting and measuring gonadotrophic activity, being injected into immature rats, in which they produced a definite increase in ovary weight of 60 per cent. over controls, the enlarged ovaries showing microscopical evidence of strong follicular stimulation. Thus an extract derived from a secretion of the bee was shown to have gonad-stimulating properties similar to those of mammalian hormones. The royal jelly is produced in a special gland in the head of the bee, the supramaxillary gland, which opens in the region of the mouth and yields the jelly as an external secretion. Heyl rightly calls attention to the similarity in position of this gland to the Rathke pouch from which the mammalian pituitary develops.

RESIDUAL INFECTIVITY OF THE PRIMARY COMPLEX OF TUBERCULOSIS

The persistence of living tubercle bacilli in the so-called healed primary tuberculous foci in the lung and hilar glands is of more than academic interest. Their presence is a constant menace to the body and may serve to explain the endogenous theory of the origin of pulmonary tuberculosis. In a review of the literature William H. Feldman and Archie H. Baggenstoss[1] conclude that there is no unanimity of opinion on the infectivity of chronic lesions of the primary complex of tuberculosis. They point out, however, that morphological evidence is not a trustworthy criterion unless the findings are supplemented by animal inoculation tests, and that even then there might be difficulty in correlating the pathological changes as viewed microscopically with the results of the virulence tests, since the same tissue cannot be used for both procedures. The authors' own investigation included examination of material from sixty-eight subjects, varying in age from 7 to 90 years (70 per cent. being in the fourth, fifth, and sixth decades of life), who had died from conditions other than tuberculosis. The tissues from the primary tuberculous lesions in these subjects were examined microscopically and, after emulsification, inoculated on to culture media and injected into guinea-pigs. In only one case were tubercle bacilli demonstrated by these methods, although microscopically the lesions (encapsulated and sclerotic, or caseous or caseo-calcareous) often showed evidence of activity. As the presence of silica in varying amounts was a fairly constant finding in the lesions, the authors suggest that in the absence of demonstrable viable tubercle bacilli in the lesions the histological signs of activity were possibly due to the silica. Their data suggest to them that in adults endogenous reinfection is unlikely to occur from lesions of the primary complex. It must be added here that such a conclusion, even if confirmed, does not invalidate the endogenous theory of pulmonary tuberculosis, as there is ample evidence that it often originates from the healed or latent pulmonary lesions developed during the stage of dissemination following the primary infection.

THE MEDICAL DIRECTORY, 1940

Messrs. J. and A. Churchill Ltd. have produced the ninety-sixth edition of their *Medical Directory* at the usual date and in the workmanlike manner to which we have so long been accustomed. Indeed there are some typographical improvements—as in the bolder printing of the names of streets in the Local List for London. There has been a net increase of 1,738 entries, but the number of pages of text has only increased by twelve. The numerical summary of the medical profession shows that there are now 62,847 names, compared with 61,109 for 1939. Increases will be found in all sections of the *Directory*: 636 under Provinces, 307 under Abroad, 245 under Scotland, 184 under London, 159 under Services, 152 under Ireland, and 55 under Wales. The price of the 1940 edition is unchanged at 42s.

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation

INJURIES OF THE SEMILUNAR CARTILAGES—II

BY

A. G. TIMBRELL FISHER, M.C., F.R.C.S.

(*Concluded from p. 1151*)

Treatment of Recurrent Cases

Repair in cases of injury to the semilunar cartilages is very sluggish, and as blood vessels can only be traced in the region of the peripheral border it is probable that true repair is largely confined to minor peripheral fractures of the menisci. This is the probable explanation of the frequency with which the original injury is followed by recurrent symptoms. The latter are well known and need not be recapitulated in detail. At first the recurrent attacks are often associated with considerable reaction; but as a rule the attacks of locking, although possibly becoming more frequent, are associated with a diminishing degree of reaction and inconvenience. There is, however, a serious risk of the onset of arthritic changes, and the patient should always be warned of this danger.

Treatment of Recurrent Cases by Operation

Often operation is delayed for many years because of the slight inconvenience, and eventually the patient seeks advice owing to the fact that the recurrent attacks are associated with increased disability. The ideal time for operation has, needless to say, then passed, although such operation may be worth while. Early operation in recurrent cases should be strongly urged, and removal of the offending cartilage is the best insurance against the onset of arthritis. Provided arthritic changes have not supervened, the operation in skilled and experienced hands has become in modern times one of the most successful in the whole realm of surgery. Opinions differ as to how much of the damaged semilunar cartilage should be removed, and in any case this must depend upon the actual nature of the injury.* When there is any doubt, I believe that the wisest plan is to remove the whole cartilage by some such operation as my combined method (Figs. 5 and 6). This does not necessitate a large operative exposure, and permits actual inspection of the back part of the cartilage, instead of blind and unsurgical groping through an exposure anterior to the corresponding lateral ligament.

The anterior end of the semilunar cartilage is first exposed by means of a curved incision through skin and capsule anterior to the corresponding lateral ligament, and sometimes this exposure is sufficient. If exposure of the back part of the cartilage is considered necessary, all that is required is to prolong the anterior skin incision backwards and upwards, thus making a small flap with its convexity downwards. This flap is reflected upwards and the back part of the semilunar cartilage exposed by a second capsular incision posterior to the corresponding lateral ligament. It is sometimes argued that it is unnecessary to expose the back part of the cartilage because, if it is injured, it springs forward with traction upon the anterior portion of the semilunar and can be readily removed through the anterior incision. It is certainly true that this sometimes happens; but since adopting the above technique I have been impressed by the number of cases in which exposure of the posterior part of the semilunar cartilage has revealed a severe lesion which it has not been possible to remove through an antero-lateral incision.

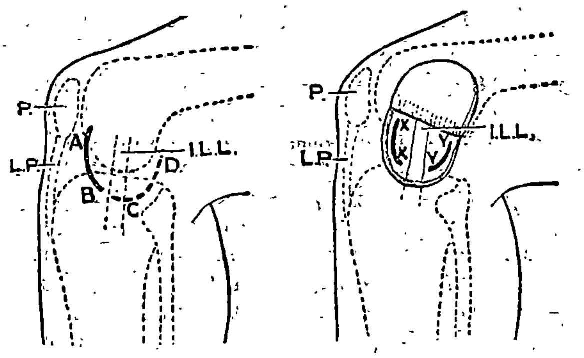

FIG. 5.—Diagram showing my method of exposure of the semilunar cartilage. P. = Patella. L.P. = Patellar ligament. I.L.L. = internal lateral ligament.

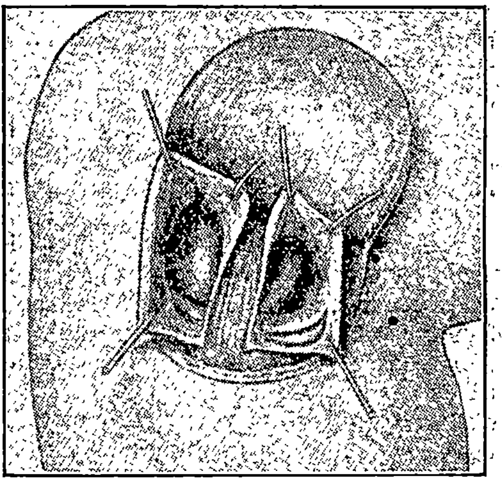

FIG. 6.—My method of exposure of the semilunar cartilage.

A word of caution is necessary against the practice of removing only the displaced handle of a bucket-handle lesion of the cartilage. In discussing the aetiology of this lesion it has been pointed out that the whole cartilage is detached, ground between the femoral and tibial condyles, and longitudinally split. The attachments of the peripheral portion must therefore have been severely damaged, and in my experience it frequently gives rise to subsequent trouble. There is no evidence that removal of the peripheral part of the bucket-handle lesion has any effect upon the stability of the joint.

It may be argued that such highly technical operative points do not concern the general practitioner. This is, however, not the case, for some of the blame for an unsuccessful operation is apt to fall upon his devoted head, and any suggested operation should be fully and freely discussed between specialist and practitioner.

---

* This question is discussed in greater detail in my book *Internal Derangements of the Knee-joint.* 2nd edition. H. K. Lewis and Co., Ltd.

Operation in Complicated Cases

In some cases a lesion of a semilunar cartilage is associated with injury to the tibial spine, with the presence of one or more loose bodies, or with osteo-arthritic changes, and an extensive exposure of the whole of the anterior compartment of the knee-joint is desirable. In such cases my patella-displacing operation, in which the joint is opened by a long paramedian incision and the patella displaced towards the outer side of the joint, gives a complete exposure. I have never observed any interference with function that could be traced to this more extensive exposure.

Prognosis after Removal of Semilunar Cartilage

The prognosis, assuming a correct diagnosis and a satisfactory type of operation by an experienced surgeon, depends upon two principal factors: (*a*) the number and severity of the attacks; (*b*) the presence or absence of arthritic changes. With regard to the former, repeated attacks of locking or giving way of the joint followed by effusion lead in time to a certain amount of stretching of the joint ligaments and joint instability. In such cases operation may be of great benefit in curing the attacks of locking, but a certain amount of joint effusion after exercise, with a feeling of weakness and insecurity, may persist for awhile. This fact obviously constitutes an argument for early operation in recurrent cases. With respect to the second of these factors, although arthritis of the osteo-arthritic type is more apt to occur in neglected cases in middle life, it may occur in the knee-joint at a comparatively early age when operation is unduly delayed. In such, operation will probably cure the attacks of locking and may call a halt to the arthritic process, but it is obvious that it can have little effect upon the changes already present. This fact also shows the importance of early operation when recurrence of symptoms has become established.

If cases in which arthritis has supervened are excluded the results of operative removal in modern times by those with special experience are extremely satisfactory, and the progress that has taken place in recent years is shown by the following table:

	1911 Figures* per cent.	1932 Figures (my own), per cent.
No recurrence of attacks	82.02	100.00
Knee as good as the other	56.17	91.80
Movements perfect	86.51	98.36
No change in shape	76.40	83.60
Knee painless	48.31	81.96

* Power, D'Arcy (1911). *British Medical Journal*, **1**, 61.

My figures include a few cases in which both semilunar cartilages were removed from the affected knee; the results of such treatment are also good. One patient, a professional footballer, from whose left knee I removed the external semilunar cartilage in 1926 and the internal semilunar in 1927, is still playing a good game.

Treatment of Recurrent Cases by Mechanical Methods

It will probably be generally conceded that the various knee-trusses and other forms of apparatus sometimes worn in an attempt to prevent attacks of locking are, as a rule, inefficient and unreliable. The results of removal of the offending cartilage by operation in experienced hands are so satisfactory that the only conditions that justify the attempt to control recurrent attacks by apparatus are those cases in which operation is contraindicated on account of age or illness.

Manipulation in Recurrent Semilunar Cartilage Lesions

A well-known bone-setter used to claim that he could bring about "the radical cure of derangements of knee cartilages without operation." What is the truth about this matter concerning which controversy has raged for so many years? It is probable that many of these "cures" were of minor injuries of the menisci which had become tethered by adhesions, and manipulation in such cases is now known to be of proved value. It is clear from physiological reasons that actual cure by repair of the torn fragments in recurrent cases is probably impossible. The fractured surfaces become covered with smooth fibrous tissue, and even if apposition between the fragments could be obtained by manipulation it would be difficult to imagine conditions less favourable to repair. It must be conceded that in some recurrent cases associated with definite locking a temporary relief from symptoms has been obtained by manipulation. In my opinion such relief is due to the fact that either the fractured portion has been freed from adhesions tethering it in some abnormal situation, or the handle of a bucket-handle lesion has been firmly forced into the centre of the joint, where it has been temporarily out of harm's way and has become fixed by adhesions. Experience teaches, however, that the "cure" is rarely lasting, and when strenuous conditions must be faced such treatment by manipulation is usually a poor substitute for operative removal. It may be tried, however, when operation is refused or is inadvisable, and when there is no likelihood of subsequent strenuous use of the limb.

MINOR INJURIES IN CIVIL BOMBARDMENT

DR. TRUETA'S ADDRESS

The City Division of the British Medical Association called a meeting on December 5, which was open to all practitioners, to hear an address by Dr. J. Trueta of Barcelona on "Medical and Surgical Assistance of Minor Injuries in Bombarded Towns." The Great Hall of the Association House was entirely filled. The chairman, Dr. C. O. S. Brooke, said that in previous discourses before the Royal Society of Medicine, notably the one published in the *British Medical Journal* of December 2 (p. 1073), Dr. Trueta had dealt with the more serious injuries. His purpose on this occasion was to deal chiefly with minor injuries and their differentiation from the more serious.

Dr. Trueta began by pointing out one respect in which the treatment of casualties due to bombardment of towns had an advantage over the treatment of the injured in ordinary military operations. Surgeons could not operate in the front line of battle; casualties had to be evacuated to the rear, some of them perhaps a considerable distance behind the lines. In the case of bombarded towns, however, the injured could be treated on the same principles as those hurt in road accidents—that is to say, any operative procedure could be undertaken almost at once on removal to the nearest hospital.

Many injuries in every air raid were caused by small splinters from the explosion of light bombs. The distribution of such splinters was horizontal, so that a large number of wounds were received in the leg and lower abdomen. Often the deeper injury was far more extensive than the slight wound of the skin would lead one to suppose, and this was apt to mislead the surgeon.

After his own tragic experience in Barcelona, where he went through more than 340 bombardments, he was strongly of opinion that in all seriously wounded cases the immediate intervention of the surgeon was the only form of first aid desirable other than the possible application of a tourniquet to a limb which bled excessively. The application of splints or bandages or other forms of first aid had been shown to be generally not only useless but harmful in that it delayed surgical treatment.

First Aid for Casualties

Treatment could be administered in three places—in the ambulance, at the first-aid post, and in hospital. The only cases which needed immediate first-aid treatment as a result of aerial bombardment were wounds of the limbs with severe haemorrhage and fracture cases. All other casualties should be sent to the hospital direct without any first-aid treatment. With regard to wounds of limbs with severe haemorrhage, in every ambulance the attendant or nurse should be able to recognize those cases which needed the immediate application of a tourniquet. Haemorrhage, venous or arterial, or both, occurred in all extensive wounds, but only in certain cases was a tourniquet necessary or desirable. If there was a continuous and abundant flow of bright red blood—usually though not always in spurts—and a rapid and feeble pulse the tourniquet should be applied immediately. If, on the other hand, the flow was not great or if the blood was dark in colour a tourniquet should not be applied; such a haemorrhage could be controlled by direct pressure. Venous haemorrhage was sometimes increased by the application of a tourniquet. The tourniquet, if used at all, should not be left in position for more than the shortest possible time, never exceeding one hour for the lower extremity.

Fractures

The majority of fracture cases did not require the application of splints for transport to hospital. Sufficient immobilization was secured by placing the patient in a good position on the stretcher and supporting the injured limb by sandbags. Where there was extensive damage to the soft tissues and severe shock, however, splints might be applied, preferably the Thomas splint.

No stretcher case should be admitted to the aid post but should go straight to hospital. Walking cases could be divided into those suffering from actual wounds but able to walk to the post, and those not actually wounded but suffering from shock. Wounded cases needed immediate and careful examination of the whole area involved. Patients wounded in the thorax and abdomen and those with penetrating wounds of the limbs must go immediately to the hospital, as must the majority of cases of lacerating wounds or severely contused tissues. Only superficial wounds should be treated at the first-aid post, where the wound should be washed thoroughly with soap and water, followed by the application of a dressing of sterile absorbent gauze. Anti-tetanic serum should be given to all wounded cases. Tetanus was a common infection, at all events in Spain, and he had seen cases of tetanus produced after superficial wounds caused by glass.

Many of the victims who had no actual wounds but were suffering from the effects of explosion could be reassured after examination and sent home. For other cases in which there was gross excitement morphine was the best sedative. An injection of lobeline should be given to patients suffering from respiratory distress after "blast." When despite all treatment there remained a feeble pulse and severe depression the case should be sent to hospital as there was a possibility of internal haemorrhage. The true service of the aid post was to help and reassure nervous people, people suffering from psychological shock, and people who had sustained falls without actual penetrating wounds. All other cases should be sent immediately to hospital.

All hospitals serving an area liable to bombardment should have two types of operating theatres—one for major operations under general anaesthesia, and the other for minor operations. Closed fractures were the only cases in which it was absolutely necessary to take an *x*-ray picture before reduction and treatment. With the pressure of cases after a bombardment *x*-ray examination of every case was impracticable.

The Service of the General Practitioner

The younger surgeons having been called up into the army, all the hard work of civil defence in Barcelona fell upon the older men. In Catalonia no men over 40 were mobilized, and thus all the surgeons of considerable experience were able to deal with air-raid casualties until the final stages of the war, when general mobilization was ordered. Even so, the number of available surgeons proved small in relation to the need brought about by frequent heavy bombardments, and general practitioners were included in the surgical units. Each unit in the hospitals of Catalonia was made up of eight medical men, including four surgeons, with some general practitioners as assistants when the number of available surgeons was not sufficient. There was also one ophthalmic specialist and one ear, nose, and throat specialist in each unit. General practitioners assisted with the *x*-ray work and blood transfusions. Physicians were in charge of the clinical work in the hospital wards, for on many days it was not possible for the surgeons to leave the operating theatres. Dr. Trueta gave some graphic details of what it was like to work under such conditions: the sense of insecurity after repeated bombardment, and the effect which the sight of severely wounded people, among whom might be discovered one's own friends and relatives, had upon those engaged in the work. Only a sense of unavoidable duty made it possible to carry on efficiently in circumstances of such depression.

For general practitioners the bombardment of great cities also brought another kind of task. As a consequence of the evacuation of the child population and its concentration in distant places, together with the unavoidable improvisation of living arrangements, every possible measure had to be taken for the prevention of epidemics. In this respect he desired to pay homage to the medical profession of Barcelona, for, despite the bad food conditions at the beginning of the war, only two epidemics occurred, one of diphtheria and the other of typhoid, the latter among soldiers in two centres at the front. Both epidemics were controlled, the diphtheria by inoculation of serum and the typhoid by improved sanitation, better feeding, isolation, and other preventive measures. The organization of preventive measures was hindered during the first six months by revolutionary disorder and was made harder by the increase of the population of Catalonia owing to the arrival of evacuated persons from other parts of Spain. When it was remembered that blockade prevented medical supplies from reaching the population it was certainly remarkable that Catalonia should have had relative immunity from the epidemics which had always accompanied war. The foresight of the medical profession prevented the death roll of revolution, war, and aerial bombardment being augmented by deaths due to infectious disease.

Dealing finally with the location of hospitals, Dr. Trueta said that in the innumerable bombardments which Barcelona suffered the five great hospitals, including his own general hospital with 3,000 beds, suffered no damage whatever, but in the little towns in the country hospitals were quite frequently destroyed, and in one such hospital eighty-three were killed and over one hundred wounded. The reason why the Barcelona hospitals were untouched was the better defence of the city, protected as it was by barrages, fighting planes, and anti-aircraft guns, which made it necessary for attacking planes to fly at great altitudes and at extreme speeds. For this reason he thought it better that civilian casualty hospitals should be organized in the large cities. Moreover, evacuation to the hospitals in the smaller towns and villages was often very difficult, with roads and bridges destroyed and possibly an inadequate ambulance service.

Discussion

Mr. W. McAdam Eccles asked what Dr. Trueta would consider to be the proper percentage of casualty beds for a given population. He hoped the term "*first*-aid post" would be dropped. There were first-aid parties who had to send certain cases to aid posts. It was extremely difficult for such parties to discriminate as to the type of case that should go to an aid post and not to a hospital. But aid posts could act as buffers. Might not such posts in a city like London be of great service, not merely to the people who were unwounded though frightened and perhaps bruised, but also for certain fracture cases? Should not aid posts be so equipped as to be able to send to hospital by ambulance or even by stretcher those cases which had been found to be of such a nature as to necessitate operation immediately somebody in authority said that the case should go? There might be some delay, but as against that there would be a certain relief of overcrowding in the casualty hospitals.

Dr. Waller asked whether it would not be better to take a case of multiple wounds straight to hospital instead of to the aid post. Dr. G. de Swiet asked what was the lecturer's experience of black-out conditions in Spain. He believed that in a black-out many lives would be lost, simply because surgeons could not get to the victims in the darkness. Dr. Camps said that it had been suggested that practitioners who were relatively unskilled should not do anything to the injured people, but stand by, leaving the injured limbs exposed during perhaps a four- or five-mile journey to hospital, the aid posts being of no service except for superficial wounds. He wondered what the ambulance service in Barcelona was like. His own experience after riding in ambulances which were converted lorries was that, although he was uninjured to start with, he felt very much injured by the time the journey ended! What was likely to be the conditions of a victim on a five-mile journey?

Dr. Trueta replied that the number of available beds in Barcelona, a town normally of one and a half million inhabitants but with a population very much increased under war conditions, was little more than 10,000. The beds were not nearly sufficient after a heavy bombardment; but it was possible to send many patients out of the town to country hospitals. His plan had been to conduct the operation in the town hospital as quickly as possible, employing the closed method with plaster-of-Paris, which enabled the patient to be moved within three or four days to a hospital perhaps a hundred miles distant, far outside the area of attacking planes. The Barcelona organization would be more applicable to towns like Manchester or Liverpool, for London needed its own special service. He thought that immobilization in a stretcher, if the ambulance man knew the simple principles of putting the wounded in good position with sandbags, was quite appropriate for a journey to hospital which occupied generally only ten or fifteen minutes. As for the black-out, the conditions were rather different in Barcelona. The warning was received ten or fifteen minutes before the actual bombardment, and central control at the electricity stations enabled the town to be plunged immediately into darkness, and the current was turned on again after the raiders had passed. In reply to a further question, he added that gas was not employed in any of the raids on Barcelona.

On the motion of Dr. James Fettes, seconded by Dr. Boyd, a hearty vote of thanks was accorded to Dr. Trueta.

Ovarian Activity and Psychological Processes.—This is an important paper correlating hormonal activity, studied by means of vaginal-smears and basal body temperatures, with independent psycho-analytic study of the emotional state. This is apparently the first satisfactory attempt to make use of accurate methods of this kind to study the hormonal background of human instinctual activity.—Correlations between Ovarian Activity and Psychodynamic Processes: I, Ovulative Phase. T. Benedek and B. B. Rubenstein.—*Psychosomatic Med.*, April, 1939, **1**, 245.

NEUROSES IN WAR TIME

MEMORANDUM FOR THE MEDICAL PROFESSION

A conference first convened by the Minister of Pensions in July, 1939, to advise the Government as to general principles for dealing with cases of nervous breakdown which may become manifest in war time has now reported to the Minister. The members of the conference were as follows:

Lord Horder (Chairman), Sir Hubert Bond, Sir Farquhar Buzzard, Dr. Bernard Hart, Dr. Gordon Holmes, Dr. J. H. MacDonald, Professor Mapother, Dr. Crichton-Miller, Dr. T. A. Ross, Sir James Purves-Stewart, Dr. Aldren Turner, together with the Directors-General of Medical Services of the Navy, Army, Air Force, and the Ministry of Pensions.

Besides making other recommendations, the conference has suggested that the following notes be circulated to all members of the medical profession.

During the last war the occurrence of large numbers of neuroses engendered by fear, shock, exhaustion, physical and mental strain, or lack of sleep, and the rapidly increasing incidence of these from 1916 onwards, caught both the Services and the medical profession unprepared with any organization by which to deal with them or with any agreed method of treatment applicable to them. The result was an accumulation of a very great number of this type of "casualty" and a consequent lowering of the general morale.

These neuroses were popularly called "shell shock," a term which came into use in 1914, when it was believed that the great bulk of nervous disorders noted in the field of war had their origin in the physical effects of concussion by high explosives or of poisoning by gases. At that time this theory was widely prevalent, and was even promulgated by neuropsychiatrists of experience. It soon became obvious that this view could not be justified, since precisely similar disabilities, and in the same proportions, occurred not only among men who had not been subjected to any such exceptional exposure but also among those who had not been over-seas. Moreover, the nervous disorders arising during the war differed in no material way from those well known in civil life. Again, many men who were blown up or buried to the same extent were able to return to duty without admission to hospital and without apparently suffering any durable effects.

However, the term "shell shock" soon became a catchword among the troops, and was welcomed by the man suffering from nervous symptoms, as he did not realize, or could not admit to himself or to others, that he might be suffering from the effects of fright or terror. The catchword appealed to the public imagination as an excellent term by which to explain a condition which could not easily be understood, and was too often adopted by the medical profession itself as a diagnosis for any functional nervous disorder appearing in soldiers during the war. Such was the appeal of the words "shell shock" that this class of case excited more general interest, attention, and sympathy than almost any other—so much so that it is feared that it became a most desirable complaint from which to suffer.

Most of these neuroses occurred either in the form of an anxiety state or as hysteria.

Anxiety States

Anxiety states reveal a common characteristic—the constant presence of fear or anxiety accompanied by vasomotor and visceral concomitants to a greater or less extent. Some are cases of mild type in which the anxiety is simply a prolongation and exaggeration of the natural anxiety experienced by everyone when exposed to war conditions. The feeling of fear is the normal reaction to threatened danger when the impulses activated by the instinct of self-preservation are aroused, but these impulses have to be kept under control if an exhibition of cowardice is to be avoided. The source of this anxiety is very commonly the fear of being found afraid and the fear that control of these natural impulses, which are regarded as shameful, will not be forthcoming when the occasion arises. In some instances natural anxiety is aroused by the fears connected with loss of business and other financial and domestic worries caused by the dislocating effects of war. In cases of more severe type the condition is induced by morbid anxiety in which there is no apparent logical connexion between war experiences and the symptoms of anxiety. In such cases the anxiety is out of all proportion to the apparent exciting cause or it may appear to have no obvious cause at all, though rationalization on the sufferer's part may seem to account for it. In most of such cases it is experienced as a diffuse state of emotional tension undirected to any specific object or situation and causes a state of fearful expectation, the patients being described as "anxious" and "apprehensive." In a few predisposed cases the anxiety reaction is characterized by the development of phobias, or the anxiety may be transferred from its original object to some other situation which appears to the patient to afford reasonable grounds for apprehension, or to preoccupations of a hypochondriacal type. It may be accompanied at the outset by some degree of depression, or depression may be a secondary development after the anxiety has been concentrated on the symptoms themselves and a vicious circle has been set up.

Hysteria

Hysteria, more than any other form of mental reaction, provides the clearest example of the onset of neurosis due to failure of adaptation as the result of conflict between individual needs and social requirements. Suggestion is the most important factor as a cause for the symptoms. Physical manifestations of severe emotional disturbance such as mutism and tremors, or the effects of a minor physical injury producing some temporary loss of power in the limbs, are readily perpetuated as hysterical symptoms by means of suggestion in men who have been subjected to physical or mental stress. Suggestions by medical officers or other attendants, in the course of examination and treatment, may have serious results and are often responsible for the onset of such symptoms.

Underlying the process of suggestion is a conflict between the instinct of self-preservation on the one hand and ideas of duty and self-respect on the other. The development of the symptom satisfies the patient's ethical requirements, provides an escape from duty on the ground of physical incapacity, and at the same time gives effect to his individual needs by removing him from an intolerable situation. In a sense hysteria is thus an unwitting purposive or defence reaction, the patient being unaware of any such motivation. This unconscious motive is a factor of the first importance because not only is it responsible for the onset of the neurosis but it helps to perpetuate it until such time as the conflict is solved by other means. It is aggravated by popular misconceptions as to the nature of the neurosis, by public opinion, by the sympathy of friends and acquaintances, and if it achieves its aim—namely, invaliding from the battlefield or the Service —the bad influence exercised is shown by an increase in the incidence of these neuroses. Further, if it should lead to any economic gain treatment is extremely difficult or often useless.

In 1920 the Army Council appointed a committee to collate the expert knowledge derived by the Service medical authorities and medical profession from the experience of the war with a view to recording for future use the ascertained facts as to the origin, nature, and remedial treatment of "shell shock." This committee issued a report in 1922 (Report of the War Office Committee of Inquiry into Shell Shock, H.M. Stationery Office, 1922). The committee reported:

> (1) The term "shell shock" has been a gross and costly misnomer, and the term should be eliminated from our nomenclature. It is a catchword which reacts unfavourably on the patients and on others.
>
> (2) The war produced no new nervous disorders, and those which occurred had previously been recognized in civil medical practice. The cases divided themselves into three main classes:
>
> (a) Genuine concussion without visible wound as a result of shell explosions; this formed a relatively small proportion—5 to 10 per cent. of all the cases of shell shock.
>
> (b) Emotional shock, either acute in men with a neuropathic predisposition or developing slowly as a result of prolonged strain and terrifying experience, the final breakdown being sometimes brought about by some relatively trivial cause; these formed 80 per cent. of all cases.
>
> (c) Nervous and mental exhaustion, the result of prolonged strain and hardship.
>
> (3) Authorities are agreed that in the great majority of (chronic) cases of war neuroses there already existed a congenital or acquired predisposition to excessive and therefore pathological reaction in the individual concerned, and that this constitutional factor was of vast importance. It appears equally certain that the neuroses of war may manifest themselves even in those of sound nervous constitution provided stress be sufficiently severe and/or prolonged.
>
> (4) No case of psychoneurosis or of mental breakdown, even when attributed to shell explosion or the effects thereof, should be classified as a battle casualty any more than sickness or disease is so recorded.
>
> (5) The following factors are generally regarded as tending to increase the incidence and severity of mental and nervous disorders in time of war:
>
> (a) All those factors by which a soldier, or even a potential soldier, is encouraged to believe that the weakening or loss of mental control provides an honourable avenue of escape from military service at whatever period of his service.
>
> (b) The ignorance of the general community, both civil and military, together with a lack of interest evinced by the medical profession before the war, regarding the origin, nature, and significance of mental, and especially emotional, disorders.
>
> (c) All those preventable conditions which undermine a man's mental and physical health and lower the power of resistance—for example, bad sanitation, bad accommodation, abuse of alcohol and drugs, venereal disease, etc. In promoting and maintaining morale, good food, good housing, recreational relaxation, and attention to the comfort and well-being of the soldier are of the greatest service.
>
> (d) The introduction and perpetuation of the term "shell shock."
>
> (e) The employment of such terms as "N.Y.D.N.," "D.A.H.," or other designation which may become catchwords and thereby lead to an increase in the number of cases.

Diagnosis of Concussion and Emotional Shock

It is important that cases of concussion should be differentiated from cases of acute emotional shock not only because inappropriate treatment of the latter in the early stages retards recovery but also because incapacity certificates for physical injuries under the Personal Injuries (Emergency Provisions) Act apply to cases of concussion. The diagnosis of concussion should be made only when the history or clinical symptoms leave no reasonable doubt that the patient has suffered physical injury by the direct explosion of a shell, by being knocked over by it or by being buried under debris of a building or shelter. The concussed patient becomes immediately unconscious or is at least severely dazed or stunned. This loss of consciousness may last for a few minutes to several days. When the immediate effect passes off there is complete amnesia for a period immediately before and after the injury. The patient is consequently unable to say what happened to him and it is not possible to restore his memory by any therapeutic measures. Patients suffering from emotional shock also frequently state that they became unconscious after the incident to which they attribute their symptoms, but by careful questioning it is usually found that they can recall eventually most of their experiences.

Evidence of Physical Injury

Evidences of direct physical injury are often associated with concussion, such as rupture of the tympanic membranes, epistaxis, contusions, and, more rarely, signs of organic injury of the nervous system. The symptoms vary with the severity of the condition and with the interval between the injury and the day on which the patient is examined. The early symptoms seen as the patient is regaining consciousness can rarely be mistaken, but those of later periods are often misinterpreted. These are neither invariable nor constant, but the most characteristic are headache, pain and stiffness of the neck, vertigo, mental and physical inertia with drowsiness and heavy sleep, which is rarely disturbed by dreams or nightmare. The pupils may be irregular and their reaction to light may be sluggish. In the early stages the tendon-jerks are usually depressed, but later generally become brisk or exaggerated. There may be fine tremors of the limbs, but the coarse tremulousness of the limbs and head which is so common in the neuroses does not develop in concussion. The headache of concussion is usually better in the morning and early part of the day and increases from fatigue as the day advances. As distinct from the neuroses there is an absence of emotional instability.

Emotional Shock

Acute emotional shock may develop independently of any close exposure to the place of explosion. The fact of being subjected to bombardment or air raid or seeing horrifying sights may suffice to precipitate it. An avalanche of emotion seems to overwhelm the patient's consciousness, releasing primitive reactions. The clinical picture in the more severe cases may be one of terror, stark panic, and confusion or one of physical and mental collapse. In the former type the tendency is to hyperactivity—aimless running, incoordination, incoherence, screaming, and disorientation. In the latter type the reverse condition of stupor of greater or less degree may occur. In this state it is difficult to gain the patient's attention and it may be impossible to elicit information. The patient may sit or lie about in an apathetic state and may be shaken with violent tremors. In such cases there may be a cataleptic state for a considerable time. In milder cases of this type stupor is less profound, and the patients may carry out simple actions, but in a slow and hesitating way. They present a dazed or confused appearance, are easily startled, and take little notice of what is going on around them. The stupor may last from a few hours to several days and then pass off suddenly or gradually.

Treatment

The immediate treatment of patients exhibiting nervous symptoms due to fear, anxiety, and other mental factors during and after air raids is extremely important, as if they are neglected the morale of the population suffers seriously. *Such terms as "shell shock," which may suggest that these nervous symptoms have a physical basis or are due directly to injury, must be rigidly avoided.* The following is an extract from the Emergency Medical Service Memorandum issued by the Ministry of Health dealing with the treatment of neuroses:

> "The first essential in the handling of these patients when they arrive at an aid post is to convince them that their symptoms indicate no serious injury and that they will soon disappear. This necessitates reassurance and the re-establishment of self-confidence combined with such methods as may lead to even temporary disappearance or abatement of the symptoms. This requires a firm and authoritative but sympathetic attitude on the part of the medical officers and their assistants. In patients who are simply frightened and in emotional cases reassurance combined with an appeal to personal and patriotic pride and a large dose of bromide will usually be sufficient. The patients should then be sent to their homes.
>
> "When confusion, excitement, loss of memory, and disorientation are the chief symptoms, rest, warmth, hot drinks with plenty of sugar or a dose of bromide (gr. 20–30) or phenobarbitone (gr. 1) will be necessary. When patients are restless or excited a hypodermic injection of morphine (gr. ¼) or preferably an intramuscular injection of sodium phenobarbitone (gr. 1½) combined with hyoscine hydrobromide (gr. 1/100) may be required. The latter is provided in tablets which are easily soluble.
>
> "It may not be possible to retain these patients for long in aid posts and smaller medical establishments, but every effort should be made to return them to their homes if they improve sufficiently to do so with safety.
>
> "When hysterical symptoms predominate an attempt should be made at once to influence or remove them by suggestion—for instance, by showing the patient that a powerless limb is not paralysed or anaesthetic, or by making a speechless patient phonate by coughing and then utter a single sound as 'Ah.' Hysterical tremor can be usually arrested by making the patient relax his muscles.
>
> "It is of fundamental importance for medical officers to understand that as the incidence of neurosis is determined by psychological factors, the severity and duration of the disorder and its extension to other individuals depend in many cases on the treatment which it receives at the onset. If patients in whom such a step is not absolutely necessary are transferred to hospital the conditions from which they are suffering may be accentuated or prolonged and the extent of neurotic disorder in the population may be greatly increased.
>
> "Every effort must therefore be made after the preliminary treatment, and whenever it is possible to do so, to send such patients back to their own homes, under escort if necessary. It will, however, be necessary in many cases to provide for sending these cases home, and consequently the question of transport and escorts will have to be considered by those responsible for organizing the aid posts. Such arrangements are not likely to be difficult where the patients reside in the area where the raid occurs, but in the case of patients occupied in the vicinity but living in the outer area some difficulty may be experienced, and therefore it is a contingency which should be borne in mind in advance. The services of some organization which is arranging to send other patients to their homes from hospital might be made available (see Emergency Medical Service Memorandum No. 2, paragraph 29).
>
> "As it will rarely, if ever, be possible for a specialist to visit an aid post it will be necessary for the medical officer to evacuate those whom it has not been found practicable to send home to a 'casualty' hospital.
>
> "Again, it cannot be hoped that there will even be a specialist on the staff of every casualty hospital, and therefore the medical officer of the aid post should ascertain which of the 'casualty' hospitals nearest to his aid post is so provided. This will avoid unnecessary delay in getting the needs of the case decided. The desirability cannot be over-stressed, however, that in circumstances that may be expected in a future state of emergency every patient suffering from a neurosis, unless the symptoms are so severe or prolonged as to make this course impossible, should be sent home. General practitioners should not send cases arising in their private work to first-aid posts but direct to the special clinics which will be set up in connexion with casualty and intermediate hospitals."

The Board of Education in a recent circular draws attention to the need for greater provision for the social and physical development of boys and girls between the ages of 14 and 20 who have ceased full-time attendance at school. This problem, the circular states, has long been neglected in this country, and in spite of the efforts of local authorities and voluntary organizations less than half of these boys and girls belong to any organization which can cater for their needs. Further, the conditions produced by war, the "black-out," and the strain and disorganization of family life constitute a serious menace to youth. The Board has accordingly undertaken a direct responsibility for youth welfare, and has appointed a National Youth Committee to advise it, while a special branch of the Board will deal with grants and other administrative duties. This National Youth Committee will have as its counterpart local committees, which in some cases will be subcommittees of the local authority and in others will represent all local interests. These committees will ascertain local needs, decide where help can best be given, and plan future development. It will not be their task directly to conduct youth activities, but to strengthen the hands of local authorities and voluntary organizations.

Correspondence

R.M.B.F. Christmas Gifts Fund

SIR,—I write on December 1 to acknowledge the sum of £278 13s. 6d. which has been received in donations towards our Christmas Gifts Fund. This will enable us to distribute gifts to our annuitants, but we also have 300 to 400 beneficiaries on our books who are in receipt of regular and annual grants. Their circumstances are similar to those of our annuitants, and in previous years they have also received the Christmas Gift. I should be very grateful if those of your readers who have not yet contributed would send a donation, however small, addressed to

Royal Medical Benevolent Fund,
Christmas Gift Account,
Wormingford, Essex.

At Christmas, 1938, we distributed £1,174, and I hope we may be able to do the same again this year, but time is short.—I am, etc.,

THOS. BARLOW,
President.

Active Service Medical Societies

SIR,—In times of stationary warfare, and particularly in the winter months, it becomes necessary to invent schemes for the counteraction of boredom and the maintenance of interest and efficiency. For the medical services there can be nothing better for this purpose than the medical society, with all its opportunities for exchange of "shop" and useful information, and with as regular and varied a programme as circumstances may permit. Medical meetings, whether under the auspices of a local society or not, played their part in the last war and are sure to be revived. Such societies may be small or large and based on an army or a corps, or have their centre at a base, or in hospitals and training areas at home. They can combine a social with scientific purpose, and their meetings should not become too formal. In the case of the Expeditionary Force they should be able to draw upon consultants or medical or surgical specialists attached to base hospitals and casualty clearing stations for papers on clinical topics. Talks among ambulance and regimental officers on aspects of their work can be equally valuable if less clinical. Pathologists and medical officers connected with sanitation and the many-sided problems of venereal disease should also have their contributions to make. Directors or assistant directors of medical services may be very profitably invited to give instruction and advice on administrative subjects and to recount experience of other campaigns to units mainly composed of civilian doctors.

The educational approach to the venereal disease problem—as opposed to the mere provision of preventive packets—and how it may best be organized for different types of unit and different ranks inevitably requires free discussion in our younger modern army. The practical and theoretical implications of the surgical methods advocated by Trueta; the known and possible contributions, and also the dangers, of sulphonamide treatment in sepsis, pneumonia, meningococcal meningitis, and gonorrhoea; the management of shock and chest wounds; the old P.U.O. problem—all these should provide food for discussion even before the advent of battle. Few problems call for more careful consideration than that of D.A.H. or soldier's heart. Many physicians, in retrospect, must feel convinced that there was a wholly unnecessary sick wastage from this cause in the last war and that physical and infective factors (as opposed to emotional factors) were far too extensively blamed; even by cardiologists of distinction who had not seen cases in their early stages and in their causal environment. A large proportion of all cases could have been reclaimed by simple psychotherapy and physiotherapy, without hospitalization or invaliding and with a great saving of expense to the country. The soldier is a simple and sensible fellow for the most part, but, like the civilian, he can either be made into an invalid by a wrong treatment or label or cured of many of his functional disorders by straightforward explanation and reassurance and short respites from bad conditions. Reminders of the advantage of re-educational camps, instead of hospitals, for all the minor neuroses (a late lesson of the last war) cannot be brought too soon to the notice of the whole medical service.

A lending library at the base and a system of circulation of important journals, manuals, and reprints should not be beyond the dreams and the scope of the best-organized army medical corps in the world. The keeping of medical notebooks and diaries should everywhere be encouraged.

Many of us look back upon our medical and surgical experience of the last war as one of the most vivid and instructive experiences of a lifetime. The good comradeship, the complete absence of the competitive evil, the living and working at close quarters of friendly teams, the direction of unanimous effort to the one object of doing the best possible both for the Service and for the individual sick or wounded soldier, sailor, or airman—all these provide an atmosphere which might with advantage, but does not yet, exist in our less united and less whole-hearted civilian organizations.

With the addition of research teams and base or army schools or instructional courses the welding and evolution of the military medical machine in time become complete and lend full support and inspiration to the common cause. The particular functions of the medical society are to bind and to leaven the official work, to facilitate exchange of views, and to maintain enthusiasm and the spirit of inquiry essential to all good medical service. We are all confronted with a new phase of postgraduate education, and Osler's happy reflections on "The Educational Value of the Medical Society" are as worthy of attention in war time as in times of peace.—I am, etc.,

Cambridge, Dec. 11. JOHN A. RYLE.

Evacuation of Small Children

SIR,—The evacuation of small children between the ages of 2 and 5 introduces major psychological problems. Schemes for evacuation are being thought out, and before they are completed we wish to draw attention to these problems.

There are dangers in the interference with the life of a toddler which have but little counterpart in the case of older children. Evacuation of older children has been sufficiently successful to show, if it were not known before, that many children over 5 can stand separation from home and even benefit from it. It does not follow from this that the evacuation of smaller children without their mothers can be equally successful or free from danger.

From among much research done on this subject a recent investigation carried out by one of us at the London Child Guidance Clinic may be quoted. It showed that one important external factor in the causation of persistent delinquency is a small child's prolonged separation from his mother. Over half of a statistically valid series of cases investigated had suffered periods of separation from their mothers and familiar environment lasting six months or more during their first five years of life. Study of individual case histories confirmed the statistical inference that the separation was the outstanding aetiological factor in these cases. Apart from such a gross abnormality as chronic delinquency, mild behaviour disorders, anxiety, and a tendency to vague physical illness can often be traced to such disturbances of the little child's environment, and most mothers of small children recognize this by being unwilling to leave their little children for more than very short periods.

It is quite possible for a child of any age to feel sad or upset at having to leave home, but the point that we wish to make is that such an experience in the case of a little child can mean far more than the actual experience of sadness. It can in fact amount to an emotional "black-out," and can easily lead to a severe disturbance of the development of the personality which may persist throughout life. (Orphans and children without homes start off as tragedies; and we are not dealing with the problems of their evacuation in this letter.)

These views are frequently questioned by workers in day nurseries and children's homes, who speak of the extraordinary way in which small children accustom themselves to a new person and appear quite happy, while those who are a little older often show signs of distress. This may be true, but in our opinion this happiness can easily be deceptive. In spite of it children often fail to recognize their mothers on returning home. When this happens it is found that radical harm has been done and the child's character seriously warped. The capacity to experience and express sadness marks a stage in the development of a child's personality and capacity for social relationships.

If these opinions are correct it follows that evacuation of small children without their mothers can lead to very serious and widespread psychological disorder. For instance, it can lead to a big increase in juvenile delinquency in the next decade.

A great deal more can be said about this problem on the basis of known facts. By this letter we only wish to draw the attention of those who are in authority to the existence of the problem.—We are, etc.,

JOHN BOWLBY.
EMANUEL MILLER.
D. W. WINNICOTT.

London, W.1, Dec. 6.

Psychological Casualties in War

SIR,—Dr. R. D. Gillespie's reply (*Journal,* December 2, p. 1110) to my letter (November 18, p. 1020) accuses me of polemics resembling Hitlerian propaganda. He makes use also of that least admirable of arguments, the sneer. I am in fact an admirer of the ingenuous Socratic method, and believe myself to be quite unskilled in the subtler technique of Goebbels. "The assertions made," Dr. Gillespie says, "are so roundly extravagant as to stupefy opposition." The heavy artillery of authority is brought to bear on me, although I introduced my main contentions with the words "I think" or "I believe." I think this is not the method of assertion.

Strangely enough, I appear to have a greater belief in the need for Dr. Gillespie's special line than he himself has. In the recent years of so-called peace the demand for psychological treatment has been such that some patients were promised treatment at one centre in the quite remote future. The period of waiting was two years or even longer. Here was an urgent problem which I, and at least some others, believed the war would make more urgent. The departments attached to general hospitals are valuable, and some patients prefer to attend these. I think, however, that Dr. Gillespie will find it difficult to convince general practitioners that they should not send their patients to "psychotherapeutic centres" which exist apart from general hospitals. In his letter in your issue of November 4 (p. 926) he says of such centres, "The divorce of psychotherapy from general medicine is apt to have as its consequence a divorce from sanity." We allow the aurists and oculists to have buildings of their own without protest. We even have a hospital for diseases of the rectum. Why deny the psychotherapists centres of their own? All specialists have to guard against a too narrow professional outlook, no matter what sort of building they attend.

Dr. Gillespie says, "No psychiatrist will agree that 'any of us is capable of being [*I wrote becoming*] psychotic.'" I had hoped that this idea was at least worth thinking about. It was in any case not asserted, but presented as a personal belief and a corollary to the hypothesis that in fortunate circumstances potential psychotics might fail to become actual. It is surely heroic to postulate for anyone an absolute immunity to psychosis. There is evidence in favour of my suggestion which goes some way towards proving it. Psychosis is sometimes cured. We might consider the cured psychotic as someone who has recovered from an illness that "the flesh is heir to." In the *Journal* not long ago you published an account of some cases of certified psychosis for whom it was claimed that dental treatment cured them. Various infections, toxaemias, and poisons have the effect of producing as a by-product symptoms of psychosis, and even clear-cut psychotic syndromes—for example, Korsakow's psychosis and G.P.I. A large book has been written by Dr. W. K. Anderson on malarial psychoses. Individual predisposition, rightly emphasized by Dr. Gillespie, may be a factor in all such cases, but how far is it a factor? Stress or trauma of some kind is, I believe, also a factor in every case of psychosis, and every human being has, I think, a threshold of vulnerability.—I am, etc.,

London, S.E.14, Dec. 3. ALLAN A. MACDOUGALL.

Treatment of War Fractures by the Closed Method

SIR,—Dr. Trueta's address on this subject, published in the *Journal* of December 2 (p. 1073), is one which every surgeon who may be called upon sooner or later to deal with wounds from war missiles should read with care. His conviction that to avoid true shock—that is, septic infection—operations for compound fractures must be performed within a time limit of two hours is one with which we shall all agree. If wholesale bombing of large cities should ever be indulged in this optimum time will, I am afraid, be very often exceeded.

The outstanding lesson of the last war as regards surgical treatment was that complete débridement of wounds was the first great essential, especially the complete exposure of the whole track of a wound and the ruthless cutting away of any dead or dying muscle. The rough-and-ready methods of deciding if muscle is in either of these conditions as evidenced by its appearance—pale pink instead of a deep red colour—and its failure to contract when nipped by dissecting forceps, are the only practical rules for the surgeon's guidance. When he has carried out these essential principles, and if the optimum time has elapsed, what guarantee has the surgeon that he has forestalled all risk of sepsis from *B. welchii* or streptococcus? The answer is, None.

If that is so there is one sentence in Dr. Trueta's address which is worthy of special notice: "When in spite of this excision there is still doubt about the vitality of the tissues that remain . . . it is essential to wait two or three days before putting on plaster." This is sound advice indeed, and it needs to be stressed; because the impression had got about that Dr. Trueta advocated the use of plaster-of-Paris in *all* cases. By covering up a doubtful wound in a plaster case the surgeon will thereby deprive himself of the use of two faculties which should warn him that all is not well with the wound. The information to be gained from the use of eyes and nose is too precious in doubtful cases to mask it under a covering of plaster.—I am, etc.,

York, Dec. 3. J. G. CRAIG.

Bipp

SIR,—In the *Journal* of December 9 (p. 1164) I see a letter with the heading "Bipp." The writer evidently does not know the true composition of it or its history, or of the fact that it was conceived by a very distinguished Newcastle surgeon, the late Professor Rutherford Morison, during the great war. After his discovery of this substance he was asked to go over to France to instruct the Army surgeons there how to use it, and he did. Whoever the individual was who gave the formula given in the letter was wrong. Undoubtedly Morison's "bipp" did revolutionize the treatment of war wounds. To put the matter beyond dispute I quote a passage from a letter sent by Professor Morison to one of his old house-surgeons, Professor Willan of Newcastle. On May 27, 1916, he writes:

> "You will be glad to hear I have accomplished the greatest thing for surgery in this war. I have discovered an antidote to true sepsis, and we are now about to leave dirty wounds undressed for a whole month. Think of what this means for compound fractures. Programme: open up and clean the wound; mop it out with spirit, then fill it with paste and cover with dressing. Paste: Iodoform two parts, bismuth subnitrate one part, paraffin q.s. to make a paste. Compound fractures have done with a dressing which has been left for two to four weeks, and several of them have united in less than six.
>
> "It took twenty-five years to make surgeons believe I could get large aseptic wounds to heal without drainage under a single dressing. I hope that the same time will not be taken in getting the same belief accepted for septic ones, but I fear it. There is

another thing I fear, and it is that we may discover drawbacks; I am honestly looking out for them, but so far without success."

The original "bipp" contains neither glucose nor balsam of Peru nor bismuth subgallate. I like to see honour given where it is due.—I am, etc.,

Newcastle-upon-Tyne, Dec. 10. Robt. A. Welsh.

Relapses after Sulphonamide Treatment of Gonorrhoea

Sir,—I have read with much interest in your issue of December 2 (p. 1080) the article by Mr. A. J. Cokkinis and Dr. G. L. M. McElligott on relapses after sulphonamide cure of gonorrhoea. I am afraid that some of us at the Whitechapel clinic were rather doubtful about the success of these "cures," and we have been justified subsequently by the number of relapses which have occurred, both early and late, during the period of observation. It was with this point in view that some considerable time ago the period of observation in females was extended from three to six months, and that also one set of tests at least was taken during the monthly menstrual period. This course seems now to be necessary.

There are three factors which lead me to expect a further increase in relapses, namely:

1. The marked increase in the defaulter rate since the institution of sulphonamide treatment: many cases disappear as soon as all symptoms have gone, before ever submitting to a proper test of cure or before the test of cure is completed.

2. The neglect of attention regarding the complement-fixation test. With this I know many people will disagree, as great variation occurs with regard to its interpretation. In my own experience I am convinced that a patient with a strongly positive (++) or a positive (+) reaction should be viewed with great suspicion when assessing a test of cure, while *one* single negative test should never be regarded as concrete evidence of cure.

3. The last factor is the failure to include in the tests of cure a culture, plate if possible, from the posterior vaginal fornix, where infection may be most persistent.

In conclusion, it would appear to me that since the advent of sulphonamide treatment there has been a marked increase in the so-called gonococcal carrier. I should be glad of the views of other readers on this point.—I am, etc.,

W. Neville Mascall,
Chief Assistant Medical Officer.

L.C.C. (Whitechapel) Clinic,
London, E.1, Dec. 5.

Sir,—We welcome the article of Mr. Cokkinis and Dr. McElligott in your issue of December 2 as emphasizing the importance of the recognition of late relapses in the sulphonamide treatment of gonorrhoea, and particularly of the necessity for cultural examination. This was evident to us some months ago, and as a consequence a circular letter was sent out in May of this year by Dr. Newsholme, medical officer of health for Birmingham, to the medical practitioners of the Birmingham area.

But with many points and conclusions in the paper we cannot agree. The authors state that their relapse rate on 1,055 cases works out at 12 per cent. They then proceed to say that more relapses *must* have occurred; we think that such an assumption is, to say the least, unproven. In Table I, by some mysterious process, they raise this relapse rate to 27 per cent. We cannot follow the mathematical conclusions of Table I; apparently they add up the percentages in the right-hand column. Now supposing they carry the time group a little further and, say, in over fifteen months one patient presents himself and is found to be a relapse. The item in the table will then read:

Time Group	Followed-up Cases	Late Relapse	Late Relapse Rate
Over 15 months..	.. 1	1	100 per cent.

They will then obtain a relapse rate of about 127 per cent.!

The Table III intended to be a comparison of three different preparations has many points which would not be good evidence. The number of cases taken for each group of drug differs very widely; the dosage, so far as we can gather, is entirely different. In many cases gonococci were not even present when the sulphonamide treatment began; surely "suspected gonococci" is insufficient evidence in an investigation of this kind. Such factors, in our view, would need a completely reconstructed table, if indeed one could make out a reliable comparison at all on the available information.

Later on in the article we read: "In most cases of proved female gonorrhoea gonococci are demonstrated only in the urethral discharge in spite of the fact that signs of cervicitis are usually present." Frankly, we fail to understand this statement; it is entirely new to us and, we feel sure, to many others. In our clinic we take as routine in all cases of suspected gonorrhoea in the female films and cultures from cervix, urethra, and rectum. In 100 consecutive cases, on the initial examination gonococci were found in both cervix and urethra 57 per cent., in urethra alone 9 per cent., in cervix alone 31 per cent., in rectum alone 3 per cent.

In conclusion, we wish to state that after giving trial to the three drugs sulphanilamide, sulphapyridine, and uleron, we have no doubt that the best of these is sulphapyridine (M & B 693). We have now used sulphapyridine as routine in well over 1,000 male and female cases, combined with vaccine treatment and, in females, local treatment. Our relapse rate works out at 13 per cent. approximately, and many of the cases have been under observation over a year. We admit the possibility or even the probability that such a percentage may have to be reconsidered as the period of observation becomes longer, but we hope not to the degree which has been suggested in the article under discussion.—We are, etc.,

E. W. Assinder,
G. H. Knight.

Venereal Diseases Department, General
Hospital, Birmingham, Dec. 6.

Sir,—In their highly interesting analytical paper on the above subject in the *Journal* of December 2 (p. 1080) Mr. A. J. Cokkinis and Dr. G. L. M. McElligott suggest that the longer treatment and more frequent need for multiple courses with sulphanilamide may account for the lower incidence of late relapses as compared with treatment by sulphapyridine (M & B 693). May I suggest another factor as likely to contribute to this difference in late relapse rates. The patient who under treatment with sulphapyridine has got over his early difficulties with little trouble and no relapses is more likely to report again for treatment in the case of a late relapse instead of becoming discouraged and defaulting as in the case of one who has had early relapses. This is true in spite of the fact that patients are more likely to report their condition if they relapse than if they remain well. On this hypothesis it is probable that the late relapse rate after treatment with sulphonamide compounds is higher than 20 per cent.

In regard to the question of delayed treatment it is not clear whether the figures analysed refer only to randomly selected cases in which the treatment was withheld until the second week or include those cases which did not report before that time. One might with reason regard patients who report in the first and second weeks respectively as belonging to different populations. It is probable that among those reporting in the first week there is a greater proportion of more acute cases, whereas in the second week one is likely to get a self-selected group in which the disease is held in check to some extent by natural resistance or in which the infection has been less severe. It does not follow that withholding treatment for a week from the former group would enable them to attain the same measure of immunity as this latter self-selected group. Again, among the more severe cases in this latter group there is likely to be a higher proportion of the haphazard type of patient who might fail to report late relapses. These considerations suggest that at least when the groups of first- and second-week cases are self-selected one might expect to get figures showing a lower incidence of early and late relapses in the second-week group.

May I conclude by expressing my appreciation of the value of the important paper on which I have based these comments.—I am, etc.,

Rochester, Dec. 2. A. Gardner, M.B., F.S.S.

Painless Injections of Sulphapyridine (M & B 693 Soluble)

SIR,—Post-operative pneumonia has for many years been the bugbear of surgeons. The blame has at times been cast upon the anaesthetists, but it has been found that this complication may follow spinal and even local anaesthetics. The introduction of sulphapyridine (M & B 693) has given us a valuable remedy in dealing with post-operative pneumonia, but there are certain difficulties in its use. Sulphapyridine taken by mouth is apt to cause nausea and sometimes vomiting. This may be a serious matter in the post-operative care of an abdominal operation, not only on account of the pain and discomfort of vomiting but also because it may cause confusion in diagnosis, it being difficult in some cases to be sure that the vomiting is due to the drug and not to some intra-abdominal complication. For these reasons the intramuscular route after abdominal operations is preferable, but the patients complain of intense pain when given the injection. This is probably due to the drug reaching the subcutaneous tissues either on the outside of the needle or during the insertion and withdrawal of the needle.

To overcome this difficulty I have introduced a two-syringe technique. (1) A 1 c.cm. Record syringe with a No. 2 serum needle is filled with 1 per cent. novocain, a weal is made intradermally, and the needle is driven through this, injecting a little novocain as it goes, until the needle is in the muscle, when 1/2 c.cm. of novocain is injected. The syringe is then detached from the needle, which is left in place. (2) A 5 c.cm. Record syringe with a large needle is used to draw up the sulphapyridine. The syringe is detached from the filling needle and attached to the needle in the patient, and the drug is injected. The empty 5 c.cm. syringe is detached from the needle and the former 1 c.cm. syringe, containing about 1/2 c.cm. of 1 per cent. novocain, is reattached. About 1/4 c.cm. of novocain is injected to clear the needle, which is then withdrawn while the rest of the novocain is injected into the track to prevent any of the sulphapyridine escaping up the track after the needle has been withdrawn. The site is massaged to move the skin on the deep tissues to close the track. If the order of events is followed as detailed above, while the ampoule of sulphapyridine is being opened and the syringe filled the novocain has time to act. The injections are painless when given this way. The patients say they are painless—and not only the nurses, who so frequently report that a patient is "quite comfortable" twenty-four hours after a laparotomy!—I am, etc.,

Hove, Sussex, Nov. 22. H. J. MCCURRICH.

Treatment of Varicose Ulcers

SIR,—It was with interest that I read Dr. J. R. A. Davies's letter (November 25) on the treatment of varicose ulcers by elastic adhesive occlusive dressings. As a dermatologist I have seen numerous cases in which this treatment has been used for this purpose, with the result that eczema, often of the eczema rubrum type, has developed on the leg treated and/or a generalized eczema has started. Years ago I came to the conclusion that if there is the slightest concurrent varicose eczema present, as is often the case, along with varicose ulceration, then the application of elastic, adhesive, and occlusive dressings is absolutely asking for trouble in the form of further skin disorder. After all, most varicose ulcers can be healed by rest or by the application of the old-fashioned Unna's zinc-gelatin supporting bandage. In my opinion the use of the zinc-gelatin bandage, when properly applied and renewed at correct intervals, is still one of the best methods of treating varicose ulcers and/or varicose eczema, although I have also found local applications of Grenz rays to be very useful in eczema rubrum of the legs.

It has been my routine practice for some years, when referring cases of varicose eczema and/or ulceration from the skin department to the varicose vein clinic at the Leicester Royal Infirmary, to send along a note asking them to use no elastic adhesive occlusive dressing. There may be three factors which can cause trouble in such treatment.

1. The locking up of the broken-down tissue products and the damming up of the excretions and secretions of the skin, with their resulting absorption into the system.

2. One of the substances used in the manufacture of these elastic adhesive occlusive bandages coming into prolonged contact with either unhealthy or normal skin, usually the former in these cases, may set up trouble. The composition of the sticky substance on these bandages is usually a mixture of rubber and an oleo-resin, either of which may give rise to trouble on some skins.

3. It is a well-known fact that in many people suffering from or predisposed to eczema the continuous application over any area of skin of even a fairly large-sized piece of plain zinc oxide adhesive strapping for a few days will often start up an eczematous condition under it.

The first factor is partly dealt with by the fact that some of the discharge can escape through the bandage and be wiped off whilst *in situ*, together with the periodical removal and reapplication of the bandage after suitably cleansing the area covered. The second is now apparently realized by the makers of the dressings themselves, by the fact that they market these bandages in the form of half-plastered-width bandages for the same purpose in which only a very small area of the sticky substance, at the beginning of the bandage, comes into direct contact with the skin surface, and this piece is generally under the thick skin of the sole of the foot, which part is not very easily irritated. The third factor cannot be dealt with. Ask anyone who has ever had to have some broken ribs strapped up with adhesive plaster on their skin if after a few days of such treatment they did not feel like giving a very good imitation of a choreic chimpanzee working overtime, in their desire to scratch that area. From what some patients suffering from "a bad leg" treated with elastic adhesive occlusive bandages have told me, this is trivial compared with the irritation they sometimes get while undergoing this treatment, resulting frequently in a "Blitzkrieg" of scratching and further trauma of the insulted dermis.—I am, etc.,

Leicester, Dec. 6. F. A. E. SILCOCK, M.D., D.P.H.

Conservation of Cervix in Prolapse Operations

SIR,—May I say how much I have been interested in Dr. J. W. A. Hunter's paper on the conservation of the cervix uteri (*Journal*, November 18, p. 991). In my opinion he has drawn attention to a most important point. For my own part I have been fortunate in not having had any Caesarean sections following amputation. In addition to the reasons mentioned there is one great objection to Schroeder's amputation—namely, its liability to be followed by a secondary haemorrhage about the seventh or eighth day. A bleeding cervix is an awkward complication which usually necessitates bringing the patient back to the theatre and the insertion of stitches. In the usual high amputation, and in Emmet's trachelorrhaphy, the dangers of post-operative haemorrhage are very slight. Emmet's operation is simple to perform and is a most satisfactory method of treating an old laceration.

I was very glad indeed to see Dr. Hunter's reference to the operation of vaginal fixation, which would seem to be a valuable method of dealing with certain cases of prolapse. For several years I have been in the habit of performing a somewhat similar operation—namely, vaginal suspension—and I find that as time goes on I employ it more frequently than formerly. In some few cases in which a period of sterility has preceded operation pregnancy has occurred and labour was uneventful. Cullen of Baltimore produced excellent illustrations of this operation, which, with his kind permission, I reproduced elsewhere. Very briefly the steps are as follows. The anterior pouch of peritoneum is opened, two or three long suspension sutures are inserted into the anterior surface of the uterus, and the long ends of these sutures are passed, respectively, on each side through the peritoneum and through the vaginal mucous membrane about a quarter of an inch from the edge of the colporrhaphy incision. Clips are then put on these sutures and the colporrhaphy is completed. The uterus is now drawn gently forwards by the suspension sutures, which are then tied.

As Dr. Hunter's paper has reference to prolapse, perhaps I may be allowed to mention one last point. Of recent times the pendulum has swung away from the older operation of interposition. Some few years ago, when in America, I heard the view expressed that interposition was one of the best methods of treating prolapse in an elderly woman in whom there was a large cystocele—that is, a case in which a cystocele is responsible for most of the symptoms. The reason given was that the uterus is thereby made to form a natural shelf for the bladder. There are perhaps objections to the operation, as to many others, but personally I employ it in preference to anything else in certain selected cases of the type just mentioned.—I am, etc.,

Londonderry, Dec. 6. R. E. Tottenham.

Cause of Gastric Ulcer

Sir,—Dr. James Ronald's article in the *Journal* of November 25 (p. 1033) has interested me much as a general practitioner who has believed that it is the high hydrochloric acid content that is largely responsible for gastric ulcer. Dr. Ronald shows that in spite of excess hydrochloric acid the ulcer heals.

So often the determining cause appears to be overwork and over-worry, and especially over-worry, and one has felt there are other factors—perhaps some endocrine disturbance—responsible for gastric ulcer formation beside those of faulty diet, irregular meals, etc. The enzyme or factor that prevents the digestion of the stomach wall ante mortem must, I think, play an important part in gastric ulcer, just as Castle's intrinsic factor has its role in the production of the sequelae of hypochlorhydria and achlorhydria. The stomach of carnivorous animals has, I believe, a far higher hydrochloric acid tolerance than the human stomach. Hog's stomach as ventriculin can supply the lack of Castle's intrinsic factor, and I wonder if the stomach of the carnivora would not supply the factor that may be lacking in the human stomach when ulceration takes place.—I am, etc.,

Tarrington, Dec. 2. H. G. Langdale-Smith.

Fracture of Femoral Condyle

Sir,—I was interested in Professor G. R. Girdlestone's article on fractures in the region of the knee in the *Journal* of December 2 (p. 1099), and would like to ask him a general question regarding operative procedure.

In the section headed "Fracture of One Condyle" he says, "This operation can be done by working through a large window in the plaster." How does he prepare the skin for such an operation? Presumably sterile sheeting would be insinuated beneath the edges of the window during the operation and clipped to skin?—I am, etc.,

Wrexham, Dec. 3. Eric Evans.

*** We submitted Dr. Evans's inquiry to Professor Girdlestone, who has kindly supplied the following answer: Dr. Eric Evans asks for details of my technique of operating through a window in plaster-of-Paris. This has been developed as a result of the experience of performing spinal fusion in many cases of scoliosis corrected by the Risser technique. The points are:

1. Previous preparation of the skin with ether and, say, 1 per cent. iodine in spirit. When the patient reaches the operating table it is necessary to:

2. Dust the area with a mop of gauze on a pair of forceps, discarding the gauze and forceps.

3. Cleanse with ether, fresh mop, fresh forceps, starting in the middle and spiralling outwards, again discarding gauze and forceps.

4. Repeat twice with iodine swabs.

5. Apply miniature sterile towels, say 10 inches by 20 inches, placing them very accurately round the window overlapping each other, then carefully expose the area of incision and fix the towel edges to the skin with Michel clips (preferably of the large strong type). These miniature towels can be handled far more exactly than larger ones.

6. Place ordinary sterile towels over the miniature towels to enlarge the sterile field.

N.B.—All the final procedures are best carried out by the surgeon himself, as meticulous care is required.

Stored Blood for Transfusion

Sir,—In the *Journal* of November 4 (p. 908) J. L. Hamilton-Paterson's paper on the use of stored blood for transfusion raised the whole question of the value of such blood. The question is not directly raised by the author, but is implicit in two of his conclusions—namely, that "dramatic improvement is less frequent than when fresh blood is used," and that "blood regeneration is slower." If these statements are confirmed they will doubtless be of far-reaching importance. However, I feel that it should be made clear that at present these conclusions are in the realm of clinical impression rather than of scientifically established fact.

The cases which illustrate the paper give uncertain support for the author's deductions, since the patients include many (for example, gastric ulcers, ulcerative colitis, etc.) who may have bled again after transfusion, and other cases (for example, lung abscess) whose toxic process presumably also continued after transfusion. It is difficult to estimate with any degree of accuracy by haemoglobin readings the value of a transfusion in such circumstances. Moreover, the number of such records in several cases is too small, and in some cases they were ill timed, so that the effect of transfusion cannot be differentiated from the patient's own blood regeneration. Further, haemoglobin percentage is misleading in a case of acute haemorrhage unless there is some indication of circulating blood volume, since the value of a transfusion may be chiefly in increasing blood volume, and may give rise to no increase in the *concentration* of haemoglobin.

There is no reference to the effect of transfusion on the blood pressure in the cases of acute haemorrhage. No records of red cell counts are given, and no cases transfused with fresh blood are described for comparison. It would be a pity if the value of stored blood were to be widely doubted upon such evidence as this, and it is clear that much more work is required before an opinion can be formed.—I am, etc.,

Adrian C. Kanaar.

Anaesthesia in War Time

Sir,—I was much surprised to read in the article by Professor R. R. Macintosh and Dr. Freda B. Pratt (*Journal,* December 2, p. 1077) the statement that basal anaesthetics such as "avertin, nembutal, and evipan" can be used to allay fear and, therefore, the danger of ventricular fibrillation during chloroform anaesthesia. Surely the consensus is that the association of avertin and chloroform is highly toxic to the liver and that there is real danger of producing acute yellow atrophy of that organ. A statement of this kind in an article deriving from the department of anaesthetics at Oxford can be responsible for not inconsiderable consequences.

While one may subscribe to the view that "CO_2 plays no part in the treatment of patients suffering with respiratory *failure,*" I would like to see also stated side by side the point that CO_2 plays a great part in the treatment of respiratory *depression* (my italics). A false impression might otherwise be created by Professor Macintosh and Dr. Pratt's statement.—I am, etc.,

E. Montuschi,
Hither Green, S.E.13, Dec. 4. Anaesthetist, E.M.S.

Barbiturate Anaesthesia

SIR,—Our attention has been drawn to the fact that in our recent article on anaesthesia in war time (December 2, p. 1077) we omitted to point out the merits of pentothal, a drug which is used extensively in this hospital. In the interests of simplicity evipan was mentioned as representative of the group of short-acting barbiturates of which pentothal is a most valuable member. Our special mention of evipan was because we realized that it is at present the most widely used drug of this group. The good features of barbiturate anaesthesia are seen to advantage with pentothal, which, in our hands, has given consistently satisfactory results.—We are, etc.,

FREDA B. PRATT.

X-ray Examination of Militiamen

SIR,—In January last by letter I brought to the notice of the War Office the advantages of *x*-ray screen examination of the thorax in respect to acceptance of recruits, receiving a reply that medical examinations would be a matter for civilian medical boards appointed under the Ministry of Health. Incidentally, at the same time I pointed out the value of what may be termed the life insurance history, as, if a recruit had been accepted or rejected as a first-class life, such information would be of obvious value.

I have since followed with interest correspondence subsequent to Dr. J. V. Sparks's letter in the *Journal* of May 13 (p. 1003) in favour of a method of thoracic examination which has been extensively used not only abroad but in large works in this country, which skilled thoracic radiologists can conduct at a negligible cost per individual if the examinations are done *en masse*; but, so far as I am awere, they are not being conducted in the case of recruits. Those with experience of the late war, particularly combatant officers, will recollect how many of the recruits should never have been enlisted. Another aspect of the matter appears, however, to have been overlooked in the correspondence—namely, that, apart from *x*-ray examination of the thorax by recruiting authorities, there is always the possibility for a family doctor to send a prospective militiaman for *x*-ray examination at a hospital if a private radiological fee is not possible, or to a private radiologist for a report, particularly in cases where long knowledge of the patient gives a record of a poor thoracic history.—I am, etc.,

Forest Gate, E.7, Dec. 2. BERNARD LEGGETT.

Virtues of "Brown" Bread

SIR,—Opened by your annotation in the *Journal* of August 5 (p. 289) and by Dr. Alfred C. Jordan's letter two weeks later (p. 426), the reiteration of the superior virtues of wholemeal bread, which is not necessarily the same as brown, may serve as some solace to the public. In normal times the Englishman exercises his right to spend his money as he likes, on pools or white bread, without regard for value obtained, and in these days of "thirty-second" breakfasts his wife is unlikely to experiment with frumenty to redress the loss of vitamin B. But in war time the decision is taken from him, and flour containing a higher percentage of the wheat grain will be milled and sold not because it is popular, nor because his doctor recommends it and the Government thinks it good for him, but because, as Sir Arthur Salter pointed out in *Nutrition and the Public Health*, it is necessary to discourage excessive consumption of the "staff of life."—I am, etc.,

London, S.W.2. Dec. 5. G. D. PIRRIE, M.B., D.P.H.

SIR,—It would appear that many advocates of wholemeal (brown) bread in lieu of white bread lose sight of three facts.

1. White bread, though admittedly lacking in the three important vitamins B_1, B_2, and E, contains more *food* than wholemeal. The average of several comparative analyses by Sir Robert Hutchison shows that, whereas the wholemeal bread contains 6.4 per cent. more non-nutritious ingredients (water, cellulose, and minerals), white bread contains 6.6 per cent. more of the nutritious ingredients (protein, starch, sugar, and dextrin). The only actual food advantage of wholemeal bread is that it possesses an extra 0.2 per cent. of fat.

2. Most people dislike brown bread; they—and especially manual workers—have an almost instinctive preference for white.

3. Your correspondent Dr. Arthur King (*Journal*, December 9, p. 1164) asserts that Italians can from the same quantity of grain turn out seven loaves of brown to six of white. But as the brown loaf contains 5 per cent. more water, as well as more cellulose, the food value of seven loaves is probably only equal to that of the six white. Moreover, as every housewife knows, wholemeal bread rapidly gets dry and stale, and therefore is not an economical asset.

As, however, the poorer classes cannot afford to avail themselves of the varied diet that supplies the vitamins lacking in white bread it is obvious that wholemeal flour is healthier for them. For this reason the enforcement of such a type of flour might be a wise war-time measure.—I am, etc.,

CHARLES M. BEADNELL,
Egham, Dec. 10. Surgeon Rear-Admiral.

Provision of Free or Cheap Milk

SIR,—Before the outbreak of war there existed in Glasgow and elsewhere comprehensive schemes for supplying necessitous children with free meals and a large number of children in the schools with one-third of a pint of milk daily at the price of ½d., the necessitous children receiving this for nothing. The benefits to health accruing from these schemes were acknowledged by all medical authorities. Since the war broke out the children have in many cases not been attending the schools through which the schemes were operated; as a result the whole organization of distribution has fallen into abeyance. The evacuated children are receiving nothing by way of free or cheap milk unless some welfare committee in the reception area decides to undertake the provision of it. So long as there is no question of there being a lack of food, the necessary arrangements should be made between the proper authorities in the evacuation and the receiving areas to ensure the continued working of these schemes. It does not take long for any improvement due to better nutrition to disappear, and the end-result of a long period without the extra food may prove more costly to the nation than would the continuance of the supply.

In addition to the milk schemes for school children there are also in existence schemes for the provision of free or cheap milk to pregnant and nursing mothers, but here again the schemes are not being operated as efficiently or as comprehensively as was previously the case. Is it a case of "women and children last" in this war?—I am, etc.,

Glasgow, Nov. 20. J. JOSEPH, M.B., Ch.B.

Animists and Vitalists

SIR,—In your review of *Life's Beginning on the Earth* (December 9, p. 1141) we read, "Now that vitalism is in full retreat and biochemistry is rapidly advancing . . ." Without inviting a discussion that might be interminable, may I say that it is quite possible for an up-to-date biochemist to be a vitalist or—what is much the same—an animist. Your reviewer's attitude seems identical with that described by McDougall as having existed in the last quarter of the nineteenth century when he wrote, concerning animism, "Its few exponents were generally regarded as survivors from an earlier age, actuated by some theological bias to offer a futile opposition to the conquering march of science" (*Body and Mind; a History and Defense of Animism*, 1911, p. 85). McDougall took a first class in the Natural Sciences Tripos and found in modern science nothing incompatible with animism.—I am, etc.,

London, W.1, Dec. 10. MILLAIS CULPIN.

Personal Hygiene in Syllabuses of Training Colleges

Sir,—The trouble with this subject appears to lie, as Miss F. C. Consitt (*Journal*, December 2, p. 1114) suggests, in the difficulty in agreeing as to what it comprises. This gives rise to the misunderstandings and inaccuracies with which she confronts me.

Miss Consitt would limit personal hygiene to those branches for which we depend mostly upon others rather than upon our own individual efforts, for that is what the word "personal" implies. She cites nutrition, when one man's meat is another man's poison; activity, though rest is often essential; sleep, when even a sermon will not ensure keeping awake; cleanliness, which depends upon the presence of water; warmth, whereas it is the hot countries from which children have to be removed, never from the cold regions; light, when it has to be sacrificed to the whims of the architects. These she classes as fundamental necessities. She omits the two branches without which existence, as such, is impossible—namely, respiration and the production and disposal of our waste products. Without breath there can be no life, and if the waste is allowed to accumulate the living being is soon consumed with the products of its own combustion.

Those teachers who have crossed my path have come from every type of school, and all assure me that they get no sound scientific instruction upon either of these two vital branches and that they are therefore not held responsible for dealing with them among the scholars. Many of them deplore the gap in the syllabus; others do not realize that there is the gap. Some of them are grateful for the help they get from lectures they hear later on the subject.

Dr. Blacktin's treatise on dust tells us that 100 per cent. more foreign particles are to be found in the lungs of the mouth-breathers than in those who breathe naturally through the nose. Dr. Priestley some years ago stated that 80 per cent. of the cases he had examined for deafness were mouth-breathers. Since "gapers in glasses" are to be seen on every side, it is likely that investigation would determine the association of defective sight with open mouths. Yet the unkempt nose passes unnoticed, although, like the city on the hill, it cannot be hid.—I am, etc.,

London, W.1, Dec. 4. Octavia Lewin.

Nicotine and Blood Sugar

Sir,—I have read with interest the annotation on "Lady Nicotine" (*Journal*, December 2, p. 1098), but note that there is no mention of an important effect of nicotine—namely, a rise in the blood sugar. You state, as is well known, that there is a general impression that smoking lessens appetite and that a cigarette will help to stave off a meal, and that many people in times of stress are apt to substitute smoking for food. It occurred to me some years ago that this effect might be due to a rise in the blood sugar. Working in conjunction with Drs. Shaw and Wood in the physiological laboratory in Leeds, I well remember coming down breakfastless in the morning and deeply inhaling the smoke of two cigarettes. I can assure even the most hardened smoker that this is not exactly a pleasant procedure. We found repeatedly that within twenty minutes the blood sugar had risen from a resting value of near 0.1 per cent. to figures of 0.45 and 0.5 per cent., the effect lasting about ten to fifteen minutes. This fact of a rise of blood sugar does not seem to have been commented upon previously, but there is no doubt that it does occur. I am unable to say whether it is due directly to the action of nicotine or to a secondary adrenaline-like effect.—I am, etc.,

Leeds, Dec. 3. John K. Drucquer.

Cancer of the Lung

Sir,—I have had several inquiries regarding my letter in the *Journal* of December 9 (p. 1159). I would like to make it clear that all the figures quoted refer only to mice older than 10 months. This holds also for the last paragraph of the letter.

Our stock of mice is on the whole not very susceptible to tumour growth. About 10 per cent. of the control mice of all ages show tumours of any organ at death. This is not unlike the condition for man; for him about one out of seven or ten deaths is due to cancer of all organs. In the mice of our stock, however, the most frequent tumour is the lung tumour, and mammary or other tumours are rare. As mice younger than 10 months very rarely show tumours of the lung, I have always neglected these in the calculations and used only the figures for mice of older age. As revealed in my papers, mentioned in the letter, we start a dusting experiment with mice about 3 months old, and the dusting goes on for a year. The time factor is important also from the point of view of the dusting. The mice are allowed to fulfil their allotted span of life.

Obviously a man who dies of lung cancer is susceptible to it, and it serves no good purpose to use non-susceptible animals for experiments.—I am, etc.,

London, N.W.3, Dec. 12. J. Argyll Campbell.

The Services

R.N.V.R. OFFICERS' DECORATION

The Royal Naval Volunteer Reserve Officers' Decoration has been awarded to Surgeon Commanders R. Hall and H. Parry-Price.

CASUALTIES IN THE MEDICAL SERVICES

Royal Navy

The official list of missing officers who were serving on the *Rawalpindi* when it was sunk by the *Deutschland* and another German ship includes the name of Probationary Surgeon Lieutenant **Frederick Herbert Weston**, R.N.V.R. Dr. Weston qualified in 1934, taking the M.R.C.S., L.R.C.P., and in the following year graduated M.B., B.S. of the University of London. Before taking up his naval duties he held appointments at the Mayday Hospital, Croydon, and the St. George-in-the-East Hospital, Stepney.

DEATHS IN THE SERVICES

Lieutenant-Colonel **William George Patrick Alpin**, O.B.E., I.M.S. (ret.), died at Richmond, Surrey, on December 6, aged 80. He was born on September 15, 1859, the son of William Alpin, postmaster of Delhi and later of Calcutta, and was educated at Oscott and St. Thomas's Hospital, and took the M.R.C.S. in 1881, the L.R.C.P. in the following year, and the M.D. of Brussels in 1883. He entered the Indian Medical Service as surgeon on April 1, 1884, became lieutenant-colonel after twenty years' service, and retired on January 6, 1910. He had a somewhat varied career in the Indian Medical Service, more so than most men. He was originally posted to Bombay, but soon after joining was transferred to Bengal. After the usual two years' military duty he entered civil employ in Bengal, but a year or so later obtained political employment under the Foreign Office as agency surgeon of Bhopal, Central India. Some two years later he entered civil employ in the United Provinces, where he spent most of his service, finishing up with another spell of military duty. On his retirement he settled at Ealing, where he was in practice for about fifteen years, after which he went to live at Paignton and a few years ago moved to Richmond. He served in the Sudan campaign of 1885, receiving the Egyptian medal and the Khedive's bronze star; in the Chitral campaign on the North-West Frontier of India, relief of Chitral, Frontier medal with a clasp. In 1914 he rejoined for service in the war of 1914–18, when he served first on a hospital ship, afterwards in Egypt, being absent from his practice for about five years. He received the O.B.E. on January 31, 1920. He leaves a widow and several children. Many friends of his own Service will lament the passing of a first-rate officer and doctor and a kindly and genial friend, though most of his friends and contemporaries are already gone, *multis ille bonis flebilis occidit*. He had been a member of the British Medical Association for thirty-three years.

Major **John Alfred Wylde Ebden**, Indian Medical Service, died at Delhi on November 10, aged 48. He was born on

February 20, 1891, and educated at Westminster and London Hospitals, where he gained an entrance scholarship and the Abrahams prize in clinical pathology. He qualified as L.M.S.S.A. in 1914, and graduated as M.B. and B.S.Lond. in 1916, also later as M.S. in 1921, and as M.D. in tropical medicine in 1926. He also took the F.R.C.S. in 1921, and the D.T.M. with distinction of the London School of Tropical Medicine in 1926. After serving as house-surgeon of the Leicester Royal Infirmary, he entered the R.A.M.C. as lieutenant and temporary captain on March 1, 1917, became captain on March 19, 1918, and resigned on July 1, 1919; rejoined as captain on August 19, 1921, and resigned with a gratuity on August 5, 1925. From 1926 to 1929 he served in the Colonial Medical Service in Malaya. He was appointed to the I.M.S. on December 6, 1929, being ranked as captain from January 20, 1924, and became major on July 20, 1932. At the time of his death he was serving as chief medical officer of Delhi. He served in the war of 1914–18. He had been a member of the British Medical Association for eighteen years.

Lieutenant ARNOLD NORMAN FLETCHER CRITCHLEY, R.A.M.C., Supplementary Reserve, was killed recently in a motor accident in France. He was educated at St. George's, and took the M.R.C.S.Eng. and L.R.C.P.Lond. in 1934. After filling the post of resident medical officer of the County Hospital at Dartford he went into practice at that town, where he was honorary medical officer to the Livingstone Hospital. He joined the R.A.M.C. Supplementary Reserve on April 5, 1939, and was a member of the British Medical Association.

Obituary

ANTON VON EISELSBERG

Hofrat Professor Anton von Eiselsberg, the famous Viennese surgeon, died on October 25. At the time of his death he was one of the eight surviving Foreign Corresponding Members of the British Medical Association. He was born on July 31, 1860, at Steinhaus, in Upper Austria, and studied at the Universities of Vienna, Würzburg, Zurich, and Paris, returning in 1884 to Vienna to work under Billroth. After holding surgical posts at Utrecht and Königsberg he became in 1901 chief of the first surgical clinic of Vienna, and was made emeritus professor in 1931. Apart from many important writings between 1890 and 1913, he was responsible for the *Lehrbuch der Chirurgie A. v. Eiselsberg,* published in Berlin. We have received from Dr. John Burke of Buffalo, N.Y., the following appreciation:

His fame was truly international, and there are hardly any civilized lands which have not paid him formal honours. With him an era of surgery becomes history and the Billroth school loses its last active member. It was as an assistant of Billroth's that he visited Lister, to return an enthusiastic advocate of antisepsis.

Even above von Eiselsberg the surgeon stands von Eiselsberg the man. To his patients and associates he will always remain an outstanding example of the nobleman in the truest sense of the word. In his clinic, in contrast to certain other Continental clinics, the physical and spiritual welfare of the patient came before all else, and the assistant or "Operateur" who neglected either was quickly informed of the error of his ways. The Hofrat's own conduct towards patients was a magnificent example. In passing it might be said that one of his more recent papers, "Arbeitsleistung und Arbeitseinteilung einer chirurgischen Universitätsklinik," is one of the finest expositions of the philosophy of the surgeon to be found.

To me the opportunity of working under him as an "Operationszögling" in the I. Chirurgischen Klinik in Vienna will be a happy memory. I think that I may speak for those of my fellow Americans who were privileged to know Anton von Eiselsberg when I say that an outstanding surgeon and a magnificent gentleman has gone to his reward.

By the death of Mr. THOMAS FRASER TODD in France on December 2 as the result of a motor accident Manchester has lost one of the most brilliant of its younger gynaecologists. Todd was a student of Guy's Hospital and qualified in 1931 with the M.B., B.S. and the M.R.C.S., L.R.C.P. He took his F.R.C.S. in 1933, the M.C.O.G. in 1934, and the London M.S. degree in the following year. He acted as house-surgeon and later as a demonstrator in anatomy at Guy's before being appointed resident surgical officer at the Preston Royal Infirmary. His work as a research fellow at the Christie Hospital and Holt Radium Institute in Manchester attracted attention, as did several papers on the treatment of carcinoma of the cervix uteri. He became honorary assistant gynaecologist to the Salford Royal Hospital and was also on the consultant staff of Hope Hospital, Salford, and of Crumpsall Hospital, Manchester. For his work on cancer of the cervix he was awarded a Hunterian professorship by the Royal College of Surgeons in 1938, and he was only recently appointed registrar to St. Mary's Hospitals, Manchester. He was one of the examiners in gynaecology for the General Nursing Council and an active member of the North of England Obstetrical and Gynaecological Society and of the Manchester Medico-Legal Society. Todd volunteered for active service at the outbreak of war and at the time of his death was a major attached to one of the B.E.F. general hospitals in France. His striking figure—he was tall, dark, and always immaculate—and the tremendous energy he brought to bear upon any and every problem soon made him well known. His untimely death at the age of 31 will be deeply regretted by many colleagues and friends in Manchester.

We regret to announce the death on December 3 of Dr. JOHN HARDWICK THORNLEY, consulting surgeon to the Scarborough Hospital, aged 62. A son of Canon Thornley, he was born at Workington, Cumberland, on August 28, 1877, and after schooldays at Cheltenham College entered Edinburgh University as a medical student in 1896. Having graduated M.B., Ch.B. in 1900, he served in turn as house-surgeon to the Edinburgh Royal Infirmary and extra assistant physician to the Royal Edinburgh Asylum, Morningside. He began his long connexion with the Scarborough Hospital as house-surgeon in 1901 and became honorary assistant surgeon in 1909. On retirement from the visiting staff he was elected consulting surgeon and a member of the Board in 1937. During the last war he served over-seas with the rank of major R.A.M.C., and won the Military Cross. Dr. Thornley had been a member of the British Medical Association throughout his professional life. He was chairman of the Scarborough Division in 1922–3 and president of the Yorkshire Branch in the following year.

We regret to announce the death of Dr. H. STEWART BRANDER on December 7 at Keighley, Yorkshire, where he had practised for many years and gained a high reputation as a surgeon. Born in 1880, he entered the University of Aberdeen, graduating M.A. in 1899, M.B., Ch.B. in 1903, and M.D. with commendation in 1906. He first went to Keighley after holding a resident appointment at James Murray's Royal Asylum, Perth, and for more than thirty years gave valuable service to the Keighley and District Victoria Hospital, becoming senior honorary surgeon in 1929. He was chairman of the medical committee, and represented the hospital on the Yorkshire Regional Committee of the British Hospitals Association. Dr. Brander was a founder member of the surgical union which was inaugurated by Lord Moynihan. He joined the British Medical Association in 1911, and had been president of the Keighley and District Medical Society. He represented the town on the Bradford Regional Radium Institute, and during the last war served with the rank of major R.A.M.C. as registrar and surgeon on the staff of the Keighley War Hospital at Morton Banks. After the armistice he was surgeon in charge of the Ministry of Pensions special surgical clinic. He published several papers on surgical subjects in the *British Medical Journal.*

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation on December 10 the following medical degrees were conferred:

M.D.—T. G. Armstrong.

M.B., B.Chir.—J. R. Squire, J. W. Lacey.

UNIVERSITY OF LONDON

The following candidates have been approved at the examinations indicated:

Third M.B., B.S.—*Revised Regulations:* *‡F. L. Dyson, *‡Lilias M. P. Gairdner, *†J. E. Richardson, *†P. T. Savage, *†Muriel C. Yates, J. C. Ballantyne, Rosalind S. Barclay, Anna M. Berry, G. Beven, Winifred C. M. Bulkeley, A. G. N. Calder, J. Colover, Jean M. Drury-White, P. McA. Elder, G. R. Fisk, J. M. French, F. J. Gillingham, J. F. Hughes, J. P. Irwin, G. C. A. Jackson, R. R. Klein, D. C. Lewin, H. F. Lunn, A. S. Oscier, J. Ll. Penistan, R. W. B. Scutt, Margaret M. Shrubsall, Joyce R. Simmons, S. C. F. Stephenson, M. Ware, Marguerite Watts, Alice Yates. *Old Regulations:* R. Asquith, J. R. Audy, I. H. Baum, R. C. S. Benson, K. M. Bhansali, J. Bleakley, A. D. Bone, J. A. Bowen-Jones, A. R. Bradley, J. R. Caldwell, D. M. F. Carter, C. D. Chilton, J. D. Craig, A. H. Cutting, H. H. Dickson, A. J. Drew, D. A. J. Ebrill, G. R. Fearnley, W. Fine, Betty Fox, H. R. W. Franklin, J. B. Franklin, F. N. Glover, A. C. Greene, W. E. Greenwood, E. R. Gubbay, Violet E. N. Harris, W. R. L. Harrison, C. F. Hawkins, S. R. T. Headley, F. A. Henley, R. N. Herson, R. N. Houlding, P. H. Jayes, J. B. Kershaw, B. Levin, W. S. Lewin, A. E. Loden, I. D. MacDonald, G. C. Mackay, A. H. Millard, H. E. Moody, A. D. Newsholme, D. A. Osborne, F. R. Philps, M. J. Pleydell, B. A. Pomryn, T. M. Ll. Price, H. V. Reeves, Constance M. B. Shaw, H. D. Smith, P. R. Stringer, F. D. G. Thomas, Joan Wagstaff, R. A. White, R. M. Williams, N. N. Wilson. *Group I:* H. A. C. Chalmers, P. W. Clarkson, J. R. Elwell, M. R. Hayes, Kathleen Hodkinson, E. G. Hosking, D. R. M. Jones, A. H. Mayne, R. P. M. Miles, I. H. Miller, J. Newsome, S. D. Perchard, F. H. Scoones, C. J. P. Seccombe, A. S. Sen, A. G. Stephenson, R. D. Ward. *Group II:* O. P. Dinnick, M. M. Ernst, S. T. Hayes, M. H. Kinmonth. *Revised Regulations—Part I:* G. C. Acres, T. A. H. Adkins, A. F. Baldwyn, D. A. Barley, W. R. Barrington, C. J. Bintcliffe, Monica M. Bird, Winifred M. Bond, Frances D. Bosanquet, G. R. Boyes, Barbara J. H. Broadwood, P. M. Burton, Joan M. Cheale, D. R. Christie, F. B. Cockett, D. P. Cocks, O. L. C. Cookson, Dorothy J. Cooper, H. P. F. Corbin, T. H. Cullen, W. Darby, E. R. Davies, J. I. Davies, L. D. de Launay, F. A. Denz, Evelyn M. Eldrid, M. Elias, G. R. Evans, I. G. Fergusson, Joan FitzHerbert, J. Freeman, H. J. Friend, K. Froome, A. D. M. Greenfield, Margaret E. Harker, J. T. Harold, J. R. Hart, D. H. Hennessy, S. W. Hinds, C. A. Holman, L. B. Holt, J. C. Houston, R. E. B. Hudson, W. H. W. Jayne, Anis Jones, Joyce A. Keeping, A. W. Kennett, H. H. Khan, W. S. Killpack, Irene M. V. King, D. R. Livingston, C. D. L. Lycett, Kathleen B. McClintock, D. G. C. Macdonald, M. McFarlane, Jean D. McKendrick, A. Maconochie, E. T. Manley, J. Marks, L. W. C. Massey, R. M. Mayon-White, F. B. Meade, Edith S. M. Merry, J. J. Messent, Margaret Middleton, J. V. Mitchell, R. Moore, B. L. Morgan, J. T. Morgan, Margaret E. Morgans, Sheila M. Newstead, Doreen Nightingale, D. Dixon, A. O. A. Ohannessian, B. C. H. O'Neill, J. W. Paulley, H. T. Phillips, P. D. Rawlence, K. O. Rawlings, H. H. Renyard, T. H. E. Richards, Joan A. Rosmarin, M. H. Rotman, R. W. Rowan, H. A. Rowley, A. F. Rushforth, A. Sakula, A. C. J. Saudek, J. N. R. Scatliff, E. Schlesinger, L. G. Scott, M. A. Shellim, Barbara M. Sibbald, Lesley P. Sitwell, Daisy M. Smith, Irene J. Stark, B. A. D. Stocker, P. H. Sutton, D. R. Syred, Margaret L. Taylor, H. A. Warbrick-Smith, J. A. E. Watts, M. Waytzman, A. Webb-Jones, R. Wigglesworth, D. W. Williams, D. A. J. Williamson, W. Wohlfarth, P. H. Woodcock. *Part II:* R. H. Anthony, Margaret Bennett, C. J. Bintcliffe, Jean R. C. Burton-Brown, Isabella S. Chalmers, I. R. Davies, Jean L. Edwards, Enid J. Fair, R. V. Jones, B. U. Meyer, E. W. Miles, D. A. Miln, Margaretta D. Morrell, A. S. S. Playfair, J. D. Randall, G. F. Smart, B. J. D. Smith, B. E. C. Stanley, May D. Westerman, Elizabeth Whatley, H. Wormald. *Part III:* Eileen M. Benison, F. Luckett, D. Munro-Ashman.

Postgraduate Diploma in Psychological Medicine.—*With Special Knowledge of Mental Diseases:* D. W. Abse, Sophie Bookhalter, H. S. Joseph, W. A. O'Connor, J. D. Sutherland, J. D. Uytman. *Part A:* C. Phillips.

* With honours. † Distinguished in pathology.
‡ Distinguished in medicine.

UNIVERSITY OF DUBLIN

School of Physic, Trinity College

The following candidates have been approved at the examinations indicated:

M.D.—A. H. Smith. D. H. T. Duggan.

Final Medical Examination.—*Part I, Materia Medica and Therapeutics, and Pathology and Bacteriology:* †S. T. McCollum, †H. Lesselbaum, †Gladys M. Byers, †Lourenza C. Steytler, †L. H. Citron, A. H. H. Guilbride, T. A. H. Black, W. Badner, Florella Starritt, Emmeline P. Crowe, B. Marcus, C. R. Griffin, M. E. Weiner, D. O. Hicks, L. H. Shrago, M. J. M. Solomons, Dorothy H. Webster, P. C. Smyly, N. J. Anderson, Kathleen M. Patterson, A. C. McReynolds, S. Smullen, N. H. Stewart, M. G. Jackson-Smyth, S. D. Killen, A. G. Barnsley, J. P. Walsh, J. G. P. Mullally. *Part II, M.B.:* *P. M. Goedvolk, *H. H. Balch, †J. McD. Dougan, †E. G. Millar, †G. O. Atkinson, †Maureen C. Johnston, †H. D. Chomse, J. H. Tyrrell, P. H. Rubenstein, K. T. Acton, M. N. O'Riordan, S. Tennenbaum, M. H. Waters, Annie Dowds, J. L. Handelman, S. F. H. Haughton, J. H. Acton, P. C. Denham, W. M. Winn, M. Polansky, J. Morris. *B.Ch.:* †Muriel Bannister, †R. G. P. Heard, †J. C. G. Moore, †C. W. Bradfield, †D. Selman, †E. G. Millar, W. E. Bamford, B. S. Good, J. McD. Dougan, S. Fine, Kathleen Dowling, J. H. Tyrrell, G. F. N. Anderson, H. J. Draffin, Moira M. Mallagh, G. A. Anderson, N. J. Hogan, R. W. Carey, Sheila Kenny, Lucia M. E. FitzGerald, E. F. Keating, P. FitzG. Longford, P. C. Denham, T. N. Arthur, D. A. Huggard, W. Jones, R. Brass, A. H. Isaacson, R. F. G. Lyons, G. E. P. Kelly, D. St.B. F. Nunan, M. Shreider, R. R. Hogg, G. O. Atkinson, L. N. Lynch, I. Shreider. *B.A.O.:* *H. FitzGibbon, †Caroline A. McEvett, †Margaret Sutcliffe, †E. Kawerau, R. J. S. Wilson, P. FitzG. Longford, Frances M. C. Wolfe, H. Menter, J. H. Acton, D. Aiken, W. F. Rogers, Isabel M. Woodhouse, Lois J. Macaulay, J. I. Stafford, G. H. Blennerhassett, D. R. McCaully, S. D. Reid, P. H. Rubenstein, J. G. P. Mullally, D. O. Hicks, H. F. Kamp, N. Marks, Margaret L. Campbell, H. Hutchinson, H. J. Smith.

Diploma in Gynaecology and Obstetrics.—M. M. Abou Ragab.

Diploma in Public Health.—*Part II:* T. S. Agnew.

* First-class honours. † Second-class honours.

Medical Notes in Parliament

Before adjourning for the Christmas recess Parliament completed consideration of the Expiring Laws Continuance Bill. The House of Commons had a secret sitting to discuss the organization of supplies. It also heard a statement about the operations of the Royal Air Force, and discussed allowances to the unemployed and also old age pensions.

The Parliamentary Medical Committee met on December 12, Sir Francis Fremantle in the chair, and again considered the prevalent propaganda against vaccination and inoculation. The committee decided to inquire about the effect of this propaganda in the Forces. Discussion arose on the treatment of psychoneuroses in the field. It was decided to inquire whether the recommendations which had been made by a War Office committee of 1922 on shell-shock cases were receiving effect. A circular issued by the Medical Practitioners' Union on treatment of air raid casualties in hospitals rather than in first-aid posts was before the committee. The committee was informed that in the arrangements in the United Kingdom full use was made of the experience gained in Barcelona during air attacks.

State Control in Medicine

In the debate on the address in the House of Commons on December 5 Dr. Edith Summerskill, after urging the Ministry of Health to plan after the war a medical service which would entirely eliminate private profit from the treatment of disease, and to institute a State medical service, said that during the last three months those who were in contact with medical services had seen a tremendous change. Harley Street and its district were practically emptied. Not only the physicians and surgeons but the patients had gone as well, and perhaps for the first time in their lives the best-paid and wealthiest physicians and surgeons—in their profession they regarded that as meaning the most successful—were being paid by Whitehall. A revolution had also taken place in the hospital service. The medical services had not functioned smoothly, partly because there had not been, fortunately, the anticipated casualties in the first weeks of war. In the hospitals there were surgeons who said that their fingers were getting rusty because they were not able to operate; in some places the hospitals were getting over-staffed. One tragedy which was not fully realized was that of doctors in evacuation areas whose practices had disappeared with the war and who were sadly in need of some kind of relief.

If a very careful examination of the position were made, she believed it would be found that, in spite of these difficulties, for the first time in the medical history of the country we had in being the framework of a State medical service. For the first time in this country there was unified control and State remuneration for doctors. Young doctors in hospitals throughout the country were being paid an adequate salary instead of the £100 or £150 which they would get as house officers. If the State had decided that this was the only way to treat civilian casualties in war time, why not perfect the system and treat civilians in the same way in peace time? She challenged anyone to look at the latest municipal hospitals equipped with the latest scientific apparatus and then to look at the voluntary hospitals struggling along. It was absurd to tolerate the out-patient system. Outside the hospitals the dependants of the workers had no medical service at all, unless they could pay for it, and the middle classes were given what was often an inferior service.

Sir FRANCIS FREMANTLE said that the idea of a national medical service was not new. Dr. Summerskill did not seem to realize that the Poor Law was the first time the idea of a public medical service was brought into existence. It was necessary to link up the medical services, whether personal or institutional, more than was the case at present. We had been working in that direction with effect, but had not yet got to a completed scheme. One way was through the medical officers of health scheme, another was through the insurance scheme, unfortunately introduced as a separate organization. Voluntary hospitals were working together much more in the way of a public utility service. A Government which tried to socialize the medical profession, whether that was right or wrong in theory, would be very sorry. It would undertake an impossible proposition. What could and must be done was to help build up the present scheme, to help it forward in the direction in which it was going now, and guide its development. Dr. Summerskill's suggestion was that under a State system the doctors would be delighted to have a definite income, definite hours of work, and definite holidays. If that were so, then God help the patients, because doctors, like other people, were human. There were good, bad, and indifferent doctors. There were those who would say that they had done their eight hours' work, that their week-end or holiday was due, and that they would make their arrangements and go. If the doctors were under State control they would, as was the case with officials in any walk of life, insist on their rights, duties, and privileges, and would feel that it was the duty of the authorities to provide for the rest. The life-and-death questions of medicine could not be dealt with in that way. That was why they must continue the voluntary arrangements and voluntary control. It would be against human nature and against the facts of the case to socialize the whole of the profession and its institutions.

Dr. ELLIOT said that Lord Nuffield's gift of 1,000,000 ordinary shares in Morris Motors, Ltd., for the co-ordination of hospital finances and policy in the provinces was a great piece of planning. Even in the midst of war they were still able to obtain these princely donations for the purposes which they all desired—namely, to organize the proper relationship of the voluntary hospital to the municipal hospital and the co-ordination of the hospital system as a whole. It would be quite unfair for him, having asked for the collaboration of all sections of the community in the Emergency Medical Service, to impose on the profession some system with which it was not wholly in agreement.

Nutrition in War Time

The debate on the address continued on December 6. Miss ELLEN WILKINSON said the Government should have an intelligent food policy, particularly for the children and the unemployed. In the last war the nation was only beginning its knowledge on protective foods and vitamins. The influenza epidemic at the end of the war followed malnutrition in certain areas and a general lack of protective foods in the last years of the war, which reduced the resistance of the poorer parts of the population. Before the nation got near that position the Government should ensure to the children, to the lower-paid workers, and to the unemployed sufficient supplies of protective foods. It was possible to submit ordinary grade margarine to a process which produced ergosterol and to have vitaminized margarine. The sale of margarine not so treated should be made illegal to protect the lower-paid workers. Children were suffering now in towns where the schools were closed and the milk service temporarily stopped.

Sir GEORGE SCHUSTER remarked that although fats were important to the life of the nation, soap was still made with the full peace-time percentage of fat. Germany had come down to a soap which contained practically no fats at all.

Dr. HADEN GUEST protested against any deterioration in soap. The epidemics in the last war arose not only from bad nutrition but from dirt and filth in large parts of Europe. He criticized the calling of young men to the colours by age groups. Further use should be made of older men, and the Government should consider jumping a period of years and taking a class of older men. He was concerned at the prospect of, say, ten continuous age groups being subjected to war strain and many killed. Could they not build on the experience of past years a scientific review of the military and civilian use of man-power with a view to the human future?

Mr. EDEN said anyone who knew the average battalion of the new armies in the last war and compared the physique of the men then with the physique of the average Territorial battalion to-day must be impressed by the change. For the organization of our human resources the nation had the Department of Scientific and Industrial Research and the Medical Research Council, but despite their help the war would set new problems and further research and co-ordination would be necessary. He could assure Miss Wilkinson that Dr. Elliot and Mr. Colville were in communication with Sir John Orr and other leading authorities to see how good results could be ensured in nutrition during the war. The Government recognized the immense importance of the subject.

Ambulance Trains

Sir ALFRED KNOX inquired on December 7 whether Dr. Elliot knew that thirty-two trains, each with eight officials of the St. John Ambulance Association, at present stood idle. He also asked what the weekly cost of these officials was, and why the train and the personnel could not be assembled quickly in case of an emergency. Dr. ELLIOT answered that the casualty evacuation trains, which, owing to the course the war had taken, had happily not been used to a great extent, hitherto numbered twenty-eight, apart from two in Scotland. They were now being reduced to eighteen. The weekly cost of the orderlies averaged about £26 per train. The mobility of the trains and the need for keeping them and their equipment in constant readiness for immediate service, if required, made it necessary to keep trains and staff continually in commission.

Treatment of Contagious Diseases in Military Areas.—On December 5 Captain ELLISTON asked the Minister of Health whether extended arrangements were being made for the treatment of contagious diseases occurring in the civil population in the neighbourhood of military encampments and munition works. Dr. ELLIOT said that the position was under review, and he proposed shortly to issue a circular to the responsible local authorities on the matter.

Medical Boards: Classification of Examinees.—On December 7 Mr. RHYS DAVIES asked whether doctors who conducted examinations under the Military Service Act were familiar with the training given in the Forces to the men they examined. He asked Mr. Ernest Brown to invite all members of medical boards to witness such training so that they might relate their examinations to what was expected of the men later. Mr. BROWN replied that the classification of men examined by medical boards in the categories specified in the National Service (Armed Forces) (Miscellaneous) Regulations, 1939, was based on medical grounds. It was for the military authorities to determine the kind of service for which men so classified were suitable and to post them accordingly. He thought it unnecessary to adopt the suggestion made by Mr. Davies.

Hospital Visiting Hours.—Mr. DAVID ADAMS said on December 7 that certain municipal and voluntary hospitals had instituted alterations in their visiting days and hours, whereby for greater safety in case of air raids the number of visitors would be substantially reduced. He asked Dr. Elliot whether he proposed to recommend similar action throughout the country. Dr. ELLIOT replied that this was not a matter upon which he had specific information or upon which he would feel it desirable to make a general recommendation to the exclusion of the discretion of the authorities concerned.

Dental Treatment for Evacuated Persons.—Dr. ELLIOT said on December 7 that dental treatment fell within the scope of the health services which local authorities in receiving areas had been urged to extend to members of the evacuated priority classes. In addition, the Board of Education had asked local education authorities in a recent circular to make special arrangements, where necessary, for emergency dental treatment, including extraction, for school children.

Notes in Brief

On December 5 Mr. HORE-BELISHA informed Sir Irving Albery that adequate arrangements had been made to provide a physiotherapy department in military hospitals and in convalescent homes for wounded.

One Act covered by the Postponement of Enactments (Miscellaneous Provisions) Bill is the House-to-house Collections Act, 1939.

Medical News

Sir Walter Langdon-Brown has been appointed President of the British Social Hygiene Council in succession to the Right Hon. L. S. Amery, M.P.

The House of the British Medical Association, including the Library, will be closed for the Christmas holiday from 5 p.m. on Friday, December 22, to 9 a.m. on Wednesday, December 27.

We are asked to announce that a child guidance clinic, providing a limited service, is available at Guy's Hospital (London Bridge, S.E.) for the hospital's area.

Plans have been made for the third Pan-Arabian Congress and the twelfth Annual Congress of the Egyptian Medical Association to be held simultaneously at Jedda from January 16 to 21 during the period of the Mussulman pilgrimage. The fee is one Egyptian pound. Further information can be obtained from Professor M. Khabet Bey, Kasr El-Ani Post Office, Cairo.

The Pan-American Congress of Rural Hygiene organized by the Government of Mexico has been postponed indefinitely; also the International Congress of Oto-rhino-laryngology, which was to have been held in Amsterdam next year.

The Hospital of the Rockefeller Institute for Medical Research, New York, announces that the following diseases are under investigation for the years 1939–40: nephritis, heart disease, rheumatic fever, measles, and acute respiratory diseases. Suitable patients may be referred to the hospital by physicians and others willing to co-operate. No charges are made for treatment, board, room, or any other services.

The Lord Mayor of London presided over the annual meeting of the Royal Surgical Aid Society on December 4. He said that 27,378 patients were dealt with last year and 36,561 appliances were supplied. The work deserved sympathy, for it not only prevented much suffering but enabled those relieved to become self-supporting. The Dean of Manchester (the Very Rev. Garfield Williams, M.B.) said that he could imagine no more discriminating charity than this, and Lord Justice Du Parcq also spoke in its support. Mr. B. Whitchurch Howell acknowledged a vote of thanks to the surgeons of the society.

The State Department of Health for Illinois announces in the *Journal of the American Medical Association* that during the current pneumonic season both serum and sulphapyridine will be distributed free to doctors.

The issue of *Le Bulletin Médical* for November 4, which is devoted to neuropsychiatry, contains the proceedings of the International Congress of Neurology held at Copenhagen from August 21 to 26, 1939.

The Drugs Branch of the Home Office has moved to Cleland House, Page Street, Westminster, S.W.1.

Dr. Alexis Carrel has joined the staff of the French Ministry of Public Health for the duration of the war.

According to the statistical office of the Reich, Germany had 4,745 hospitals with 630,000 beds in 1937.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

In England and Wales an increase was recorded in the incidence of the commoner notifiable diseases, with the single exception of pneumonia (primary and influenzal), but the diseases for which comparable figures are available were less prevalent than in the corresponding week last year. Certain less common but serious notifiable diseases—for example, cerebrospinal fever, the enteric fevers, and acute poliomyelitis —all showed slight decreases compared with last week, and, cerebrospinal fever excepted, with the corresponding week last year. In London notifications of diphtheria were considerably higher, of scarlet fever unchanged, and of measles and whooping-cough somewhat fewer. As mentioned in these columns previously, the very low incidence in London of diphtheria and scarlet fever compared with previous years can only be attributed to the effects of the evacuation of a large proportion of non-immunes, but it is not justifiable to conclude that the somewhat lower incidence of these diseases in England and Wales as a whole is due to the abnormal distribution of these individuals, although this may well prove to be the case. The effect of evacuation on the London figures is even more strikingly exemplified by the notifications of dysentery; although the disease is almost as prevalent in the whole country as it was last year, no case was notified in London during the present week and only one in the previous week. Dysentery was more prevalent, absolutely as well as relatively, in Scotland than in England and Wales a few weeks ago, due in large part to the occurrence of an epidemic in Edinburgh. Of the 28 cases recorded in Scotland during the week, 11 were in this city; in the previous week the figures were 39 and 16 respectively. The disease was mild and appears to have had no effect on the mortality from enteritis and diarrhoeal diseases in children under 2 years.

Notifications of whooping-cough were slightly and of measles much in excess of those recorded in the previous week. At present whooping-cough is fairly evenly distributed among urban and rural areas in England and Wales; only seven administrative counties are free from it—namely, Cambridge, Isle of Ely, Isle of Wight, Hunts, Rutland, Westmorland, and Anglesey (Wales), compared with ten counties free from measles—namely, Berks, City of York, Hereford, Isle of Wight, Norfolk, Rutland, Suffolk West, and the Welsh counties of Cardigan, Montgomery, and Radnor. Considerable differences were encountered in the comparative incidence of whooping-cough and measles; in London 32 against 6 and in Birmingham 40 against 4 respectively, while in Liverpool and Manchester measles were low and the differences slight. The bulk of the measles cases in each county occurred in the urban centres: Cumberland 183 (Workington M.B. 84); Devon 137 (Okehampton M.B. 42); Lancaster 185 (Blackpool C.B. 41, Great Harwood M.B. 35, Lancaster M.B. 23); Salop 103 (Newport 43, Whitchurch 20); Warwick 102 (Leamington M.B. 46). Anomalous findings are not infrequent. Thus, in Berks there were 24 cases of whooping-cough and none of measles, and in the adjacent county of Bucks there were 79 cases of measles and only 5 of whooping-cough; in the West Riding of Yorks there were 82 cases of whooping-cough against 59 of measles, and in the East Riding the corresponding figures were 69 and 6 respectively.

No. 47

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 25, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)

† Death from puerperal sepsis.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The TELEGRAPHIC ADDRESSES are

EDITOR OF THE *BRITISH MEDICAL JOURNAL*, *Aitiology Westcent, London.*

SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Dochtúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Erythema of Eyelids

Dr. W. A. MUIR writes: A girl of 18 is subject to redness of eyelids, especially after spending a day out in the open. She has been subject to this for some years. General health is good. Ung. hyd. ox. flav. and optrex have been tried without much success. Can any reader make suggestions for treatment?

Chronic Muco-purulent Otorrhoea

Dr. F. C. COLLINSON (Rotherham) writes: I wonder if any of your readers could help me with suggestions in the treatment of a case of middle otorrhoea, thick muco-purulent discharge going on for more than a year, large perforation in each drum; the discharge is loaded with diphtheria bacilli of a non-virulent character. The patient is very fit now, though he had an artificial pneumothorax and was in a sanatorium for a long time. The ear condition is undoubtedly due to an attack of measles he had when a child. The treatment has been keeping the ears as dry as possible, douching with antiseptics, electric treatment, and diphtheria antitoxin. Up to now no improvement has taken place so far as discharge is concerned, and he is certainly somewhat more deaf.

Muscular Twitchings

Dr. E. J. BOWMER (Liverpool) writes in reply to " H." (November 25, p. 1072), who asked for suggested treatment to control general twitching of the muscles: I have had several cases of generalized twitching associated with tremors which appeared to be of the Parkinsonian type: unsteady gait, " pill-rolling " of fingers, irregular movements of arms, and twitching of the facial muscles. While there is little hope of arresting the progress of the disease in these senile cases, I have found that they respond well to administration of genoscopolamine granules, one to two t.d.s., p.c. The preparation is the amido-oxide of scopolamine prepared by Lab. Amido.

A Historic X-ray Apparatus

Dr. GEOFFREY A. HOFFMAN writes from Cranham, Gloucester: With reference to Dr. R. T. Gunther's inquiry under the above heading (November 25, p. 1072), I am doubtful of the correctness of Captain E. G. Spencer-Churchill's statement. On Professor Roentgen's discoveries of *x* rays in 1896 my uncle, the late Dr. J. Hall-Edwards of Birmingham, at once became keenly interested in the subject. In February of that year he produced the first radiograph taken outside London and the first radiograph of the spine. The first operation in this country as a direct outcome of the application of the rays was made from one of his negatives. I understand that Dr. Hall-Edwards equipped a portable apparatus for use in warfare, and, in addition, on the outbreak of the Boer War in South Africa he became attached to the Imperial Yeomanry Hospital as surgeon radiographer under the leadership of Sir Alfred Fripp. In an article written by himself he states that he dealt with 120 cases in the hospital at Deelfontein in the first five months alone, and gives an interesting account of it.

Income Tax

New Partnership—Old Debts

" PERU " refers to a reply in our issue of April 29 last, and inquires whether he has been right in acquiescing in the bringing into the firm's cash receipts of amounts paid on old accounts—that is, for services rendered before the present partnership came into being.

⁂ The reply quoted referred to different circumstances. In that case the former proprietor had retired, his professional earnings had ceased, and there was no question of his being assessable for subsequent years as a practitioner. In " Peru's " case he is still chargeable in respect of professional earnings. None the less he could have declined to have the old receipts brought into the new firm's accounts, but in that case the inspector of taxes would have rightly claimed that the cash receipts were not a fair index of the gross earnings of the practice, and would have insisted on the basis of bookings less an allowance for bad debts. Rather than become involved in the inconveniences of that method of computation most practitioners prefer to adhere to the cash receipts basis, even with the necessary corollary—that is, that *all* receipts be brought in, whatever their destination.

Honorary Appointment Expenses

" R. H." was, before the war, doing honorary work for a London hospital which entailed travelling once a week between London and the provincial town where he lives. Can he deduct the expenses so incurred?

⁂ If during the period in question " R. H." was in general practice we think that the Inland Revenue authorities would not object to the merging of the travelling expenses in those of the practice—as would certainly be done if " R. H." had been receiving a small fee for his services. But it is clear that he cannot deduct those expenses from other earnings—for example, from his pay, etc., as an officer in the R.A.M.C.

LETTERS, NOTES, ETC.

Treatment of Angina and Hyperpiesia

Dr. H. W. HALES (Bedfordshire), with reference to the leading article in our issue of November 4 (p. 915) on the drug treatment of angina and hyperpiesia, writes: I have had no small measure of success in both angina and hyperpiesia with a combination of colonic lavage with potassium permanganate and a diet reduced for some days to water and then to oranges and grapefruit only for some weeks. I do not know whether the results may be attributed to the potassium or the manganese ion, but it is certainly obtained when this salt is used for colonic lavage and not obtained when other salts are employed.

Calendars and Diaries

The high quality of the calendars and diaries produced by John Walker and Co., Ltd. (5 and 6, Warwick Lane, E.C.4) remains unchanged despite war-time conditions. The bindings of the samples sent to us display the same attractiveness as in former years, and the prices of the diaries range from 1s. upwards.

The Dental Mnaufacturing Company Ltd. (Brock House, 97, Great Portland Street, W.1) have issued their diary of appointments for 1940. It contains, as usual, space for half-hourly appointments, a week's appointments being visible at an opening, and much information of interest to dental practitioners. The detachable finger-indexed address book must be a great convenience to those using the diary; its price (plain edition) is 6s. 6d., postage 6d. extra.

Chocolates for Christmas

Samples of Messrs. Cadbury's well-known goods have been sent to us, and we are informed that in addition to making chocolate for the men and women in the Forces and for Civil Defence workers, chocolate boxes for Christmas presents will be available as usual. Prices of the gift boxes and caskets range from 6d. to 40s., and there are supplies of the varieties obtainable all the year round.

Corrigendum

Dr. W. NEWTON CHALMERS (Kirkcudbright) points out that the legend under Fig. 1 in the article by Mr. Philip Wiles on " Fractures of the Neck of the Femur " (*Journal*, November 4, p. 920) is incorrect. It should read, " Adduction fracture with upward displacement and *external* rotation "—not " *internal* rotation."

HYPERTENSION

A CONSIDERATION OF ITS SURGICAL TREATMENT*

BY

WINCHELL McK. CRAIG, M.D.

Section on Neurosurgery, the Mayo Clinic, Rochester, Minnesota

Richard Bright, more than a hundred years ago, after his memorable clinical and pathological studies, reasoned that the production of hypertension was due to an altered quality of the blood, which in turn caused hypertrophy of the heart together with the primary disease in the kidney. Thirty years later Gull expressed the opinion that the underlying cause of hypertension was widespread vascular lesions. Since that time much clinical and experimental evidence has been collected which lends support to both hypotheses. Allbutt and others have advanced clinical conceptions in favour of Gull's view, which, in general, has been accepted in the last twenty-five years by students of the problem of essential hypertension. However, a few investigators—for example, Volhard and Fahr—have expressed the belief that the primary cause of essential hypertension is renal dysfunction. The recent experimental work by Goldblatt lends support to such a hypothesis.

The treatment of hypertension by operation on the sympathetic nervous system has stimulated a new interest in the subject. Fifteen per cent. of all adults are assumed to have hypertension and 23 per cent. of all deaths at an age greater than 50 years are supposed to be directly attributable to this disease. Cardiovascular-renal disease, of which hypertension is an important factor, causes more than four times as many deaths as cancer, and hypertension apparently accounts for more deaths each year than does either cancer or pneumonia. Hypertension is therefore one of the most common and serious conditions that come under the care of physicians, and any therapeutic innovation which may lessen the mortality should be carefully examined. Arterial hypertension is considered to be present when the systolic blood pressure of adults persists at 150 mm. Hg or over. It is probably true that the blood pressure does not increase normally after maturity, and the blood pressure of infants and children is significantly lower than that of adults.

The treatment of hypertension has been complicated by the erroneous opinions that the elevation of blood pressure is not a disease but a symptom, and that the elevation of blood pressure in essential hypertension is beneficial and necessary for normal functioning of organs such as the kidneys. Study of patients whose blood pressure has been reduced to normal by operation at the Mayo Clinic indicates that the kidneys function as efficiently as, or even better than, they did when the pressure was high. In our experience there is no basis for the belief that patients who have essential hypertension feel unwell when the blood pressure is reduced, and we are convinced that it is extremely desirable to lower the blood pressure in all cases in which it is significantly high.

Secondary Hypertension

Hypertension may be divided into two main groups—secondary, and essential or primary hypertension. Secondary hypertension results from such lesions as pyelonephritis, glomerulitis, hydronephrosis, coarctation of the aorta, and tumours of the suprarenal glands. Primary renal lesions should be excluded by careful study, particularly by intravenous urography, because removal of a diseased kidney may cause the blood pressure to return to normal.

COARCTATION OF THE AORTA

This condition should always be suspected in young persons who have hypertension. This congenital anomaly is characterized usually by normal or low blood pressure in the lower extremities (normally the blood pressure in the lower extremities is significantly higher than it is in the arms), palpable arterial pulsations or bruit in the intrascapular region, and diminution in strength of pulsations in the arteries of the lower extremities. Roentgenologic examination of the thorax may show absence or deformity of the aortic shadow and erosion of the ribs attributable to development of the large collateral arteries.

TUMOURS OF SUPRARENAL GLAND

Tumours of the suprarenal gland that cause hypertension are comparatively rare. Those of the medulla or medulla-like tissue usually give rise to paroxysms of hypertension, which manifest themselves clinically as episodes of epigastric or substernal pain, pallor, palpitation, tachycardia, and marked elevation of the blood pressure. Since the medullary portion of the suprarenal gland is derived from the embryonic sympathetic nervous system, tumours which involve the medullary portion of the suprarenal gland might be expected to give rise, among other things, to an excessive supply of adrenaline. The most important tumours of the medullary portion of the suprarenal gland are the paragangliomas, which are benign in character, and the syndrome caused by them is characterized clinically by attacks of paroxysmal hypertension.

Five cases of tumour of the medullary portion of the suprarenal gland have been reported in the literature by Donzelot, Robert, Orth, Labbé, Vaquez, Oberling, and Jung. The sixth case, the first in which cure was brought about by operation, was reported by C. H. Mayo (1927). The seventh case, that of Shipley and Pincoffs, was operated on successfully and a large amount of adrenaline was demonstrated in the tumour by biological assay. Cases were subsequently reported by

---

*Read before the Section of Surgery at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

Potter, Kalk, and Laubry and Bernal. Bauer, in Vienna, reported a case in which the suprarenal gland was normal, but in the same case Leriche found a paraganglioma the size of a walnut (about 3 cm. in diameter) between the vertebral column and the aorta.

No satisfactory explanation for the paroxysmal character of the hypertension in the cases of paraganglioma has been made. Periodic haemorrhages into the centre of the tumour may force out the adrenaline. Unusual physical exertion such as bending may express adrenaline from the tumour. Emotional reaction such as fear or anxiety, which normally stimulates an increased flow of adrenaline, may in the presence of a paraganglioma provoke an abnormally large discharge of that substance. The complete absence of signs of arteriolosclerosis in cases of hypertension caused by paraganglioma is of particular interest as being evidence against the conception that adrenaline plays a part in cases of arteriolosclerosis and essential hypertension. Kelly, Piper, Wilder, and Walters (1936) reported a case of suprarenal tumour and paroxysmal hypertension.

Hypertension associated with tumours of the suprarenal cortex is not paroxysmal in type. Obesity, hirsutism, deep voice, and amenorrhoea may be associated changes. Ordinarily the potassium in the blood is low and the sodium is high. Binger and Craig (1938) reported a case of atypical suprarenal tumour.

RENAL LESIONS

One should always suspect the presence of tumours of the suprarenal glands as well as primary renal lesions in cases of hypertension. Barker and Walters (1938) reported a case of hypertension in which the blood pressure became normal after surgical removal of a renal lesion. This was a case of unilateral chronic atrophic pyelonephritis in which hypertension appeared after the chronic pyelonephritis was well developed and the kidney had become atrophic.

The incidental association of chronic pyelonephritis and hypertension is suggested by the experimental work of Goldblatt (1937), who showed that hypertension could be produced by partial obstruction of the flow of blood through the renal artery. The idea that in some cases hypertension may be caused primarily by renal disease, especially if the arterial blood supply of the kidneys has been impaired, has been revived. Complete sympathectomy performed on dogs does not influence the hypertension produced by Goldblatt's technique. An ischaemic kidney of one dog transplanted to the neck of a second dog produced hypertension in the latter. The hypothesis has been advanced that this renal type of hypertension is produced by liberation of some pressor substance from the kidney. Longcope (1937) found definite hypertension in 50 per cent. of twenty-two cases of pyelonephritis. Butler (1937) reported six cases of chronic pyelonephritis associated with hypertension among children. In two cases in which the pyelonephritis was unilateral, nephrectomy was followed by normal blood pressure.

The exact relation of chronic pyelonephritis to hypertension is still debatable. In many cases of chronic pyelonephritis the blood pressures are normal. However, the degree and type of injury to the renal parenchyma may vary greatly in cases of pyelonephritis. It seems reasonable to suppose that in Barker and Walters's case the patient had the capacity for developing hypertension in the first place and that the degree and type of renal damage which would produce it then developed. There was certainly enough evidence of arterial disease in the renal cortex to produce definite obstruction of the renal circulation. One must consider that the hypothetical pressor substance produced by a kidney rendered ischaemic by Goldblatt's technique might also be produced by some other type of renal injury such as occurs in certain cases of chronic pyelonephritis.

Secondary hypertension, then, is the elevation of the blood pressure that can be attributed to some associated lesion or other condition of the body, whereas essential hypertension is an elevation of the blood pressure in which the cause or aetiological factor is not known.

Essential or Primary Hypertension

In regard to essential hypertension much is known about the mechanism of elevation of the blood pressure. Three factors are responsible for maintaining normal blood pressure, and derangement of any one of these may cause a change in the blood pressure. The cardiac output, the volume or viscosity of the blood, and the resistance offered to the flow of the blood through the peripheral parts of the arterial system determine the blood pressure. It has been proved that cardiac output or viscosity of the blood is not altered in cases of essential hypertension, but that the calibre of the peripheral vessels is decreased. The situation is comparable to a garden hose at the end of which a nozzle is attached. If one decreases the diameter of the opening of the nozzle pressure within the hose increases, as is shown by the greater distance to which the stream is thrown. The decrease in diameter of the peripheral vessels is attributable to (1) a condition inherent in the arterioles, and (2) an abnormal reaction of the arterioles to vasomotor stimuli. Wide fluctuations of blood pressure would be indicative of an abnormal response of arterioles to vasomotor stimuli. A high sustained blood pressure with little fluctuation would be indicative of an inherent or automatic constriction of the arterioles.

There is a large hereditary factor in essential hypertension, as revealed by Ayman (1934), who found that in families in which both parents had absolutely normal blood pressure the incidence of elevated blood pressure among the children was only 3 per cent. In families in which one parent had hypertension the incidence rose to 28 per cent., and in families in which both parents had arterial hypertension the incidence was 45 per cent. Hines has shown that a family history of hypertensive cardiovascular disease is five times more frequent among individuals who have hypertension or who are hyperreactive to a standard stimulus (immersion of the hand in ice-water) than it is among individuals who react normally to the test. The exact inherent quality responsible for this is not known, but probably a hyperreacting sympathetic nervous system responds abnormally and produces unusual vasoconstriction as a result of various emotional stresses and strains.

Hypertension that has been produced experimentally in animals has some characteristics of essential hypertension in man. Goldblatt (1937) has produced hypertension by diminishing the flow of blood to the kidneys of dogs by means of clamps applied to the renal arteries. The hypertension of dogs closely resembles that of man, but complete evidence that it is the exact counterpart is entirely lacking. Those who have accepted the identity of Goldblatt's hypertension in dogs and essential hypertension in man believe that both are due to some chemical or hormonal substance. Up to this time there is no concrete evidence that essential hypertension is due to an abnormal pressor substance, and, reducing the problem of the aetiology of essential hypertension in man to its simplest form in the light of our very inadequate knowledge of the subject, heredity and the stresses and strains of life seem to be the most important factors.

Essential hypertension has been classified into four groups by Keith and Wagener: (1) slight to moderate increase in the blood pressure, which ordinarily becomes normal as a result of rest, and mild sclerosis of the retinal arteries, usually without symptoms; (2) moderate to severe hypertension, moderate sclerosis of the retinal arteries, and occasionally venous thrombosis; clinical symptoms are present or absent; (3) moderately severe hypertension and angiospastic retinitis, almost always associated with clinical symptoms of hypertension; and (4) severe hypertension, angiospastic retinitis, oedema of the optic disks, and, always, clinical manifestations of hypertension.

This grouping does not indicate the degree of hypertension, although the blood pressure is often higher in one group than in the group which numerically precedes it. The hypertension of any patient may progress from group to group until group 4 is reached. Mortality among patients who have hypertension groups 1 and 2 is 30 to 42 per cent. respectively in four years. Mortality among patients who have hypertension group 3 is 78 per cent. in four years; and in group 4, 98 per cent. (Keith). This high mortality should be noted carefully by those who are inclined to consider that hypertension is not ordinarily a serious disease. Malignant hypertension and essential hypertension are not separate conditions, for malignant hypertension is a type of essential hypertension. The term "malignant" is used loosely to designate severe forms of hypertension.

Medical Treatment of Essential Hypertension

On the whole, medical treatment of hypertension has been unsatisfactory. It has been stated that a great many preparations reduce blood pressure in cases of essential hypertension; however, on close examination it is evident that in most of these instances diminution of the blood pressure supposedly resulting from a specific remedy occurred only as a part of the usual wide fluctuations of blood pressure that are characteristic of essential hypertension. Such drugs as are available for the reduction of blood pressure usually possess unpleasant side effects or short action. The specific need in the medical treatment of hypertension is for a drug which will produce vasodilatation for a comparatively long time (three to six hours) and which does not produce harmful or unpleasant side effects. Sodium nitrite, sodium nitrate, purine derivatives—for example, theobromine and theophylline—iodides, and tissue extracts—for example, padutin (a preparation obtained from the pancreas), liver extract, and adenosin—are of little or no value in the treatment of hypertension. Occasionally when hypertension develops during the menopause it may be reduced by administration of theelin or progynon. However, it is inadvisable to treat such patients with these hormones for long periods unless a definite reduction of the blood pressure rather promptly follows adequate dosage.

Of all the drugs commonly used in the treatment of hypertension the sedatives are the best, and of them phenobarbital is as good as any. The ideal sedative is one that reduces nervousness and irritability but does not interfere with the essential cerebral activities. Ordinarily, 3/4 grain to 1½ grains (0.05 to 0.1 gramme) of phenobarbital three times a day is advisable.

Comparatively recently a new drug, potassium sulphocyanate, has been introduced for the treatment of essential hypertension. Its action is uncertain, but it is supposed to produce peripheral vasodilatation. Barker has shown that the blood-pressure in about 50 per cent. of hypertensive patients is reduced by careful treatment with potassium sulphocyanate. The amount of this drug that is administered orally should be determined by frequent calculations of the concentration of cyanates in the blood. The concentration in the serum should range between 8 and 12 mg. in each 100 c.cm. of blood. As little as 3 grains (0.2 gramme) or as much as 12 grains (0.8 gramme) of potassium sulphocyanate must be administered each day to cause this concentration in the blood. Barker has described a method for determination of cyanates in the blood; this has been modified by Griffith and Lindauer. Such symptoms as headache, insomnia, and nervousness may be relieved, according to Barker, when the blood pressure is reduced. Fatigue, macrocytic anaemia, and enlargement of the thyroid gland may occur even if administration of the drug is well controlled. If concentration in the blood is too great, lethargy, mental confusion, weakness, difficulty of speech, cutaneous lesions, and collapse may occur.

Experience at the Mayo Clinic with the use of potassium sulphocyanate in the treatment of hypertension has been somewhat limited, but relief of symptoms such as headache is often striking. There is definite reduction of blood pressure in some cases. It is advisable to continue well-controlled treatment for about three months before a decision is made that the treatment is not of value, as blood pressure may decrease slowly in instances in which it is reduced at all. Potassium sulphocyanate should never be administered for a long period unless the amount given is based on studies of concentration of cyanates in the blood. It is imperative for the physician prescribing sulphocyanates to familiarize himself with the literature on the subject before treating the patient with them. Not only does the administration of potassium sulphocyanate help patients who have not had an operation for the condition, but also in some of the cases in which little or no benefit has been obtained from operation its use has been followed by very gratifying results. In some cases in which potassium sulphocyanate was given before operation without benefit the administration of the drug after extensive sympathectomy has produced marked lowering of the blood pressure.

Rest and the reduction of nervous stresses and strains are important in the treatment of many patients who have essential hypertension. In general, it is advisable for such patients to obtain nine hours of rest in bed at night, to lie down for an hour or an hour and a half in the middle of the day, to take vacations frequently, to acquire a calm philosophic outlook on life, and to avoid nervous stresses and strains. Young individuals who follow strenuous occupations may well consider it advisable to change to an occupation that is more restful.

Many diets have been advised in the treatment of hypertension, but there is little evidence that diet influences blood pressure. We do not feel it advisable to restrict protein or salt in diets of hypertensive patients. Individuals who are over weight should reduce, for obesity throws an additional strain on the heart by increasing the work that it must do and as a result of deposition of fat in heart muscle and around the organ. Restriction of intake of alcohol and coffee is not imperative unless they serve as stimulants. They do not themselves increase the blood pressure appreciably. Smoking increases greatly the blood pressure of many patients who have hypertension, and if this can be demonstrated by having the patient smoke after his blood pressure has reached a basal level it is well to consider sharp restriction or complete elimination of smoking.

Indications for and Results of Surgical Treatment of Essential Hypertension

The surgical treatment of hypertension is based chiefly on the assumption that the increased arteriolar tone can be released by operation on the sympathetic nervous system, thus lowering the blood pressure. Arteriolar tone can be diminished by sympathectomy, as has been established clinically in the treatment of Raynaud's disease and thrombo-angiitis obliterans. Extensive sympathectomy produces two other effects that may be of value in the treatment of essential hypertension (Fig. 1)—namely, an increase in the blood supply to the kidneys and prevention or diminution of spontaneous release of adrenaline from the suprarenal glands. If the type of hypertension experimentally produced in animals by Goldblatt is comparable to essential hypertension in man, extensive sympathectomy is designed to destroy the sympathetic innervation of the kidneys and thus increase the blood supply to them. We believe that sympathetic denervation of the suprarenal glands, which is accomplished as part of the procedure of extensive sympathectomy as performed at the Mayo Clinic (Fig. 2), is probably of value only because it diminishes or prevents episodes of marked release of adrenaline from the suprarenal glands. Whether extensive sympathectomy is more valuable in the treatment of essential hypertension than partial sympathectomy, such as supradiaphragmatic splanchnicectomy (Peet) or coeliectomy (Crile), I do not know, but extensive sympathectomy is a more logical procedure, for it relieves sympathetic control of the kidneys and the suprarenal glands as well as that of the intra-abdominal regions and of a large portion of the lower extremities.

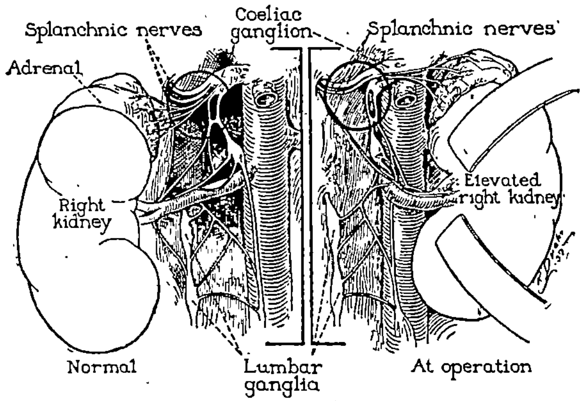

FIG. 1.—Extensive subdiaphragmatic sympathectomy in which the major, minor, and lesser splanchnic nerves with a portion of the coeliac ganglion and upper lumbar sympathetic trunk are removed.

From the discussion stimulated by the papers presented at the last International Surgical Congress in Brussels in a symposium on the surgical treatment of arterial hypertension it was evident that the surgical treatment of hypertension has proved of value in most clinics. Three factors in the causation of essential hypertension were stressed—namely, suprarenal, renal, and vasomotor. Hereditary, constitutional, and psychic factors, as well as the factors linked with certain hyperexcitable conditions of the sympathetic nervous system, were also discussed.

The futility of carrying out extensive sympathectomy in cases of hypertension in which there is irreparable damage to the cardiovascular mechanism is apparent. Nor should operation be considered in a case in which a mild and slowly progressive disease is amenable to medical treatment. Operation seems most efficacious in the definite vasospastic type of hypertension, in which sharp and brisk elevations in blood pressure occur when the hands are immersed in cold water, and in cases in which a marked fall in blood pressure is produced when pentothal sodium, sodium amytal, or a nitrite is administered. As an average rule the patient must be less than 50 years of age and the hypertension must be classed as of group 2 or 3.

One group of patients whose records seem discouraging are symptomatically relieved, especially of headaches. In one such case the pre-operative studies indicated little decrease in blood pressure and the post-operative blood-pressure readings were disappointing, but the patient was completely free from a disabling headache for eighteen months following operation.

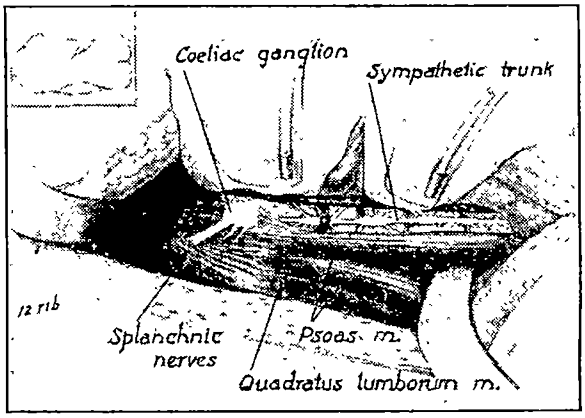

FIG. 2.—Resection of a portion of the twelfth rib and exposure of splanchnic nerves, coeliac ganglion, and lumbar sympathetic trunk ; *inset*, incision employed.

The contraindications to extensive sympathectomy are congestive heart failure, angina pectoris, marked renal insufficiency, and advanced arteriosclerosis. The operative mortality is negligible in properly selected cases, and, although some of the patients eventually die of the disease, operation seems neither to have hastened nor to have delayed death. Experience with 237 patients who have undergone extensive sympathectomy without an operative death has demonstrated that the operation, as performed at the Mayo Clinic after careful examination and selection, has a definite place in the treatment of essential hypertension. The symptomatic relief following operation has exceeded the effect on blood pressure. The proportion of patients relieved of headache when the effects of the operation on the blood pressure are recorded as good, fair, or poor was as follows: 100, 80, and 76 per cent. respectively. Nervousness was relieved after operation when the effect of operation on the blood pressure was recorded as good, fair, or poor, in 80, 66, and 67 per cent. of cases respectively. The proportion of patients relieved of non-anginal pain in the left side of the thorax after operation when the effects of operation on the blood pressure were recorded as good, fair, or poor was 90, 75, and 60 per cent. respectively. Fatigue on exertion was relieved after operation in 41, 44, and 50 per cent. when the effect of operation on the blood pressure was recorded as good, fair, or poor respectively; while dyspnoea on exertion was relieved in 50, 46, and 48 per cent. These figures bear out in a striking manner isolated clinical observations that frequently patients are relieved of such distressing symptoms as headache, in spite of the fact that reduction of their blood pressure does not seem apparent. The results of the operation for hypertension in the 237 cases were classed as follows: failure in 20 per cent., temporary relief in 28 per cent., fair results in 28 per cent., and good results in 24 per cent.

The women obtained good or fair results from operation in a slightly higher proportion of cases than the men, the percentages being 55 and 48 respectively. The duration of the hypertension before operation did not influence significantly the effect of operation. In contrast to previous conceptions regarding the influence of age, this factor did not seem to influence the good or fair results, although patients in the third decade of life received a slightly smaller percentage of good or fair results than did those in the fourth, fifth, and sixth decades.

Allen, Lundy, and Adson (1936) reported a case in which operation was followed by lowered blood pressure until pregnancy occurred. After interruption of the pregnancy the blood pressure decreased to the previous level. The inference to be drawn from this case is that hypertension can be caused from toxaemias and can act, with regard to sympathectomy, in a manner similar to Goldblatt's experimental animals. There seems, therefore, to be some difference in the mechanism of production of essential hypertension and of the hypertension that occurs as a part of toxaemia of pregnancy. Allen, Lundy, and Adson concluded that until more was known about the subject it was probably desirable for patients operated on for hypertension to avoid pregnancy if possible; if such patients become pregnant careful observation of the blood pressure should be made, and if there is any evidence of an increase the pregnancy should be terminated.

Since this case was reported several women who have had extensive sympathectomy for hypertension have completed their pregnancies successfully without any change in blood pressure, and therefore we have come to the conclusion that if a patient who has had a sympathectomy for hypertension becomes pregnant the pregnancy should be allowed to continue until toxaemia and increasing blood pressure indicate an impending danger.

In analysing the results of surgical treatment by extensive sympathectomy it is evident that fixed rules with regard to the selection of cases for operation are difficult to formulate. In general it can be said that patients probably will obtain good results from operation when the diastolic blood pressure decreases pre-operatively to less than 110 mm. Hg as a result of rest, administration of sodium amytal, and injection of pentothal sodium, and when sclerosis of the retinal arteries is absent or slight. Also, the probabilities that a patient will secure good results from operation are small in the presence of advanced sclerosis of the retinal arteries, when the maximal diastolic blood pressure exceeds 150 mm. Hg, or when the liastolic pressure does not decrease to less than 120 mm. s a result of rest, intravenous injection of pentothal odium, or administration of sodium amytal. It has been emonstrated that operation can be carried out safely. he operation does not disable, and it often produces markable effects on blood pressure.

Comment and Summary

n the treatment of hypertension, primary or essential ertension, which exists in 85 per cent. of cases, and ndary hypertension, which is present in 15 per cent. cases, must be considered. Secondary hypertension lts from such lesions as pyelonephritis, glomerulitis, onephrosis, coarctation of the aorta, and tumour of suprarenal glands. The surgical treatment of essential rtension is based on the assumption that increased arteriolar tone can be reduced by operation on the sympathetic nervous system, and thus lowering of the blood pressure is effected. Two other effects of surgical treatment that may be of value in the treatment of essential hypertension consist of an increase in the blood supply to the kidneys and prevention or diminution of the flow of adrenaline from the suprarenal glands. In analysing the surgical results it has been found that patients who suffer from a high fixed blood pressure associated with cardiac and renal damage do not obtain enough improvement from operation to warrant its use. Patients whose blood pressure tends to decrease with rest and after administration of sedatives on pre-operative observation have proved suitable for serious consideration of operative treatment. A decrease of both the systolic and diastolic blood pressures is important, and the best results have been obtained when the diastolic pressure decreases to less than 110 mm. Hg under observation. Results have been classified as good, fair, and poor. Included in the good results are those patients whose blood pressure has returned to normal or nearly to normal and has remained so for long periods of time. In addition, relief of symptoms was also noted. Fair results are considered to have been obtained in cases where there is a small reduction of blood pressure with relief of symptoms over long periods of time. Those patients who have experienced a slight or moderate decrease of blood pressure with temporary relief of symptoms are adjudged to have obtained poor results.

In considering the results of surgical treatment of essential hypertension, it is apparent that the operation is of a physiological rather than a pathological nature and that the post-operative response depends on the amount of associated pathological changes in the peripheral vessels, heart, and kidneys.

In analysing the surgical results it is also necessary to keep in mind that patients who suffer from progressive hypertension face a four-year mortality rate of 30 per cent. in group 1, 42 per cent. in group 2, 78 per cent. in group 3, and 98 per cent. in group 4. Although sympathectomy may not be the ideal remedy, there is much evidence that it may prevent or delay complications that all too frequently cause death in the most productive period of the patient's life.

THE VITAMIN K ACTIVITY OF 2-METHYL-1:4-NAPHTHOQUINONE AND ITS CLINICAL USE IN OBSTRUCTIVE JAUNDICE*

BY

JAMES M. MACFIE, M.B., M.R.C.P.Ed.
Kirk Duncanson Research Fellow,
Royal College of Physicians of Edinburgh

A. L. BACHARACH, M.A., F.I.C.

AND

M. R. A. CHANCE, B.Sc.
(Glaxo Laboratories, Ltd., Greenford, Middlesex)

Recognition that the chicken anti-haemorrhagic factor of Dam (1935) and Almquist and Stokstad (1935) might have therapeutic uses followed several publications in this country and the United States (Butt *et al.*, 1938; Dam and Glavind, 1938; Warner *et al.*, 1938; Illingworth, 1939; Stewart, 1939; Rhoads, 1939). Attempts to isolate, identify, and synthesize vitamin K led to the discovery that 2-methyl-1 : 4-naphthoquinone (formula 1), though not identical with any of the naturally occurring forms of the vitamin, had anti-haemorrhagic properties when tested on chickens (Almquist and Klose, 1939b; Thayer *et al.*, 1939a; Ansbacher and Fernholz, 1939). Recent announcements by at least two groups of workers (Binkley *et al.*, 1939; Fieser, 1939) show that one of the naturally occurring forms of vitamin K has the structure 2-methyl-3-phytyl-1 : 4-naphthoquinone. Its action on the chick appears identical with that of the simple quinone containing no phytol residue.

Batches of the quinone have been prepared in the Technical Research Laboratory of Glaxo Laboratories, Ltd., under the direction of Dr. E. Lester Smith; all the samples used for biological test or clinical trial have conformed to the following specification:

Methyl-naphthoquinone	not less than 98.5%
$E^{1\%}_{1\ \mathrm{cm.}}$	231 mμ, not less than 150
	250 mμ, not less than 1150
Loss *in vacuo*	not more than 0.15%
Chromium	not more than 0.01%
Melting-point	104° to 106° C.

The methyl-naphthoquinone was estimated by titration with titanous chloride, according to the method of Pinder and Singer (1939).

The compound has been found by us to be fully active on chicks in doses of the same order as those of the samples of natural vitamin examined by various authors. We have ourselves not had available highly purified specimens of the naturally occurring phytyl derivative, but we have been at some pains to compare the activities of various natural "concentrates" with one another and with the synthetic methyl-naphthoquinone.

The methods of biological test used did not differ substantially from those described by a number of previous investigators (Schonheyder, 1936; Almquist and Stokstad, 1937; Ansbacher, 1939; Thayer *et al.*, 1938), and we would only call attention to certain points of technique, some of which constitute minor modifications in this type of work and may be of interest.

The diet consisted of rice flour (from polished rice), ether-extracted fish meal, and ether-extracted dried yeast, with adequate quantities of sodium chloride, cod-liver oil, and ferrous sulphate. The naphthoquinone supplements were fed to chicks that had received only this diet from 2 days old to 14 or 15 days. It was dissolved in cod-liver oil, and administered by means of a graduated pipette or a micrometer syringe straight into the chicken's gullet. Both crude blood-clotting times and "prothrombin times" (Almquist and Klose, 1939a) have been determined.

At first we experienced considerable difficulty in obtaining responses regularly graded to dose, although substances having vitamin K activity invariably promoted a clearly marked difference in mean blood-clotting times between chicks receiving no supplement to the vitamin-K-free basal diet and those receiving the diet with an adequate supplement of the substance. After a considerable number of experiments we have devised a method for obtaining samples of blood and determining its crude blood-clotting time that has overcome our difficulties; a description thereof may possibly assist others. On theoretical grounds it was obviously desirable to reduce to a minimum variations in the amounts present of the different substances taking part in the blood-clotting system; of these it seemed to us that thrombokinase was likely to be one of the most variable, particularly as it is known to be absent from blood and liberated rapidly by damaged tissues. After some discussion with Professor A. St. G. Huggett, to whom we are indebted for his interest in the matter, we concluded that direct puncture of the heart was likely to introduce an adequate though not excessive, and a nearly constant, amount of thrombokinase, whereas the methods adopted earlier, such as puncture of the alar vein, involving varying degrees of laceration, would almost certainly not do this. These considerations have been justified by experience.

The birds are lightly anaesthetized with ether, and the heart is then exposed. A puncture is made in the left latero-ventral surface of the ventricle with a 22 S.W.G. syringe needle detached from any syringe. The needle has previously been thinly coated inside and out with paraffin wax. This is easily brought about by dipping the needle into a xylol solution of the wax and then draining it and removing the solvent by light suction. We attach much importance to thorough mixing of the blood immediately after it has been withdrawn; this is done by allowing the blood to be pumped by the heart's own action to the rim of the syringe needle and standing this for a few seconds in a vertical position. The well-mixed sample is then distributed into the required number of glass capillaries made from ordinary glass tubing and having an internal diameter of from 2 to 3 mm. Several of these are filled from each sample of blood and are laid on the bottom of a flat metal dish, of which the under sid is immersed in a water-bath controlled thermostatically a 38.5° C. ± 0.3. Portions of the capillaries are broken o from time to time and examined; as soon as a clot is forme —easily observed by breaking the capillary and pulling th two pieces apart—the time is noted as the crude blood-clotti time of the sample. Good agreement is shown by duplica samples and, as will appear below, quite reasonable cons tency in a group of animals receiving the same dose.

Samples of the compound have also been tested for th effect on the "prothrombin time" as recommended Almquist and Klose (1939a); here again significant lowerin the prothrombin time was obtained with doses of the s order as those producing significantly lowered crude bl clotting times. Two portions of the same sample can be to determine both blood-clotting time and prothrombin

In spite of the practice of a number of investig who attempt to define in "units" the vitamin K ac of methyl-naphthoquinone or other substances sh vitamin K activity, it is not, in the absence of a sta preparation for vitamin K, desirable to make more a qualitative statement as to the activity of such substances.

---

* Received for publication on October 13, 1939.

Indispensable prerequisites to standardization are the elaboration of methods having as low an inherent error as possible and the preparation of a stable standard material. A recent test carried out by us on one sample of methyl-naphthoquinone seems to indicate that this should not present insuperable difficulties. The doses given to the individual animals were divided into four equal portions and administered apart from the basal diet, as described above. The animals were killed five days after the first dose, the final twenty-four hours representing a no-dose period designed to eliminate any irregularities of response due to delayed absorption. Blood was collected in the manner described and the prothrombin times of all samples were determined, as well as the crude blood-clotting times. The results of both sets of measurements are given in Tables I and II and illustrated in Fig. 1. It will be observed that in our hands determination of crude blood-clotting times appears to offer a better means of biological assay than determination of prothrombin times, contrary to the recent finding of Almquist and Klose (1939a); nevertheless, the two sets of results follow the same general trend.

TABLE I

Dose of Methyl-naphthoquinone (microgrammes)	Number of Chicks	Crude Blood-clotting Times in Minutes			Prothrombin Times in Seconds		
		Mean	Coeff. of Variation*	Standard Error of Mean	Mean	Coeff. of Variation*	Standard Error of Mean
Nil	10	All animals gave over 30 minutes: six gave over 40			Not determined		
0.4	7	23.6	22%	2.0	86	35%	11.4
0.8	9	16.0	24%	1.3	59†	24%	5
1.6	10	9.8	18%	0.55	53	32%	5.5
3.2	7	4.4	20%	0.31	27	37%	3.7

* $\frac{100 \times \text{standard deviation}}{\text{mean}}$ † Eight animals only.

TABLE II.—P (*Probability that Differences are due to Chance—that is, to Random Errors of Sampling*)

Doses (microgrammes)	Crude Blood-clotting Times	Prothrombin Times
0.4 and 0.8	1 in 20	1 in 20
0.8 and 1.6	Less than 1 in 1,000	1 in 3
1.6 and 3.2	Much less than 1 in 1,000	1 in 1,000

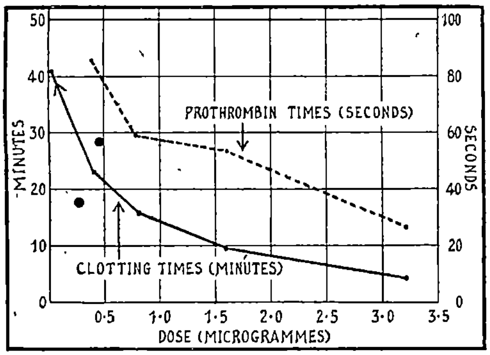

FIG. 1.—Showing the effect of 2-methyl-1:4-naphthoquinone on the crude blood-clotting times and the prothrombin times of vitamin-K-deficient chicks.

The relation between y, the response (crude blood-clotting times), and x, log dose (in microgrammes), is found to be expressed by the equation: $y = 14{\cdot}6 - 21.9x$. The usual test was applied to the plotted points for departure from linearity of regression, but the mean square due to "deviations from linear regression" was less than that "within doses." The value of z was -0.40 with a 5 per cent. point of 1.5. Hence there is no significant departure from the linear relation.

Thayer *et al.* (1939b) have suggested the use of 2-methyl-naphthoquinone as a suitable standard preparation for the assay of vitamin K; it was with the same idea that we prepared (before their publication was available) the dosage/response curves shown in this paper. It seems to us, however, that the argument can be developed a stage further. If the methyl-naphthoquinone is found to have the same therapeutic action on human patients as concentrates of naturally occurring vitamin K it would be possible to dispense altogether with biological assays and the need for a standard preparation—except in so far as estimates of vitamin K in different food materials were required for use in dietary surveys. This possibility appealed to us the more in that the biological tests cannot, in our experience, be depended on always to give clear-cut results. The mean blood-clotting time produced by the same dose of vitamin K in different groups of chicks varies, as does the difference in mean blood-clotting times produced by a given difference in dose level. In other words, the test has a high inherent error, due both to high variance of the animals in a test group and also to variations in the slope of the dosage/response curve. Although a number of workers have published particulars of tests carried out at various dose levels (notably Ansbacher, 1939, and Thayer *et al.*, 1939c), such publications have not always included adequate statistical analysis of the results.

As Thayer *et al.* (1939b) have pointed out, the methyl-naphthoquinone needs no biological assay; its purity can be established by chemical and physico-chemical tests. The methods of Pinder and Singer (1939) can afford far greater guarantee of purity and potency than any test on animals. One of us has therefore investigated the effect of pure 2-methyl-1:4-naphthoquinone itself on a short series of cases; the substance was administered as a sterile solution in olive oil.* Unfortunately the investigations had to be abruptly stopped owing to the outbreak of war; it was, however, thought that the results warranted publication.

The prothrombin times of these cases were estimated by the method of Quick *et al.* (1935) and the prothrombin indices expressed in the manner described by Illingworth (1939). It will of course be realized that the "prothrombin index," as distinct from the "prothrombin time," determined in the chick experiments, is directly related to the blood-clotting time. As this decreases and the patient's condition improves, so the prothrombin index increases; the prothrombin time of Almquist and Klose diminishes with increasing doses of vitamin K or methyl-naphthoquinone.

Case I

A man aged 62: this patient had been ill for eight weeks. At the onset of the illness his appetite became poor and fatty foods began to upset him. A week later jaundice appeared, and progressed steadily till the time when he was first seen. The jaundice was of an obstructive type.

On examination marked jaundice was present. There was slight guarding of the muscles of the right upper quadrant of the abdomen. No enlargement of liver, gall-bladder, or spleen was detected. The prothrombin index was 29 per cent. Naphthoquinone 10 mg. was given intramuscularly; 5 mg. was given next day, and 5 mg. on the third day. The prothrombin was again estimated, and found to be 78 per cent. At this time he had some vomiting and nausea, which passed off in two days. On the sixth day the prothrombin was 93 per cent., no more naphthoquinone having been given since the third day. On the eleventh day he was operated upon and extensive adhesions and a large carcinoma of the pancreas were found; cholecyst-gastrostomy was performed. There was a moderate ooze at operation. He was given 5 mg. of naphthoquinone that day and the next. On the third day after operation he was given 5 mg., and the prothrombin was 100 per cent.: he was somewhat drowsy. From the fourth day after operation onwards he had 10 mg. naphthoquinone daily by mouth. On the seventh day after operation the prothrombin was 93 per cent. By this time he was drowsy and confused. The cholecyst-gastrostomy did not function. He died on the eighth day after operation.

* Available under the name of "kapilon" G.L., as 0.5 per cent. solution in 1 c.cm. ampoules.

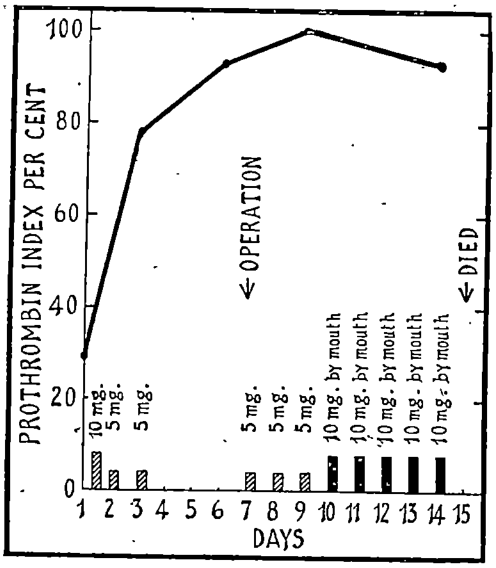

Fig. 2.—Chart of Case I.

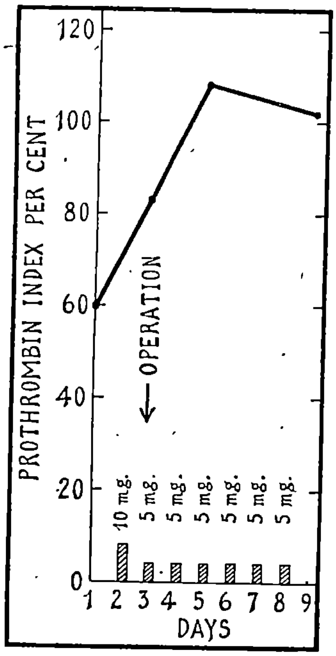

Fig. 3.—Chart of Case II.

Case II

This patient was a woman aged 69 who had had digestive symptoms for two years. She suffered chiefly from nausea and flatulence. For a year or so she had occasionally been jaundiced, and on admission had been jaundiced for three months. She had a constant dull ache in the epigastrium.

On admission she was moderately jaundiced. There was tenderness and slight guarding of the muscles in the epigastrium. No enlargement of liver or gall-bladder was detected. There was no evidence of functioning gall-bladder on radiological examination. The prothrombin index was 60 per cent. She was given 10 mg. of naphthoquinone next day and 5 mg. daily by intramuscular injection thereafter. On the third day the prothrombin was 83 per cent. She was operated upon that day, and carcinoma of the liver and bile ducts was found: no relief of the jaundice was possible. On the second day after operation the prothrombin index was 108 per cent. She was feeling better. On the fifth day the administration of naphthoquinone was stopped. Next day the prothrombin was 102 per cent. Her condition was stationary. The patient was evacuated from hospital and lost sight of.

Case III

This case was that of a woman of 69 who had had silent progressive jaundice for three weeks before she was seen. For a week or so she had had severe vomiting after food—even water made her sick. On examination she was very frail and weak. Marked jaundice was present. No enlargement of liver or gall-bladder was detected. Operation was deemed inadvisable. The prothrombin index was 37 per cent. She was given 10 mg. of naphthoquinone intramuscularly on the first day, 5 mg. on the second day, and 5 mg. on the third day. By this time the prothrombin index had risen to 125 per cent. There was some difficulty in getting the specimen of blood; this may explain the exceptionally high figure. On the fourth day 5 mg. of naphthoquinone was given, administration thereafter being stopped. Her clinical condition remained the same until the seventh day, when the index was 98 per cent.

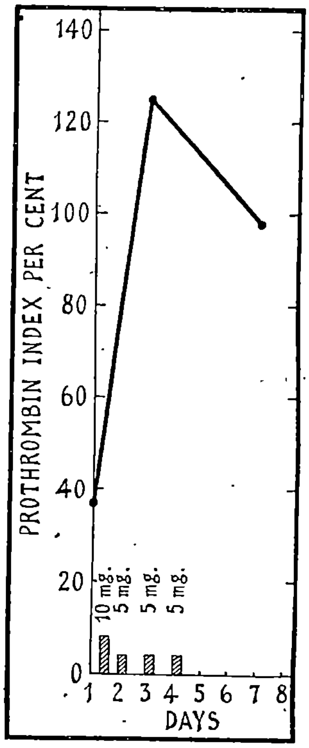

Fig. 4.—Chart of Case III.

Case IV

This patient, a man aged 55, had a five-months history of illness. At the beginning he had abdominal pain and diarrhoea, followed two days later by jaundice, which responded partially to treatment as catarrhal jaundice. The condition persisted, and when first seen he was a well-covered man showing marked jaundice. The gall-bladder was enlarged and palpable. The prothrombin index on the first day was 39 per cent. At 9 p.m. he was given 10 mg. of naphthoquinone; at 8 a.m. next day he received a further dose of 10 mg. A specimen of blood was taken at 9 a.m., and the prothrombin index was 78 per cent. At operation two days later a large carcinoma of the pancreas was found: a cholecyst-enterostomy was done. The writer was then called away. On the fourth day after operation the index was estimated

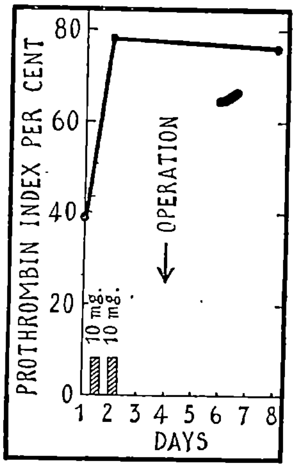

Fig. 5.—Chart of Case IV.

by Dr. A. G. R. Lowdon and found to be 76 per cent., no naphthoquinone having been given in the interval.

Commentary

The problem of haemorrhage in jaundice has recently been reviewed by Illingworth (1939).

Butt, Snell, and Osterberg (1939) found that the effects of intramuscular administration of vitamin K concentrates were not striking. The results herein reported of the use of 2-methyl-1 : 4-naphthoquinone as a synthetic substitute for natural vitamin K are most striking. This preparation, when given to four cases of obstructive jaundice with low prothrombin indices, has raised the index considerably in all of them within two days. In the last case the change was evident within twelve hours: it is probable that the effect was present in the other cases at that stage too, but was not recognized because the index was not estimated soon enough. It is hoped that, when conditions are favourable, further work will be done on the question of the rapidity of this change.

The results suggest that the intramuscular use of this synthetic product is effective in raising the prothrombin index in cases of obstructive jaundice. Its value in the prevention and treatment of haemorrhage in jaundice is apparent. The rapidity of its effect as shown in Case IV —within twelve hours—suggests that it may be particularly valuable in the treatment of post-operative bleeding in jaundice. There was no opportunity of investigating this in the present series of cases.

Our thanks are due to Professor Illingworth for his kindly encouragement and advice, and the thanks of one of us in particular (J. M. M.) to the physicians and surgeons to the Royal Infirmary of Edinburgh for allowing access to their cases; we are also indebted to Mr. T. Middleton for technical assistance in the experiments with chickens.

Addendum

While this paper was in the press we have learnt from Dr. K. K. Nygaard, who has described the successful use of vitamin K concentrates in the treatment of neo-natal haemorrhage (1939), that 2-methyl-1: 4-naphthoquinone is also effective. He writes: "A dosage of 5 mg. intramuscularly and 5 mg. per os seems sufficient. The prothrombin content is usually within normal limits after ten to twenty-four hours. The same dosage is used parenterally for prophylaxis, the injections being performed after the delivery of the baby."

THE SIMPLIFICATION OF TECHNIQUE IN PERORAL ENDOSCOPY*

BY

V. E. NEGUS, M.S., F.R.C.S.

Surgeon for Diseases of the Ear, Nose, and Throat, King's College Hospital

Peroral endoscopy is a difficult and dangerous art, and for most of us who practise it everything must be done to simplify the technique. Even with every available aid that can be provided there are still many failures and disasters. It is impossible for the average laryngologist to emulate the success of those who devote their whole lives to this branch of surgery, nor do many possess the necessary skill. For my part I have recognized my limitations, and have constantly endeavoured to make such alterations as appeared practicable—not with the ambition of improving on the work of my teachers but rather to make up for lack of skill by simplification of methods and thereby to obtain some measure of success.

Anaesthesia

For the safe performance of *endoscopy* the patient must lie quietly for as long as desired, without changing position and without being restrained. If this desideratum is not attained there will be mental anxiety for both surgeon and patient and greatly increased difficulties in manipulative technique. It is essential that the operator should not be hurried.

I myself prefer to carry out *oesophagoscopy* under general anaesthesia, except when dealing with cases of cardiospasm. The tubes used are of large size, and the manipulation is often lengthy, as, for instance, in the insertion of radon seeds. It is most important that the position of the subject should remain unchanged, otherwise perforation of the mediastinum or aorta might follow. Particularly during the removal from the oesophagus of sharp foreign bodies such as bones or pins, complete relaxation and immobility must be obtained, and for this type of work I consider general anaesthesia to be essential in every case. A preliminary basal anaesthetic, such as avertin, paraldehyde, or morphine and scopolamine, is given, followed by intratracheal administration of gas-and-oxygen.

Bronchoscopy is far less upsetting than oesophagoscopy, especially as, in my practice, large oesophagoscopes are employed. In adults bronchoscopy and laryngoscopy may be carried out satisfactorily under local anaesthesia, after a preliminary injection of morphine and scopolamine. Children are more readily examined after being given a rectal injection of paraldehyde; this by itself is usually sufficient, but if there is much restlessness a little inhalation anaesthetic may be required.

Position of Patient

The use of a head-rest, elaborated from that of Haslinger, facilitates endoscopic procedures for the majority of surgeons. There is then no necessity for a skilled assistant to hold the head, nor is there any change of position, however long a time is taken in examination or manipulation. The position of the patient is under the direct control of the surgeon and can be regulated minutely. With a head-rest there is no necessity for the operator to alter his position: the table is raised or tilted so as

---

[*] Read in opening a discussion in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

to bring the lumen of the bronchoscope or oesophagoscope into line with the surgeon's eye. This is of especial advantage in examining the lower end of the oesophagus, when a crouching position would be necessary if the table remained stationary. Arm-rests keep the patient's body in a central position and replace a second assistant. Instruments are kept at hand in a sterilized holder or quiver, and are thus readily available.

Instruments

Laryngoscopes.—To facilitate examination of the larynx an attempt was made to produce an instrument with an unobstructed lumen but with a powerful beam of light thrown beyond the lower aperture. This desideratum was attained by the use of twin lights set obliquely into the walls of the laryngoscope, provided with lenses to focus each light into a parallel beam; the two beams overlap just beyond the lower aperture of the tube. The instrument designed is evenly balanced and is easily sterilizable.

Bronchoscopes have been designed with slight changes from those of Chevalier Jackson. The upper third, which remains in the mouth and pharynx, is funnel-shaped, so as to give more room for inspection and for the introduction of instruments. The light and its carrier are extremely thin, and are carried in a groove and not in a tube; with small bronchoscopes the consequent gain of a millimetre is of considerable advantage. Distal illumination is relied on, with the addition of an attachable proximal projector for general inspection of the bronchi on occasion; oblique lighting, as used in my laryngoscopes and oesophagoscopes, is unsuitable for bronchoscopes.

The *oesophageal specula* and *oesophagoscopes* have been designed on lines similar to the laryngoscopes already described. The obliquity of the lamp must be so designed that the full beam of light can pass uninterruptedly out of the lower aperture of the instrument, without any reflection from the walls. It is an advantage, in fact, if the walls are dull; they must never be polished. Any light reflected from the walls dazzles the operator and impedes his manipulations. The oesophagoscopes used are very large, up to a full size of 20 x 18 mm. It is sometimes forgotten that the oesophagus is wide and lax; it is more readily examined if held open by a big speculum or oesophagoscope, thus enabling a comprehensive view of the whole viscus to be obtained without movement of the instrument. The bronchi, on the other hand, are relatively narrow and rigid, and will only accommodate tubes of a size too small to be effective in the gullet.

Endoscopic Trolley.—A movable trolley, containing a powerful and silent suction pump, is used; the pump can produce a complete vacuum, which is of advantage when fine bronchoscopic suction tubes are in use. Rheostats are built into the trolley to transform current from the main down to the desired voltage. All the controls are detachable and sterilizable, thus enabling the operator to adjust the lights for himself.

Forceps.—The forceps used are made with an extended sliding tube, to prevent bending of the stylet.

Suction Tubes.—Bronchoscopic suction tubes are made with a flexible end of gum elastic to allow of easy introduction into bronchi diverging from the main stem.

Dilators.—Dilating bags of two sizes are used, mounted on a flexible gum-elastic end connected to a metal tube. They can be passed through strictures under direct vision.

Eye Shield.—To enable a clear view to be obtained throughout a bronchoscopic examination a glass shield is employed. It consists of a toughened glass disk, sterilizable by boiling. The disk, if soiled, can be rotated so as to bring a clear area in front of the operator's eye.

Conclusion

The goal to be attained is the establishment of efficient endoscopic centres in every large town and city, in charge of capable surgeons. It is my sincere hope that the technique described may be of help in fulfilling this object.

TREATMENT OF GASTRO-INTESTINAL ACHALASIA BY SPINAL ANAESTHESIA

BY

E. D. TELFORD, B.Chir., F.R.C.S.

Emeritus Professor of Surgery, University of Manchester

AND

H. T. SIMMONS, M.D., Ch.M., F.R.C.S.

Research Fellow, the Royal Infirmary, Manchester

The mechanism of gastro-intestinal peristalsis is not yet fully understood. The smooth muscle of the tube is under the control of the autonomic nervous system, but the exact extent of this control is not known, because an unknown but not inconsiderable part in peristalsis is played by the automatic action inherent in the smooth muscle cell. Of the two antagonistic or complementary halves into which the autonomic system is divided it would appear that the sympathetic is the "filler" nerve, whilst the parasympathetic is more concerned with propelling material along the tube. This view is possibly too simple to be true, because it may be that the action of either of these systems will vary with the state of the tube at any given time. There is, however, considerable evidence, clinical and experimental, for the view that the sympathetic system, by its control of sphincteric action, maintains a section of the tube in a full condition, and on relaxation of the sphincteric action the parasympathetic passes the contents along the tube.

Such mechanism implies a delicately co-ordinated balance between the sympathetic and parasympathetic systems, and if for any reason that balance is disturbed some disorder of function will result. Should the imbalance take the form of over-action of the sympathetic or of under-action of the parasympathetic there will be a failure of sphincteric control adequately to relax, with the result that the section of tube above the obstruction will in course of time become dilated and hypertrophied. To this failure of sphincteric action to relax Hurst has given the name of achalasia, and in this condition is to be found the most likely explanation of congenital megacolon and of mega-oesophagus (the so-called cardiospasm).

Congenital Megacolon

There can be no doubt that, while many of the less severe forms are amenable to medical measures, the treatment of the more severe types should be by surgery. The earlier interventions of the surgeon took the form of resections or short-circuiting. These methods, always dangerous and often futile, were discarded when the neurogenic basis of the disease was discovered, and the attack was then directed to an interruption of the sympathetic supply. This method, carried out in various ways, has given most excellent results, but a recent paper by Stabins, Morton, and Merle Scott (1935) causes one to doubt whether these operations are really necessary for the cure of congenital megacolon. These writers have made the important observation that in a number of cases of congenital megacolon in which a spinal anaesthetic was given purely for diagnostic or prognostic purposes the patients, on subsequent examination, were found to be "practically completely cured."

As the result of this suggestion we have, since January, 1938, treated six cases of congenital megacolon in children by spinal anaesthesia alone, and to these we are able, by the courtesy of Mr. R. L. Holt, to add a seventh case. These seven cases were all severe types of the disease, suffering from most obstinate constipation, with radiological evidence of an enormously dilated redundant colon. They showed also in a marked degree the sallow facies, the under-development, and the lethargy, both mental and physical, which are always so striking a feature of the severer types of the disease. The patients were six boys and one girl, and their ages ranged from 6 months to 12 years.

The spinal anaesthetic was with two exceptions given by Dr. Falkner Hill, the drug used being decicaine in heavy solution. The nature of the drug used is probably immaterial, but it is essential that the upper limit of anaesthesia should reach the anterior root of the sixth thoracic nerve. This is necessary to ensure that the whole of the sympathetic supply to the gut is affected by the anaesthetic. The after-treatment has consisted of a regular daily dose of liquid paraffin, with a simple enema on alternate days. This treatment has been carried out for two weeks only.

Each case has been regularly examined since the anaesthesia, and all the children have been seen within the last month. The results are remarkably satisfactory. Four of the children are completely cured, and have had neither purgative nor special diet since they left hospital—they each have a normal daily motion. Three are almost completely well, but still need a small weekly dose of a mild laxative. In all cases there is evident the same gain in weight, colour, and energy as is seen after a successful sympathectomy. Those which have been re-examined by barium enema show that although function is perfect the enlarged bowel has not returned to normal, but is about half its former size. This again is in keeping with the radiological findings after sympathectomy.

Case Histories

Case 1.—A boy aged 11½ years. Severe constipation since birth. Had been given enemata regularly, but averaged ten days between motions. He was undersized, sallow, and lethargic. The abdomen was distended and contained several large faecal masses. Barium enema showed gross dilatation of the descending and pelvic colon, with an extra loop of pelvic colon. A spinal anaesthetic was given on January 16, 1938, and resulted in complete cure of the symptoms. The boy is now well grown, of good colour, and is doing well at school and games. He has had no purgative medicine since leaving hospital.

Case 2.—A boy aged 4½ years. Constipation since birth. Under treatment in hospital the bowels acted twice in ten days. A thin pale child with distended abdomen. Spinal anaesthetic given on January 20, 1938. This patient has shown great improvement. His general condition is now excellent, but a small occasional dose of paraffin is still needed. (Mr. R. L. Holt's case.)

Case 3.—A boy aged 10 years. History of constipation from birth, alternating with long periods of "diarrhoea." On admission he had several fluid motions in the day. These were due to a retention colitis. The distended abdomen showed several faecal masses, one as large as a coconut. Spinal anaesthetic on May 24, 1938. This patient remains completely cured. No purgatives are needed, and the improvement in his general condition is evident from the fact that he has gained a scholarship at his school and has distinguished himself in swimming.

Case 4.—A boy aged 12 years. Always constipated, and on two occasions admitted to a hospital for "obstruction." On admission he had a distended tender abdomen with colic. The bowels were unloaded with difficulty. A barium enema showed "a very distended colon with poor haustration." Spinal anaesthetic on July 14, 1938. He has been seen regularly, and the last note reads: "Result most satisfactory. General condition excellent. Good colour and full of energy. Bowels move daily without aid."

Case 5.—A boy aged 9 years. Had always been constipated, and averaged seven days between motions. A thin sallow boy with enlarged abdomen and palpable pelvic colon. Spinal anaesthetic on October 6, 1938. This boy remains almost completely cured, but needs a "chocolate laxative" once a week. He is growing well, is of healthy colour, and is very active.

Case 6.—A girl aged 5 years. A thin, under-developed, and very sallow child who has needed regular purgatives and enemata since birth. Frequent abdominal colic and occasional vomiting. Had a distended abdomen, and the barium enema showed "much dilatation of the colon, chiefly in the rectal and pelvic sections." On January 17, 1935, a lumbar sympathectomy was attempted under general anaesthesia, but owing to an anaesthetic mishap it is certain that the operation was incomplete, and no benefit resulted. On October 21, 1938, she was given a spinal anaesthetic, since when she has been much improved. She needs senna once a week. A barium enema given on July 7, 1939, showed "slight ballooning of the rectum and distal part of the pelvic colon. The proximal part of the pelvic colon shows lack of haustration. The rest of the colon shows normal haustration and appears to be of good tone."

Case 7.—A boy aged 6 months. Constipation since birth, with an enormous abdomen and "very definite radiological evidence of enlarged colon." This case had been very thoroughly treated in a special hospital, but without any improvement in the condition. The baby was under weight, and the abdomen was enormous, with wide separation of the recti. A spinal anaesthetic was given on February 14, 1939, and from that time the bowels have acted daily without assistance. The child is now of normal weight and colour. The abdomen has steadily diminished in size, and the infant now appears normal in every way.

Mega-oesophagus (Cardiospasm)

This condition is now regarded as an achalasia, or failure of the cardio-oesophageal sphincter to relax. This causes the obstruction to which the dysphagia, the oesophageal dilatation, and the other distressing symptoms are due. The treatment has so far proved difficult and disappointing. Some of the less severe cases are able to carry on by periodical use of the mercury bougie. The more severe have been treated by retrograde digital dilatation, or by the attempt to establish an anastomosis between the stomach and the dilated oesophagus. Owing to the difficulties and grave dangers of these methods Knight's (1934) suggestion that the sympathetic supply to the cardiac sphincter might be interrupted by the simple operation of resection of the left gastric artery was received with enthusiasm. The operation was practised by several surgeons, but most unfortunately the results have not justified the hope that was aroused. Our own experience of the operation is limited to three patients, in only one of whom was there a slight improvement. The failure of this easy and attractive procedure is explained in a paper by Mitchell (1938), who has shown that those fibres which accompany the left gastric artery are merely one part of what is in fact a very complex innervation, and that Knight's operation must inevitably fall short of a complete sympathetic denervation of the sphincter.

In view of the good results obtained in cases of megacolon by spinal anaesthesia alone it seemed to us obvious that the same method should be tried in mega-oesophagus. Accordingly, when in July, 1938, a very typical example of mega-oesophagus in a young man was referred to us for treatment, we asked Dr. Falkner Hill to administer a spinal anaesthesia which should include the first thoracic nerve, and so paralyse the whole of the sympathetic outflow from the spinal cord. This was done, and on the same evening his power of swallowing was completely restored, and he has not had the slightest difficulty with any type of food since the anaesthesia. Short notes of the case are as follows:

A male slipper worker aged 26 had suffered from dysphagia during two years. Difficulty was always present. At the best he could get down some solid food with the help of copious drinks, but often a whole meal was returned unaltered a few minutes after he had eaten. He had lost one and a quarter stone in weight, was very weak, and was unable to work. Routine clinical examination showed nothing abnormal. The radiological examination revealed an enormous oesophagus with a rounded cul-de-sac from which emerged a thread-like trickle of barium. Spinal anaesthesia, including level of T.1, was given on July 29, 1938. The relief of symptoms was immediate and complete. A barium swallow some six months afterwards showed that the bulk was passed direct into the stomach. The oesophagus was still large, but had been reduced to about a half of its former size. A portion of the barium was held up in the cul-de-sac. It will be noted that this finding is exactly similar to those in successful cases of megacolon, in which, although function is fully restored, the anatomical restoration is far from complete. The patient remains completely cured, and in July, 1939, he wrote: "My cure is maintained. I ate yesterday toast, cheese, potatoes, onions, and kippers. My weight has returned to 10 st. 4 lb., which is as much as I ever weighed."

Discussion

We offer no explanation of these results from the use of spinal anaesthesia alone, but think it worth while to record the facts which have emerged from this work. The temporary but complete knock-out administered to the sympathetic supply appears to have brought the two halves of the autonomic system once more into step.

Although mega-oesophagus may be of congenital origin, it is a fact that in later life the actual onset of symptoms is in some patients precipitated by a shock, and it may be that the further shock of the spinal anaesthetic corrects the imbalance. Mega-oesophagus is a rare condition, and it is unlikely that any one surgeon will meet with a number of cases large enough to permit an authoritative opinion on its treatment. We therefore publish this single instance in the hope that this simple treatment may be put on trial.

The ever-present handicap to the successful treatment of disease by interventions aimed at the sympathetic nervous system is the existence of secondary fibrotic changes in the affected organ. This fibrosis eventually converts the viscus into a fibrous bag and progressively destroys the normal neuromuscular mechanism, on the restoration of which the operation depends for its success. For this reason the method we describe, if it is to succeed at all, will be more hopefully tried in the earlier cases.

Summary

Seven cases of megacolon in children have been treated by spinal anaesthesia alone with excellent results.

A case of mega-oesophagus (cardiospasm) treated by spinal anaesthesia remains completely cured.

DIPHTHERIA PROPHYLAXIS

A REVIEW OF THE ANTIGENS AND METHODS AVAILABLE

BY

J. TUDOR LEWIS, M.D., D.P.H.

(From the Health Department of the County Borough of Croydon)

Attention has been directed in earlier communications (Lewis, 1939a, 1939b) to the lack of uniformity in the current processes adopted in this country for controlling diphtheria by active immunization. A questionary issued by Dr. O. M. Holden, the medical officer of health for Croydon, to the medical officers of some 140 of the larger urban authorities revealed an astonishing miscellany of method, not confined to the organization of the schemes but extending to the antigens themselves. Quite clearly there is no consensus of opinion on the merits of the various preparations.

A review of the literature was made for the purpose of this paper, but it has been sacrificed to the present urgent pressure on editorial space. Some of the earlier workers in this field reported rather low rates of conversion to the Schick-negative condition after the use of various antigens, though little doubt can remain in one's mind that by the proper use of toxoid—T.A.M. or T.A.F.—highly satisfactory results can be obtained. Up to 1938 in this borough approximately 99 per cent. of children who had previously received three injections of T.A.M. or T.A.F. were found to be Schick-negative. Glenny and colleagues (1926, 1931a, 1931b) discovered the antigenic advantage resulting from the employment of alum with toxoid. For some time certain workers used these alum preparations in one dose—the so-called "one-shot" method—but in some series a disappointingly high percentage of the children were found to be Schick-positive when tested later. Chesney (1936), on the suggestion of Dr. R. A. O'Brien, used a first small dose to "detect" children who were unusually liable to troublesome reactions, followed four weeks later by 0.5 c.cm. In groups of 185 children in 1936 and 1,555 in 1938 and 1939 Chesney (1938, 1939) obtained a 99 per cent. Schick-negative rate four weeks after the second injection. A number of authors quote percentages from 97 to 100.

Results obtained in Croydon

It may help, at a time when large numbers of town children are being transported to rural and potentially susceptible districts, to give the results that have been obtained in the county borough of Croydon. With three fortnightly doses of 1 c.cm. of T.A.M., 2,163 children originally Schick-positive gave a conversion rate to Schick-negative of 99 per cent. A.P.T. was given to 1,039 children—760 originally Schick-positive and 279 not

Schick-tested. At first the earlier dose was 0.1 c.cm., but, since virtually no reactions were met with, this dose was increased to 0.25 c.cm., and the period between inoculations lengthened from two to four weeks; 99 per cent. of the children, tested eight to twelve weeks after the second injection, were Schick-negative.

One of the supposed disadvantages that have militated against a more general use of A.P.T. is its alleged tendency to cause severe reactions. In the present series the parent of each child was specifically asked what discomfort, if any, each injection had caused. "Discomfort" was accepted as a reaction if the child had himself complained without being questioned; or if he were obviously unwell within a day or so of the injection, there being no other explanation of his malady. In the accompanying table are given the reactions that were recorded. Thirty-five of these were mild and occurred after the first injection of 0.1 to 0.25 c.cm.; eight were severe, seven occurring after the first injection and one after the second injection.

Reactions after A.P.T.

Age Group	Total Cases	Total Reactions	Reactions %
1–5	402	4	0.99
5–8	334	11	3.3
8–10	154	9	5.8
10–14	192	19	9.9
1–14	1,082	43	3.9

Of the eight severe reactions one occurred in a child aged 5, three in children aged 8, three in children aged 9, and one in a child aged 14. There was a slight superficial fluctuation in one case, which, however, resolved without incision. The others consisted of extensive redness with brawny swelling extending over the whole of the back of the arm, with pain and tenderness, lasting in some cases for more than three weeks. Only one severe case occurred in 736 children under 8 years of age and seven in 346 children of 8 years or more, a percentage of 2. So far, therefore, as fear of reactions is concerned, it is safe to give 0.5 c.cm. as a first injection to children under 8 years; over 8 years, with two severe reactions per 100 children, it will be wise to limit the first dose to 0.25 c.cm.

Discussion

The results obtained by some workers with T.A.M. and T.A.F. have varied widely, and those following the use of "one-shot" A.P.T. have been so diverse as to make this method clearly untenable. All the reports of the use of two injections of A.P.T. are in accord with a consistently high Schick-negative rate. The fears of reactions after A.P.T. seem to have been ill founded, as the table clearly shows. No doubt in the early days high proportions of reactions were registered, but the manufacturers are now able to produce a very refined product, so that it may soon be justifiable to consider whether larger dosage should not be employed. These well-documented facts should go a long way towards giving A.P.T. by two injections a more accredited place in immunization schemes. This method is now employed in a little over 40 per cent. of schemes investigated (Lewis, 1939b); there is no reason why the other 60 per cent. should not have equal confidence in its efficiency.

Summary

In Croydon 2,163 children originally Schick-positive gave a conversion rate to Schick-negative of 98.9 per cent. when tested three months after three injections of T.A.M.

A group of 760 children originally Schick-positive and 279 not previously tested were given two injections of A.P.T.—mostly 0.25 c.cm. followed by 0.5 c.cm. four weeks later. The former group gave a conversion rate to the Schick-negative condition of 99.2 per cent.; the latter group 98.9 per cent. No significant difference was found in different groups aged from 1 to 14. The number of reactions was small and no serious trouble occurred. This method of preventing diphtheria merits a greater popularity than it at present enjoys.

I wish to record my thanks to Dr. O. M. Holden and Dr. D. D. Payne, medical officer of health and deputy medical officer of health respectively of Croydon, for help in the preparation of this paper; and to the former for permission to publish it.

Clinical Memoranda

Fractured Femur due to Muscular Violence in a Case of Epilepsy Treated by Epanutin

This case is of particular interest from two points of view. First, although fracture of the femur as the result of the muscular violence of a cardiazol or triazol convulsion is now a recognized entity, an extensive search of the literature failed to reveal such an occurrence due to the muscular violence of an epileptic fit. Secondly, in view of the present vogue for the use of epanutin in the treatment of epilepsy the possibility that this fracture may be a complication of its administration is worthy of note.

CASE HISTORY

A man aged 37 was admitted to Cane Hill Mental Hospital on June 17, 1938, suffering from "insanity with epilepsy." He was subject to many fits, the majority of which were nocturnal. From the time of his admission until March, 1939, he was given 1 grain of sodium luminal thrice daily. During this period he had bouts of confusion both before and after fits. He was querulous, quarrelsome, and bad-tempered, and at times impulsively aggressive to the patients or nursing staff.

On March 9, 1939, he was given epanutin. A complete transference was effected, so that his sole medication was one capsule of epanutin thrice daily. On this his temperamental condition began to improve, but he still had many fits. On April 11 the dosage of epanutin was increased by a further capsule, given at 9 p.m. This produced a complete cessation of fits. From that day till the end of June (ten weeks in all) the patient had no fit. Unfortunately about six weeks after complete freedom from fits he started getting confused, and this gradually became worse. It remained continuously present and eventually necessitated bed treatment. As the patient had remained in this state for four weeks, on June 23 his epanutin was reduced to three capsules a day, with the idea of bringing on a fit.

On July 5 he had one fit during the day and one at night. He next had a fit on July 26 at night and another on the following night. The night nurse witnessed the latter fit and found the patient under the bedclothes, with these tucked in and in a normal position, so that there was no question of his having fallen. He recovered from his fit in the normal way. He made no complaints and at no time got out of bed, so the night nurse handed him over to the day nurse with no idea that he was injured.

Soon after the day staff had come on duty the patient complained of pain in the right thigh and knee. On examination I found that he had pain on the slightest movement of the hip-joint in any direction, and suspected a fracture. An *x*-ray photograph confirmed the existence of an intertrochanteric fracture of the neck of the right femur, but revealed no abnormality of bone structure or density. It is to be noted here that it was the opinion of the nursing staff that his fits during epanutin therapy, although much less frequent, were considerably more violent than on sodium luminal.

Until recently the explanation of this fracture would have seemed obscure, but the occurrence of intertrochanteric fractures directly due to the muscular violence of cardiazol convulsions described by Louis Carp (1939) and Hamsa and Bennett (1939) points to a similar explanation in this case. The missing link would seem to be the increase of the intensity, with the diminution of frequency, of epileptic convulsions during the treatment by epanutin.

I have to thank Dr. Lilly, medical superintendent of Cane Hill Hospital, for his permission to publish details of this case.

Donald Blair, M.B., D.P.M.,
Assistant Medical Officer, Cane Hill Hospital.

An Unusual Case of Ruptured Ectopic Gestation

The following case is reported because it presents certain unusual features—namely, a large ovarian cyst on the contralateral side, with an acute appendicitis, the whole being distinguished by a notable absence of clinical signs. From the point of view of differential diagnosis the patient presented a confusing clinical picture.

Case Report

On September 26, 1939, a married woman aged 29 was admitted to the Warneford Hospital, Leamington Spa, with the complaint of intermittent abdominal pain of four days' duration. She had enjoyed good health all her life, and was the mother of two healthy children, the elder born in June, 1937, and the younger in November, 1938. Both confinements were quite normal in all respects.

From the birth of her second child the menstrual cycle had been regular, and the onset of her last period took place on the morning of September 18, the flow ceasing four days later. No abnormality was noted at the time. On the following day she had an attack of abdominal pain of some severity. The pain was peri-umbilical and "colicky" in nature. It was sudden in onset, and was associated with a feeling of nausea and some active vomiting. The vomitus was bilious. The pain persisted, but altered in quality and site. It became dull and aching in character, and was occasionally maximal in the right iliac fossa, while at other times it was more severe in the left iliac fossa, flitting from one side to the other for no apparent reason. When felt on the left side there was also a complaint of pain "in the middle of the back." The nausea and sickness diminished in severity after a few hours. She stated that "her period began again" on the 24th; there was fresh vaginal bleeding, slight in degree. The vaginal haemorrhage and abdominal pain persisted, and on the evening of the 25th the pain became more acute, this time in the right iliac fossa, and she sent for her doctor, who arranged for her admittance to hospital.

On admission her general condition was good. The temperature was 100°, pulse 100, and respirations 20. The pulse was of good quality and regular; the blood pressure was 125/75. The mucous membranes were fairly well coloured, although the cheeks showed some pallor. Examination revealed some generalized degree of rigidity of the abdominal muscles, principally in the right lower quadrant. On the left side some pain was felt on palpation, but the pain was most acute just below McBurney's point. No hyperaesthesia was found. No mass could be palpated, and there was no asymmetry of the lower abdomen. Vaginal examination revealed some fullness in both right and left fornices, with tenderness maximal in the right. The position and size of the uterus were normal.

The abdomen was opened through a right lower paramedian incision, with the patient in the Trendelenburg position. No free fluid or blood was found. The appendix was acutely inflamed and pelvic in position. The offending organ was removed, the intestines having been packed off from the pelvic viscera. The fingers were passed into the left side of the pelvis and delicate adhesions freed. At once a considerable quantity of blood gushed up into the wound, and a mass was felt in the left tube, which was withdrawn for inspection. The tube was distended with blood clot and ruptured in its ampullary portion. The condition was diagnosed as the intraperitoneal rupture of a tubal gestation, and left salpingectomy was performed.

The right side of the pelvis was now explored and a large cyst of the ovary identified and exposed. The cyst was about the size of a tennis ball, and no ovarian tissue was visible macroscopically in its wall. It was a simple serous cyst and had destroyed the whole ovary. A right oophorectomy was performed. The pelvis and pouch of Douglas were mopped clear of blood and the wound closed in layers. The patient made an uninterrupted recovery.

Commentary

This case has several features of interest. The combination of ruptured ectopic gestation, acute appendicitis, and large ovarian cyst is in itself unusual, but the presence of such marked pathology with relatively so few clinical signs is even more unusual. It is also of interest to note the size of the ovarian cyst, as simple serous cysts are generally of smaller proportions.

The diagnosis of acute appendicitis was established before operation on the history of peri-umbilical colic settling down in the right iliac fossa plus the rigidity and tenderness in the appendix area; but the possibility of a coincidental ectopic gestation was borne in mind because of the mass in the left fornix on vaginal examination, the occasional pain in the left side of the pelvis, and the vaginal bleeding. It is noteworthy in this connexion that there was no history of a missed period or of any menstrual abnormality whatsoever, while the woman did not present clinically any signs of internal haemorrhage, and the pain felt upon vaginal examination was not in the left side but rather in the right. It was thus possible to establish an accurate pre-operative diagnosis as regards the appendix and tubal pregnancy, but the ovarian cyst was found only after opening the abdomen.

Certain authorities are opposed to the removal of an appendix when there is free blood in the pelvis, on the grounds that the blood forms an ideal medium for the growth of bacteria and the resulting development of peritonitis. Provided that the patient is in the Trendelenburg position, and the intestines are packed well off from the true pelvis, appendicectomy may be performed with safety, and, of course, when the organ is acutely inflamed no other alternative can be considered. The risk of pelvic or general peritonitis is slight.

George B. Mair, M.D., F.R.C.S.Ed.,
Senior Resident Surgical Officer, Warneford Hospital, Leamington Spa.

Reviews

INDUSTRIAL HEALTH AND PREVENTIVE MEDICINE

Health in Relation to Occupation. By H. M. Vernon, M.A., M.D. (Pp. 355; 50 figures. 15s. net.) London: Oxford University Press. 1939.

In this volume the author attempts to make an estimate of the relative importance in industrial health of three main conditions—heredity, social environment, and occupation. For this purpose a survey is made under various headings of many contributing conditions bearing on the major points. The extent of ill-health and its underlying causes are fully explored with the help of statistics, records, and graphs related to the subject-matter. The book is an important and comprehensive study of the great field of preventive medicine and its application to modern conditions of life in general and to industrial life in particular. Each chapter has its appeal to the student of preventive medicine, and the subject-matter is presented in a most readable style. Those on "Heredity and Environment," "The Nutritional Requirements for Healthy Life," "The Effects of Inadequate Nutrition," and "The Economic Factor" will be of particular interest to the general reader.

It will be obvious that the interdependence of the three main points presents an almost insuperable difficulty in arriving at a conclusion as to their relative importance. This is well illustrated by the study of intelligence. Primarily a hereditary factor, it has so obvious an effect on occupation and social environment that any attempt to evaluate its effect on each seems impracticable, however interesting the task may be, and of minor importance to the study of the remedies needed to deal with the problem as a whole. Important reference is made to B.M.A. reports, especially to those on Nutrition and Physical Education. This is gratifying in view of the scant acknowledgment in other quarters of this pioneer work of the Association.

The last chapter deals with general conclusions and the steps needed to improve the general health by prevention of disease. These in the main are eugenic advances, the raising of wages, and the improvement of medical services. We venture to suggest an even more important and basic remedy. In our view the most urgent need of to-day is the education of the public and the profession in preventive medicine. The B.M.A. reports already referred to stand as evidence that the profession is becoming conscious of a corporate responsibility to the public and the State. We are still waiting for something more than lip-service to the teaching of preventive medicine in our medical schools. Not till this is achieved will the family doctor, the medical officer of health, and the industrial medical officer work together in a common effort to advance the public health. Along with this is the need for the education of our school children in the primary laws of health and hygiene. It is in this direction that we look with most hope for the future health of the nation.

We congratulate the author on this book and commend it to the profession.

THERAPEUTICS

The Essentials of Medical Treatment. By David Murray Lyon, M.D., D.Sc., F.R.C.P.Ed., Professor of Clinical Medicine, Edinburgh University. (Pp. 448. 15s. net.) London and Edinburgh: Oliver and Boyd. 1939.

It is an encouraging sign that of recent years so many books have been devoted to treatment. Professor D. Murray Lyon's *Essentials of Medical Treatment* is in fact the second contribution from the Scottish schools this year, and one of decided merit. A perusal of its pages reminds us how greatly and in how many respects methods have been changing. From the point of view of the pharmacist this has not been an unmixed blessing. There is little scope for the chemist who used to take such pride in the preparation of his own fresh infusions and the elegance of his dispensing. Now much of his time is taken up in handing out packets of tablets and bottles of proprietary drugs, while much of his revenue comes from toilet articles. At a time when his training has become increasingly scientific, he finds a good deal of the scientific and technical interest of his occupation going.

But to return to the book before us. We were particularly impressed by the sections on artificial pneumothorax, gastric ulcer, and nephritis. The discussion on the therapeutics of digitalis and quinidine will also prove very helpful to the student. We were interested in the description of a postural method of treatment for obliterative arteritis to replace the expensive apparatus in vogue, and in the plea made for controlling blood sugar by giving insulin as long as two hours before a meal. Another specially interesting point is the suggestion that the occurrence of epileptic fits may depend on an increased hydration of the body. Pituitrin, by holding up the output of water, may greatly increase their frequency. We are reminded of the late Sir Maurice Craig's persistent belief in some pituitary factor in obese epileptics. Of late it has been urged that pituitary obesity may largely depend on water retention in the tissues. This justifies Professor Murray Lyon's opinion that measures tending to reduce the body content of fluid should help in the treatment of epilepsy. He does not, however, mention salyrgan among those measures, although it has proved helpful in pituitary obesity. We note that he supports the popular lay opinion that sugar is bad for arthritics by pointing out that they often have a lowered sugar tolerance, but we remain unconvinced that sugar is really harmful for arthritis unless complicated by obesity or glycosuria.

It is, of course, unlikely that a book of this kind would contain nothing which challenges dispute. Thus we do not like the idea of such a depressing drug as apomorphine for acute gastritis, while on the other hand we have not found vinum antimoniale "much too depressing for ordinary use" in doses up to 10 minims. It is true that leeching is seldom employed nowadays for acute pericarditis; more's the pity, for it seems to relieve pain quicker than anything else. Its desuetude is probably due to the difficulty in supply and application than to any ineffectiveness. It is also true that gelatin has the reputation of favouring coagulation in an aneurysm, in spite of the experimental evidence that it actually quickens circulation time. We are surprised to learn that bismuth covers the normal gastric mucosa but not an ulcer, because this makes it difficult to understand how an ulcer crater is detected radiologically. Is it correct to say that the cystin of cystinuria is partly derived from the food? The late Sir Archibald Garrod maintained that the patient could deal with his exogenous cystin perfectly well, and that the condition was entirely an inborn error of endogenous metabolism. Many authorities would not agree that it is unsatisfactory to allow a diabetic to pass just a trace of sugar (especially if protamine insulin is being used). Hypoglycaemia is a greater danger than hyperglycaemia. We would commend bismuth iodo-subgallate to the author's notice for the treatment of haemorrhoids, and we found no mention of the ambulatory treatment of phlebitis which is gaining ground. We don't think the thyroid is the leader of the endocrine orchestra. That phrase was originally applied to the pituitary, and recent work has strengthened its claim to that position. Professor Lyon quotes the old adage, "Feed a cold and starve a fever," with approval, but how does one apply it to a feverish cold?

Some of these refer to legitimate differences of opinion —and none of them serious perhaps—but a more serious one is the omission of any precautions in the use of sulphonamide, whether for septicaemia (p. 30) or for urinary infections (p. 215). The whole book, however, is attractively written and the facts are clearly presented. There is a very useful appendix describing the technique of such procedures as blood transfusion and lumbar puncture, together with some convenient prescriptions for ordinary use. Altogether a serviceable book for students and practitioners.

DISORDERS OF THE FOOT

Functional Disorders of the Foot. Their Diagnosis and Treatment. By Frank D. Dickson, M.D., F.A.C.S., and Rex L. Diveley, M.D., F.A.C.S. (Pp. 306; 202 illustrations. 21s. net.) Philadelphia, London, Montreal: J. B. Lippincott Company. 1939.

Disorders of the feet have of late been attracting much more attention than formerly. From the time of Ellis's classic in the last century to the appearance of the first edition of Lake's *The Foot* in 1935 no book devoted exclusively to foot disorders had been published in this country. Almost simultaneously, however, Dudley Morton's *Human Foot* was published in the United States, and it is possible to see the influence of both these recent books in the latest addition to the literature of the foot, *Functional Disorders of the Foot,* by Drs. Dickson and Diveley of Kansas City. Although the title might suggest that the book was very limited in its scope, this is not the case, for it includes such structural and organic disabilities as hallux valgus and rigidus, march fracture, calcaneal spurs, etc. In so far, however, as most organic changes produce disturbances of the function of the foot the title is justified, and it is proper to add that a large section of the book is devoted to the subject of "foot imbalance." In this section it is especially commendable that a large amount of attention has been given to the foot of the growing child and to the question of disturbances of foot balance in childhood. In the earlier chapters evolutionary development, anatomy, and physiology are briefly reviewed; the authors accept the ideas of Lake and Morton that the arches are architectural features of the foot and not mere postures. The importance of a short and hypermobile first metatarsal and of metatarsus varus in the production of "imbalance" of the foot is well stressed.

Particularly interesting are the authors' views on the correct type of footwear for children and adults; for the former the heel should be wedged on the inner side one-eighth of an inch higher than the outer, while the rigid shank should be moulded so as to support the developing longitudinal arch. A shoe of this type would be regarded in this country as a corrective shoe, but it is the authors' contention that it should become the correct standard type, since "in the growing foot it is more important to maintain it in a balanced position on the leg than to build up muscle control." To many imbued with the doctrine that muscular control is all-important in the maintenance of the form of the foot this suggestion of providing any artificial support to the growing foot will be anathema, but the reviewer believes there is much wisdom in the authors' statement that "ideal natural conditions [for the development of the child's foot] do not exist in modern life, as most of the child's weight-bearing is on hard and non-resilient surfaces which, instead of providing a suitable medium for exercise and development, put an additional strain on the growing foot from which it must be protected by shoes providing sufficient support to make up for an insufficiency in the foot caused by restraint on development."

These quotations are enough to show the general character of this work, and there is no need to go further to demonstrate that it is a very worthy addition to the subject of foot diseases. It is well and copiously illustrated; the printing and general format are of high American excellence.

OPHTHALMIC SURGERY

The Principles and Practice of Ophthalmic Surgery. By Edmund B. Spaeth, M.D. (Pp. 835; 1,031 figures; 4 coloured plates. 45s. net.) London: H. Kimpton. 1939.

Dr. Spaeth's book is a welcome addition to the sparse English literature on operative ophthalmology. None of the current volumes is recent, and none covers quite the same field as this, which deals not only with operative technique but with the whole background of the surgical aspects of ophthalmology. The book is thus a contribution to surgical ophthalmology rather than a textbook of operative surgery in the narrower sense. It is unique in this respect in English ophthalmic literature. It is also unique in its comprehensiveness, and its 820 pages cover satisfactorily a big field which has not been so fully dealt with before. How fully the author has covered his subject is shown by the fact that half of the text is devoted to extra-ocular operations. This does not imply that the more usual intra-ocular procedures which constitute the greater part of the ophthalmic surgeon's work are dealt with schematically, but it emphasizes Dr. Spaeth's wide knowledge of the less common operations and the satisfactory way in which he has dealt with them. Indicative too of the thoroughness with which the work has been done is the fact that fully forty-three pages are taken up by the discussion on the surgical pathology and treatment of exophthalmos. Withal the book is well balanced, and what is particularly gratifying is its modernity in outlook, though here and there there is an occasional lapse, as in the omission of immediate mucous grafting for caustic burns of the conjunctiva and cornea.

The chapters on plastic surgery are particularly well done, and the illustrations are really helpful. The section on corneal grafting has been contributed by Dr. Castroviejo, and constitutes an authoritative statement on the subject. Goniotomy is dealt with equally authoritatively by Dr. Barkan, and the author has not hesitated to obtain information on other specialized procedures from primary sources. The chapter on retinal detachment is a concise and adequate presentation of a growing field. It is more than an uninspiring statement of different procedures; it is written with knowledge and critical sense. With so much that is satisfying it is regrettable that occasional defects, which could easily have been avoided, should mar the book. There is some looseness of style, and this is hardly balanced by elaborate tables on indications for different methods of operations. These tables give an air of finality which is most unreal. Some few statements are open to question; at any rate in this country cocaine is not used for infiltration anaesthesia. On the whole there is little in the teaching to which exception can be taken, and there are few operating surgeons who would not derive both pleasure and useful information from a perusal of this book.

THE PSYCHOLOGY OF AGGRESSION

Frustration and Aggression. By John Dollard, Leonard W. Doob, Neal E. Miller, O. H. Mowrer, Robert R. Sears, in collaboration with Clellan S. Ford, Carl Iver Hovland, Richard T. Sollenberger. (Pp. 209. 9s. net.) London: Oxford University Press. 1939.

In the foreword to *Frustration and Aggression*, a book published for the Institute of Human Relations by the Yale University Press, there is the surprising statement that "it is no wonder that co-operative research is unpopular in our scientific culture." From this side of the Atlantic it seems, on the contrary, that nothing is more popular in America than such research, or, at any rate, than the publication of its results jointly by a vast number of authors and associated persons. The volume now under notice has required only the relatively modest number of five authors and three additional collaborators. It is, nevertheless or therefore, a very good book, and is particularly illuminating in present international circumstances. The thesis that frustration has a causal relationship with aggression is not new and has been clearly stated by Freud and others. This book consists partly of a systematic and formal elaboration of this hypothesis and partly of a large amount of new illustrative material. It perhaps goes a little further than the previous statements in maintaining that frustration is *always* followed by aggression: to this end the connotation of the latter word is a little unduly extended. The necessary definitions are first given and the psychological principles concerned stated. Then applications are made and illustrations given in reference to American social conditions, especially in relation to children; to the problems of adolescence especially as relating to sex; to criminality; to governmental action under its different forms; and to a primitive society (the Ashanti). The chapter on "Democracy, Fascism, and Communism" is appropriate, clear, illuminating, and suggestive. The publishers claim that "its scope and implications should make it a significant book to anyone seriously concerned with the problems of human relations," and this claim is justified.

Notes on Books

The 1940 edition of *Who's Who* makes its appearance well ahead of Christmas, and contains more than forty thousand brief autobiographies of living men and women within the familiar scarlet covers. The pages of biographical material number 3,532, and there are well over a thousand new entries, replacing those omitted on account of death during the past year. *Who's Who* is indispensable in all libraries, clubs, institutions, and large offices, and is often turned to in private houses that are well provided with books of reference. Every sphere of public activity is covered, with medicine and the sciences well represented. The publishers are Adam and Charles Black, and the price in stout buckram binding is 63s.

The revised fifth edition of Professor JAMES YOUNG'S *Textbook of Gynaecology* continues to be a bargain at the modest price of 16s. (A. and C. Black, Ltd.). It contains a rich store of information which for the most part has been carefully selected and so arranged as to be of the maximum value to students and practitioners. The biggest defect is still to be found in the references to operative work, although these constitute but a small section of the book. Inadequate details are given of those minor procedures, such as dilatation and curettage and tubal insufflation, which are often performed by practitioners, while unnecessary space is devoted to manœuvres such as interposition and the Alexander Adams operations, which are seldom performed by the specialist. The author still appears to prefer the bare finger to the gloved one when making vaginal examinations, but gives no reason for the choice. Illustrations throughout are good and the book can be warmly recommended to all students of gynaecology.

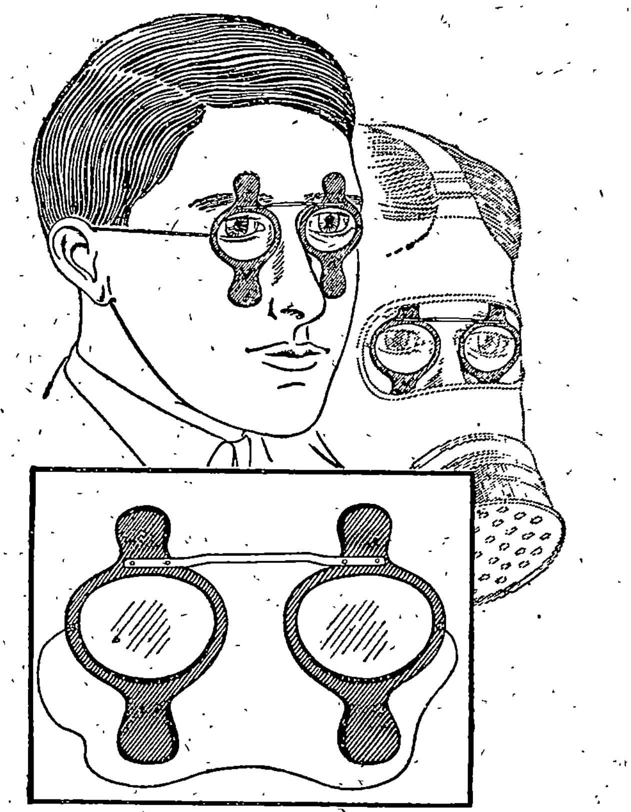
A new edition (the seventh within thirteen years) has been published of *Modern Methods of Feeding in Infancy and Childhood*, by DONALD PATERSON and J. FOREST SMITH (Constable and Co., 7s. 6d.). The importance of breast-feeding is again stressed and the views of Harold Waller are noted. The new designations of the various classes of milk are explained and the section on premature feeding has been revised. The food tables are brought up to date. Eight diet sheets from this book are now issued separately by the publishers at 9d. the set, with reductions for larger quantities of single sheets.

Preparations and Appliances

A SPECTACLE FRAME TO WEAR UNDER THE CIVILIAN GAS-MASK

Dr. MARGARET DOBSON (London, W.) writes:

The spectacle frame shown in the accompanying figure is made of celluloid and the eye-pieces are held together by means of a rigid bar, which does not touch the root of the nose. Two small pad extensions from above and below the middle of the lens rims act as supports and can be adjusted to any face by means of the bar. The upper support rests upon the frontal bone above the eyebrow, while the lower pad rests upon the prominence of the malar bone. The frame is kept in place by means of very fine easily compressible elastic, which is attached to holes in the outer rims of the frame.



The elastic passes over the ears and under the chin, so that the head straps of the gas-mask cannot disarrange the spectacle frame while being worn. The frame is made by Theodore Hamblin of 15, Wigmore Street, W.1.

RECENT PROGRESS WITH VITAMIN K

A year and a half ago[1] we summarized the steps which had led to the recognition of vitamin K and the appreciation of its value in the haemorrhagic tendency of jaundice. First Dam and his co-workers observed that when chicks are fed on a diet deficient in certain fat-soluble compounds but otherwise adequate they develop a haemorrhagic state which is apparently due to a fall in the amount of prothrombin in the plasma. Next it was found that alfalfa grass and fish meal were especially rich in the curative factor or *Koagulationvitamin* (abbreviated to vitamin K), and oily concentrates and finally highly active crystalline products were obtained from these sources. The concentrates were somewhat unstable; they required biological standardization, which is always a tedious and uncertain process; and generally they could be given by mouth only. In patients with jaundice oral therapy necessitates the simultaneous administration of bile salts or the fat-soluble vitamin is not absorbed, and it is not always well tolerated. There were therefore strong practical incentives for the isolation of the pure vitamin, but one cannot read the subsequent progress without marvelling at the wonderful research machine which the biochemists have created. The story is brought up to date in a recent article by Koller.[2] Concentrates of vitamin K showed a characteristic absorption spectrum identical with that of the naphthoquinones, and it was soon found that vitamin K belongs to the group of the naphthoquinones and contains in addition phytol. The quinones readily take up hydrogen to form hydroquinones, and in this way they can play a part in the oxidation-reduction processes of the organism, though it is not yet clear how this influences the mechanism of blood coagulation.

Vitamin K resembles vitamin E inasmuch as it consists of a naphthalene derivative linked to the complex alcohol phytol. Another point of resemblance is that both are representatives of a group of substances of similar though variable activity. The vitamin K effect occurs in a whole series of naphthoquinone derivatives, even those without a phytol linkage, and it is not yet clear in what exact form or forms the natural vitamin exists. The first pure preparation to be used in man was phthiocol (2-methyl-3-hydroxy-1:4-naphthoquinone). Phthiocol was isolated in 1933 from the pigment of the tubercle bacillus by Anderson, who supplied synthetic phthiocol for the experiments at the Mayo Clinic.[3] It was administered to ten patients with jaundice and hypoprothrombinaemia—in nine intravenously in doses of the order of 50 mg. and in one by mouth. The clotting time returned to normal in twenty-four to forty-eight hours and haemorrhage was controlled. Phthiocol has also been successfully given intravenously to two women with jaundice by Smith and co-workers,[4] who used doses of the order of 20 c.cm. of a 0.2 per cent. solution. Both patients were afflicted with nausea and vomiting, and attempts to give the vitamin by the oral route had failed. A series of American chemical papers[5] suggests that phthiocol is the simplest member of a homologous series of anti-haemorrhagic substances, and that nearly all of the derivatives of 1:4-naphthoquinone show vitamin K activity. 2-methyl-1:4-naphthoquinone and the related 2-methyl-1:4-diacetyl naphthoquinone were successfully employed in man by Koller. Having found that a dosage of 60 mg. per kilo was tolerated by dogs, he treated six human cases of obstructive jaundice with a dosage of 3 mg. per kilo by mouth, and restored the coagulation of the blood to normal in all. Vomiting occurred in three of the patients. He concludes that methyl-naphthoquinone is probably more effective than the natural vitamin. Methyl-naphthoquinone has also been used successfully in mothers in labour to increase the prothrombin content of the blood of the newborn child.[6] In our current number J. M. Macfie, A. L. Bacharach, and M. R. A. Chance (p. 1220) report experiments, unhappily interrupted by the war, in which methyl-naphthoquinone was administered not only by mouth but also intramuscularly as 0.5 per cent. solution in olive oil. Doses of the order of 5 to 10 mg. a day were effective and the prothrombin returned to normal in twelve to seventy-two hours. Most of the naphthoquinones are insoluble in water, and the final choice of the form of vitamin K most suitable for clinical use will probably depend on factors such as solubility, tolerance, and speed of action.

What, then, are the conditions in which the use of vitamin K may be indicated? Haemorrhagic states may result from an absolute deficiency of vitamin K or from a conditioned deficiency. Absolute deficiency is seen most characteristically in the infant, in whom it provides the explanation of the haemorrhagic disease of the newly born. The full-term infant usually has only one-sixth to one-third of the adult proportion of prothrombin, and premature infants have much less. In the most deficient babies the condition becomes manifest as a haemorrhagic state. The low prothrombin levels in infants can be raised by feeding vitamin K to the mother before delivery or to the infant directly after birth.[7] In infants with icterus gravis or the related anaemia neonatorum the haemorrhagic state is unusually frequent and persistent, and vitamin K then relieves the haemorrhagic state but not the anaemia or jaundice.[8] Direct deficiency in the adult is probably unusual, but Kark and Lozner[9] have described four patients who had eaten diets very deficient in fruit and vegetables in whom the prothrombin time was prolonged and in whom the oral administration of vitamin K without bile salts was followed by a prompt return of the prothrombin time to normal. Deficiency may be conditioned by failure of absorption of fat and therefore of the fat-soluble vitamin, or by hepatic insufficiency, for the liver appears to play an essential part in the process whereby vitamin K enables prothrombin to be synthesized. Deviation of bile from the intestine by obstruction or fistula may produce prothrombin deficiency and haemorrhage, but the most intense forms are found in cases in which long-continued obstruction not only prevents the access of bile to the intestine but also damages the hepatic parenchyma. Operation to relieve the obstruction may temporarily aggravate the symptoms, and hitherto death from post-operative bleeding has been greatly feared. It may be too sanguine to hope that the risk has been completely eliminated by the discovery of vitamin K, but the results need no exaggeration. Townsend and Mills[10] report ten cases of obstructive jaundice in which the plasma prothrombin levels were low and there was an abnormal tendency to bleed. Administration of vitamin K and bile salts by mouth restored the clotting time to normal, except for one failure in which no adequate explanation could be found, and no abnormal bleeding followed operation in those so treated. Haemorrhagic states associated with a diminished prothrombin content of the plasma probably occur also in all other varieties of steatorrhoea, both the idiopathic forms such as sprue[11] and the forms which are secondary to gross disease of the intestine, such as fistula, stenosis, granulomatosis, and obstruction.[12]

Finally it must be emphasized that vitamin K is of no value in haemophilia, purpura, and intrinsic diseases of the blood-forming organs, or as a non-specific haemostatic. The chief indications are the haemorrhage of jaundice and the haemorrhage of the newly born, and its use for unsuitable purposes can only bring discredit on a valuable addition to therapeutics. The curve of publications on vitamin K is rising rapidly, and it is difficult to believe that the quality of the early work can be maintained at this rate.

EPIDEMIC ENCEPHALITIS

When von Economo and Wiesner described in 1917 a series of cases of encephalitis in Vienna with characteristic symptoms similar to those later, but independently, observed in France by Netter and in England by Hall the term "encephalitis lethargica" was coined. Subsequently, when the disease assumed epidemic proportions in Italy, Switzerland, and Denmark in 1920, and spread to Sweden, Finland, Great Britain, the U.S.A., and Russia, lethargy was by no means found to be a constant feature. When it was observed it was often evanescent and quickly replaced or interrupted by great excitability. Perhaps for this reason the Americans preferred to describe this form of encephalitis as "epidemic encephalitis," and it was to pursue investigations into it that a Commission came into being in 1927 by the generosity of Dr. William J. Matheson. The Matheson Commission has now issued its third report.[1] The American nomenclature has proved as inadequate as the European, for events have proved that more than one kind of encephalitis may become epidemic. Apart from the encephalitic form of poliomyelitis, transmissible entities of a similar but distinct character have come to be clearly recognized, including St. Louis type, Japanese B type, American Eastern and Western equine encephalomyelitis, Australian *X* disease, haemorrhagic encephalitis, post-vaccinal encephalitis, and encephalitis following some of the acute infectious diseases. Most of these are generally accepted as being caused by viruses. Several of them may become epidemic, and, indeed, outbreaks of the St. Louis type and Japanese B encephalitis have been even more sudden and sharp than those of encephalitis lethargica. Somewhat resembling this group of diseases are others less closely allied—for example, louping-ill (a virus disease of sheep), lymphocytic choriomeningitis,[2] and the infective polyneuritis known as the Guillain-Barré syndrome.

The Matheson Commission, set up to investigate one disease, thus finds itself concerned with many. References to original publications on all of them are to be found in the valuable and complete bibliography which occupies more than two-thirds of the present volume. The epidemiological contrasts between some of the forms of encephalitis are interesting. While encephalitis lethargica has been, with reasonable consistency, a disease of winter and spring and specially liable to occur in the temperate zones, both the St. Louis and Japanese B types favour warmer regions and have so far assumed epidemic form between July and October —that is, in the warm seasons of the northern hemisphere. Such outbreaks are usually preceded by abnormal heat and prolonged drought. Droplet infection, which sufficiently explains the spread of the lethargic form, has therefore seemed a less adequate hypothesis for these others, and the same attention in relation to them has been paid to food, water, and biting arthropods as in the case of poliomyelitis, with results almost equally unconvincing. Some Japanese workers have satisfied themselves that mosquitos may transmit the viruses of both Japanese B and St. Louis encephalitis, but the circumstances attendant upon epidemics, and especially the quickness of their spread, are more suggestive of aerial transmission by numerous carriers or mild cases. There are differences, too, in the incidence and fatality of the several types. Encephalitis lethargica and Japanese B type are highly fatal, as measured by deaths among definitely ascertained cases; St. Louis type is less so and less attended by grave sequelae. While all three types increase in fatality with age, the 1933 St. Louis epidemic showed this feature most markedly, and both it and Japanese B type exhibit increasing incidence with advancing age, in contrast to the small variation usually observed in the age incidence of the lethargic form. These differences are in line with differences in the three viruses, which are distinct serologically and in the reactions they induce in laboratory animals.

Gay and Holden, working for the Matheson Commission, have made a vaccine ("F" vaccine) by formalinization of a herpes virus which has now been under trial in the treatment of the lethargic form for about five years. Although its value is still unproved the immediate results in both acute and chronic stages of the disease are hopeful. Apart from this, the careful follow-up of cases by the Commission over a long period of years has revealed no other specific remedy, but the report deals fully with symptomatic treatment. Indeed, this publication gives a complete picture of encephalitis from the aetiological, clinical, therapeutic, and epidemiological points of view.

HYPERPARATHYROIDISM AND RENAL CALCULI

Hyperparathyroidism is a rare disease and to most clinicians it suggests a syndrome of weakness, lassitude, wasting, and muscular pains, which are associated with striking changes in the bones through cyst formation and decalcification and with the occurrence of spontaneous fractures. It is therefore rather surprising to learn that in a series of thirty-six cases studied by Chute[1] more than half the patients had as their predominating and presenting symptoms complaints referable to the urinary tract, and that in hyperparathyroidism the greatest danger arises from the renal complications. Renal calculi, which are usually multiple and bilateral, were found in thirty of the thirty-six cases. They may give rise to renal colic or may be complicated by pyelonephritis and cystitis, leading possibly to renal insufficiency. Other cases develop calcium deposits in the renal parenchyma, which, if extensive, may give rise to renal failure and uraemia, so that the case may present itself as one of advanced disease of the kidneys. These conditions no doubt result from the excessive excretion of calcium and phosphorus. Chute calculates that 3 per cent. of all cases of renal calculi are due to hyperparathyroidism, and the clinician should bear in mind this possibility when dealing with any case of stone in the kidney. Suggestive symptoms are weakness and constipation, thirst and polyuria, and pains in the bones and joints simulating arthritis or neuritis. In doubtful cases the fasting blood calcium should be estimated; a figure greater than 11.5 mg. per 100 c.cm. strongly suggests hyperparathyroidism. Sulkowitch[2] has described a useful test for indicating approximately the amount of calcium in the urine. An oxalate buffer mixture is added to an equal amount of urine which is acid to litmus paper or has been made so by the addition of 50 per cent. acetic acid. The test-tube is inverted and shaken, and the turbidity observed after two minutes. In cases of hyperparathyroidism the turbidity is very pronounced, whereas with the urine of patients whose calcium excretion is normal the cloud is much less dense. The specimen of urine should be taken while the patient is on a diet free from milk and anything else which might increase the excretion of calcium. Sulkowitch suggests that a negative result practically rules out hyperparathyroidism, whereas a positive test is strongly suggestive, though it should not be taken as final evidence. The reagent employed consists of 2.5 grammes of oxalic acid, 2.5 grammes of ammonium oxalate, and 5 c.cm. of glacial acetic acid dissolved in distilled water and made up to 150 c.cm.; 5 c.cm. of this reagent is added to 5 c.cm. of urine. In hyperparathyroidism a solitary adenoma of one gland is usually found, but in a few cases there is uniform hypertrophy of all the parathyroids. Johnson[3] points out that the relation between the parathyroids and the kidneys is further complicated by the fact that in cases of primary renal failure hypertrophy of the parathyroid glands is common, though symptoms of hyperparathyroidism do not appear. He gives a full report of an interesting case in which the patient complained of pain in the right hip, weakness, loss of weight, thirst, and polyuria. He had had a fracture of the right humerus a year before when throwing a ball, and *x*-ray examination revealed a cyst in the region of the fracture and multiple cysts in other bones. An adenoma of the right lower parathyroid gland was removed, the bone lesions healed, and the patient improved and returned to work. Symptoms of chronic nephritis gradually developed, however, and four years after the operation the patient's blood pressure was 210/120 mm. Hg and his blood non-protein nitrogen 66 mg. per 100 c.cm.; some months later he died of uraemia. A necropsy revealed enlargement of the remaining parathyroids and an extensively calcified horse-shoe kidney, the calcification occurring almost entirely in the renal pyramids. Microscopically there were large masses of calcium causing obstruction and disorganization of the collecting tubules. There was also pronounced sclerosis of the arterioles of the kidneys, pancreas, spleen, and adrenals, some of the vessels having undergone necrosis. The author discusses the possibility of this being a case of hypertension becoming malignant independently of the hyperparathyroidism, but as similar cases have been recorded in relation to parathyroid disease it is probable that the extensive renal calcification was the lesion causing the hypertension and the secondary vascular changes.

REACTIONS BETWEEN OVARY AND PITUITARY

It has been known for many years that hypophysectomy leads to ovarian atrophy, and that this can be prevented by the implantation of pituitary tissue. After this discovery gonadotrophic extracts were prepared from the pituitary and other potent sources—urine from the pregnant woman and serum from the pregnant mare. The earlier testing of such extracts was carried out largely on normal rats or mice. The observation of Selye, Collip, and Thompson[1] that extracts of pregnancy urine (chorionic gonadotrophin) when injected into immature hypophysectomized rats produced only luteinization, although provoking both follicle stimulation and luteinization when injected into normal immature rats, showed that the pituitary of the test animal seriously interfered with the results. Noble, Rowlands, Warwick, and Williams,[2] comparing the effects of numerous gonadotrophic extracts on normal and hypophysectomized immature female rats, found that in all cases the quantitative response in the latter was less than in the former. The qualitative differences were in some cases, however, even more striking. Whereas all the extracts gave rise to follicle stimulation and luteinization in the normal rats, those from the urine and serum of pregnant women and from the ox hypophysis were purely luteinizing, and those from certain human glands purely follicle-stimulating, in the hypophysectomized rats. Extracts from the pituitaries of sheep, horse, and pig, and from the serum of the pregnant mare, had both activities even in the operated animals. All this shows that the injection of follicle-stimulating gonadotrophin provokes the secretion of luteinizing gonadotrophin, and vice versa. It is difficult to determine whether these responses are elicited by the injected materials themselves or by the secretions of the ovary in its follicular and luteal phases. Large doses of oestrogen have an inhibitory effect on the pituitary, as is shown by Ruth Deanesly,[3] who has observed that implantation of oestrone or oestradiol tablets in male rats or mice leads to degeneration of the gonads and accessory sex organs. This is attributed to hypophyseal depression, since the growth rate is also diminished. Similar results have been obtained in rats of both sexes by Noble,[4] using stilboestrol tablets. He also demonstrated that the gonadotrophin content of the pituitary of the animals so treated was diminished. The qualitative aspects of this diminution are not yet established, nor are the similar aspects of the diminution produced by progesterone. It is apparent that the relations between ovary and pituitary are complex, and that complete replacement therapy in hypophysectomized animals will present great difficulty until the constituents of the gonadotrophic complex are separated in a physiologically pure state. The difficulty is exemplified in the work of Liu and Noble,[5] who find that, while the loss in ovarian weight from hypophysectomy can be arrested by daily injection of extract of pregnant mare's serum, the effect does not last and regression sets in after a few weeks in spite of continued injection. During the injection period the animals are continuously in oestrus, and although mating occurs pregnancy does not result. Injections of chorionic gonadotrophin had similar effects, though the regression in ovarian weight set in earlier and oestrus only persisted for a few days.

THE LAURENCE-BIEDL SYNDROME

Syndromes with many hereditary components have a special interest because of the mechanism of their association. Sometimes, as in the syndrome of brittle bones, blue sclerotics, and otosclerosis, a uniform embryological basis is available, for mesodermal structures only are involved. In arachnodactyly, however, an embryological conception breaks down, for the subluxation of the lens is due to a deficiency of the suspensory ligament, which is ectodermal in origin, whereas the other manifestations arise from defects of mesodermal tissue.[6] In the Laurence-Biedl syndrome there is an undisputed mixture of mesodermal and ectodermal defects. The obesity, hypogenitalism, and polydactyly are mesodermal disturbances, and the mental deficiency and the pigmentary degeneration of the retina are ectodermal. It is possible to hold that these various manifestations are secondary features of one underlying disturbance, and that the distribution in ectodermal or mesodermal tissue is accidental. Against this hypothetical approach there is considerable genetic evidence that a variety of manifestations may be the result of linkage within the same chromosome. It is thus that the bizarre combination seen in the Laurence-Biedl syndrome can best be explained. In 1935 Cockayne, Krestin, and Sorsby in an exhaustive analysis suggested that the syndrome was determined by two recessive genes in the same chromosome, and as the same recessive mutation in two neighbouring genes was unlikely to happen more than once they held that all cases of the syndrome probably had a common origin. This explanation must now be admitted as too simple, for in a new study of the subject Sorsby, Avery, and Cockayne[7] draw attention to cases reported outside the Caucasian race, particularly among Japanese. This makes the suggestion of common ancestors unlikely and leaves a distinctly difficult problem as to how such a variety of manifestations as are seen in the syndrome all arise from changes within one and the same chromosome. Hereditary lesions of the central nervous system associated with digital abnormalities have been produced experimentally by Bagg and Little, and Sorsby has shown the association of hereditary macular colobomata with digital defects in patients clinically. That there is indeed some close association between hereditary ocular anomalies and digital anomalies can also be seen from such conditions as arachnodactyly, syndactyly with aniridia, lobster-hand and aniridia, and the Apert syndrome. All this evidence suggests that it may be possible ultimately to map out the components of a chromosome that seems to contain, besides others, genes controlling development of the brain, eye, and the peripheral skeleton. That a chromosomal defect involving several genes underlies the Laurence-Biedl syndrome rather than one pathological lesion with secondary manifestations is made likely by the three post-mortem records of the syndrome now available. Nothing definite was found, though it must be admitted that the reports are not as conclusive as they might be, particularly in regard to the possibility of lipoid disturbances. Several other points of interest emerge from the present study. That adiposity need not be a constant symptom even in the same patient is shown by the fact that one of the patients described by the authors was distinctly obese as a child and is now thin. The variety of allied conditions listed and discussed in this paper emphasize how little is as yet known of the fundamental nature of syndromes with many components and of the interrelations between them.

TUBERCULOSIS IN YOUNG ADULTS

The optimism often expressed as to the trend of tuberculosis in this country has not been shared by those workers who have examined mortality statistics for this century with more than a superficial glance. For while the mortality for most age groups in England and Wales has declined steadily since 1870, except during the war period of 1914–18, the mortality for young adults, which had declined satisfactorily until the beginning of the present century, has shown a retardation for young women since 1900–4, and for young men since 1912–14. This retardation has been particularly severe amongst young women, whose mortality in 1931–3 was scarcely lower than it had been in 1901–3. Moreover, the retarded decline in mortality from respiratory tuberculosis among young adults has been most serious in the large urban areas of the country. Actually at the present time nearly half the deaths from all diseases among women are due to pulmonary tuberculosis. Up to now attempts to explain this phenomenon have been little more than mere conjecture. In a report recently published[1] Dr. D'Arcy Hart and Professor Payling Wright present an elaborate and carefully worked out statistical study of the possible responsible factors, paying particular attention to social conditions. The trend of mortality from respiratory tuberculosis for England and Wales as a whole, especially that for young adults, is considered in relation to the changes in the general level of social conditions (standard of living) as estimated mainly from changes in real earnings. The experiences in phthisis mortality in the different English county boroughs are then considered in relation to the local variations in their social conditions as estimated from poverty and housing data; and as a control for the results arrived at the death rates from diseases other than respiratory tuberculosis are considered in a similar way. The possible distorting effect of "internal migration" upon the relations between the above mortalities and certain social conditions in the different county boroughs was borne in mind, and an attempt is made at correction for this effect for young women. Again, particularly in young women, the effects of recent changes in the volume of occupation upon respiratory tuberculosis are considered. And, finally, the mortalities from phthisis in the different London boroughs are examined in the light of social data, some of which are, and some of which are not, available for the county boroughs. In the last chapter the more important findings under the headings just given are discussed in relation to one another. In a short note it is clearly not possible to attempt even a brief summary of the authors' findings. Everyone connected with the social or public health aspects of tuberculosis must study the report himself. The general conclusions can, however, be stated. It is suggested that the retardation in tuberculosis mortality among young adults has been brought about by (*a*) a predisposing factor—that is, the special sensitiveness of young adults to social conditions as regards their mortality from respiratory tuberculosis; (*b*) general determining factors—that is, the contemporaneous country-wide changes in general, social, and economic trends affecting the mortality from respiratory tuberculosis in young adults in all areas, the most important of these changes being the check to the rise in the standard of living occurring about 1900, which was accompanied by a setback in the improvement in general housing conditions, and the accentuated increase in the industrial employment of young women also taking place about that date; (*c*) local determining factors—that is, unsatisfactory social conditions rendering the effect upon the young adults in certain localities especially severe. Of these local conditions housing appears to be of great importance, the part played by other factors in poverty being less clear, though there is some evidence from the London boroughs that inadequate nutrition has also played a part.

It has not been possible yet to settle the date and place of the meeting of the next annual congress of the International Association of Cosmobiology postponed from last September owing to the outbreak of war. The proposed places are Rome, Barcelona, Geneva, or Antwerp. The official representatives of Governments and of contributing learned societies are asked to send notification of any changes of address to the general secretary of the International Association, Dr. M. Faure, Rue Verdi 24, Nice. The *Revue de Cosmobiologie* continues to be published at present in the more convenient form of separate pamphlets.

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation

FRACTURES OF THE SHAFTS OF THE TIBIA AND FIBULA

BY

ARTHUR ROCYN JONES, M.B., F.R.C.S.

When considering the fracture of a long bone, the position and the nature of the break in continuity are frequently determined by the structure of the bone. A broken tibia often illustrates this relation between fracture and structure. The upper third of this bone is thick and prismatic, but the lower two-thirds becomes increasingly thinner until near the lower end, when some expansion again occurs to form an articular surface of the ankle. It is the lower slender part of the tibia that is most frequently broken, and here, too, is one of the well-known sites for non-union of a skeletal fracture. Furthermore, the whole length of the inner surface of the tibia lies immediately beneath the skin, and there is thus a greater liability for a fracture of this bone to become compound than is the case with most bones. Fractures of the bones of the leg may arise from direct or indirect violence, the severity and nature of which will decide whether one or both bones are broken and also the particular variety of fracture inflicted. Direct violence, such as that of a crushing force applied to the limb, usually produces a transverse fracture, and very often with comminution. On the other hand, indirect violence, such as occurs when falling from a height, as a rule causes severe twisting of the leg with the foot momentarily fixed on the ground. The fracture which follows such a torsion strain is either oblique or spiral in character. Comminution may occur with all varieties, and frequently there is a detached triangular piece present, the so-called "butterfly fragment." Again, the tibia, whether broken alone or in company with the fibula, is almost invariably severed in its lower two-thirds; if both bones suffer the fibula is fractured at a higher level than the tibia.

The more severe the injury the easier the diagnosis. A simple fissured fracture of the fibula may readily escape detection except by radiographic examination in two planes. Clinically there is local tenderness at the site of bone injury accompanied by some swelling due to extravasation of blood, and lateral pressure on the fibula either above or below is painful at the fracture. But a person with a broken fibula may be able to walk without great discomfort, and this fact is very disarming to the unwary. A fracture of the tibia, on the other hand, is at once disabling. There is local pain and swelling at the point of injury, and if the examining fingers follow the crest of the tibia from above downwards a sudden interruption is experienced at the fracture and the lower end of the upper segment can be felt. These signs are enough to diagnose a fracture without recourse to the eliciting of crepitus or of abnormal mobility at the break. The obtaining of the last two signs is inadvisable, for they can only be secured with pain to the patient and some risk of disturbing what may be a reasonably good alignment of the fragments. A fracture of both bones presents no difficulty of diagnosis: the grave disability, the angular deformity, and the great swelling of the parts are only too obvious.

Treatment

Once the clinical diagnosis of a fracture of one or both bones of the leg is made the protective treatment of the fracture should begin, without waiting for an *x*-ray examination. Neglect to protect the injured leg during transport from the scene of the accident may have irreparable consequences. Fractures of both bones in their fresh state may present the fragments in good anatomical alignment, but if left unprotected these may easily become so disturbed by the time they reach the *x*-ray table that their realignment may baffle the skill of the most experienced. It is important, therefore, that these fractures be protected on the spot; for this early splinting may well be the most important step of all, in spite of whatever procedure may follow. In a fracture of the fibula alone the uninjured tibia acts as an adequate splint. For a broken tibia the uninjured fibula is something of a protection, but it is safer to adopt the plan that is recommended where both bones are broken, which is as follows. The leg should be supported by an assistant, while the foot is then brought up to right angles with the leg and some traction applied. With the leg in this position, a padded box splint, with foot-piece, is bandaged to the limb. If only one side splint is available it should be applied to the outer side of the injured limb, and then both lower limbs should be tied together at the feet, ankles, mid-calf, knees, and thighs. Even if no splint is available the limb should be tied as indicated.

As soon as possible the radiographs should be taken in two planes, and the whole tibia and fibula examined to avoid missing any undetected fracture at some distance from the main injury. A skiagram alone will reveal the true nature of the fracture, and by indicating the disposition of the fragments will serve to point out what the right line of treatment should be.

Fracture of Fibula Alone

Fractures of the shaft of the fibula are rarely of great importance, for the body weight is transmitted almost entirely by way of the tibia. Sometimes, however, a fracture of the neck may be accompanied by injury to the external popliteal nerve, with consequent drop-foot paralysis; but as a rule the paralysis is only temporary, although it may take some months to recover. An absolute irreparable paralysis is excessively rare. Fracture of the lower end of the shaft may be part of a Pott's fracture and should be treated as such. With an intact tibia there is usually no gross displacement of the segments of a fractured fibular shaft. The fracture is best treated in a plaster-of-Paris cast. Stockinet is put on the limb, and the slightly inverted foot is held at a right-angle to the leg and manual traction exerted; by this means displacement of the fragments will be corrected. While the foot is thus held under traction the plaster is applied direct to the stockinet from the toes to just below the knee and without any wool or felt padding. A walking-iron, preferably with a rubber disk for comfort, is incorporated in the cast, taking care that the iron lies in the axis of the leg and is not tilted forward below the sole of the foot (Fig. 1). Lastly, the edges of the stockinet at each end are folded back and are fixed in the cast by the turns of the last plaster roll. When the cast is dry and well set, walking may begin with the aid of a stick. The plaster may be removed in three to four weeks, for by then there is usually enough callus present to keep the segments immobile.

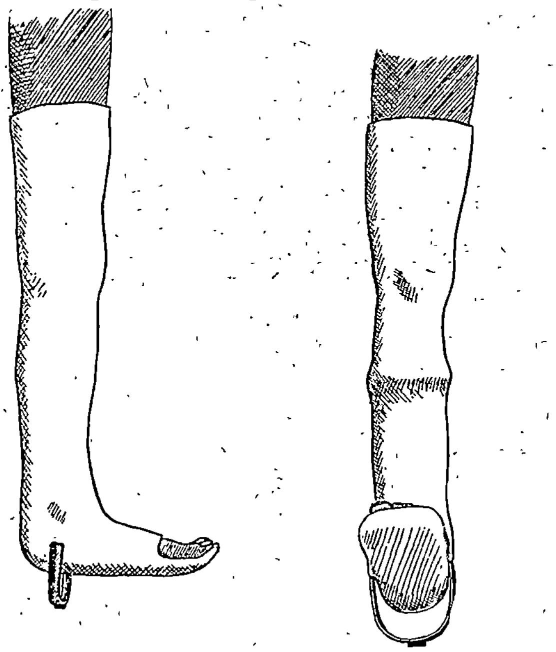

Fig. 1.—Plaster cast with walking-iron incorporated.

Fractures of Tibia Alone

A fracture of the tibia is completely disabling, and reduction should be attempted without delay. It is much easier to reduce displacement during the first few hours while the muscles are relaxed than it is after a day or two when the exudation has increased and the muscles are more resistant. The anaesthetic should be such as will produce complete relaxation of the limb. The knee is first held flexed at nearly a right-angle, and traction and counter-traction are employed, with lateral pressure on the fragments if necessary. Should this procedure fail, then deliberate angulation of the fragments with traction and counter-traction may succeed in bringing the ends together. If this occurs the leg is straightened, bringing the fragments into alignment. Care, however, must be taken to avoid thrusting the sharp end of a fragment through the skin. The result should be checked by the fluorescent screen, and if unsatisfactory the manipulation should be repeated. When good reduction has been obtained the limb should be encased in a plaster cast on stockinet from the toes to the groin, and a walking-iron incorporated; but it is a good precaution to make two or three longitudinal slits in the front of the cast so that it can be prised open a little if the patient complains of undue discomfort some days later. A radiograph in two planes should be taken as soon as the plaster is dry, and again a week later. In spite of every care the fragments sometimes change their position even in the cast, and this is due to the fact that with the absorption of the exudate and the diminution of the swelling the plaster does not grip the limb so well as when first applied.

There are three things in particular that must be watched: that there is no angulation at the fracture; that the articular surface of the tibia at the ankle is horizontal; and that the foot is at a right-angle to the leg. The avoidance of angulation is of more importance than end-to-end apposition, provided the axes of the tibia and fibula are parallel. Permanent angulation or obliquity of the articular surface will mean future ankle strain, with a weak foot in a valgus or varus attitude, and a foot fixed in plantar flexion may lead to contraction of the tendo Achillis. If there is angulation of the fracture it must be corrected forthwith by removing the plaster, manipulating the leg, and applying a fresh cast. An alternative method is to remove a wedge from the cast on the side to which the angulation is pointing and continue the narrowing slit around on either side for two-thirds of the circumference of the cast. The angulation can then be corrected by approximating the edges of the gap left after the plaster wedge has been removed; but this should be checked by the *x*-ray screen. If the deformity is abolished fresh plaster should be applied to close the slit and bind the cast. The plaster should be kept on the limb for eight to ten weeks or even longer, according to the severity of the fracture. But before walking is permitted a radiograph should be taken to determine whether sufficient consolidation of the callus has occurred.

If the fracture resists manual reduction, or if there is a persistent separation of the segments in spite of all attempts to approximate them, then it is probable that muscle is interposed between the fragments or the intact fibula is obstructing reduction. In these circumstances it is best to explore the limb by open operation, reduce the fracture, and maintain the reduction securely with a metal plate. This procedure will be safer if the "no touch" technique be observed throughout.

Fractures of Tibia and Fibula

Fractures of both bones are more disabling and far more difficult to treat than the fracture of a single bone. They are usually the result of greater and longer-continuing violence, so that the displacement and comminution of the fractures and the injuries to the soft parts are more serious. The attitude of the leg is characteristic: there is anterior bowing at the fracture, due to the upward pull of the quadriceps on the upper fragment and the retraction of the lower fragment by the tendo Achillis. The treatment of these fractures will depend upon the amount of displacement, overlapping of the fragments, and whether there is any muscle interposed between the ends of the bones.

MANUAL REDUCTION AND FIXATION BY PLASTER CAST

In attempting manual reduction of fractures of both bones the same principles obtain as described for fracture of the tibia alone; also, checking by fluorescent screen and by subsequent radiographs must be followed in similar manner. If the reduction is satisfactory and the alignment of the fragments correct, a plaster cast, with incorporated walking-iron, should be applied to keep the bones fixed in position. There is, however, a greater liability to displacement of the fragments under the plaster than in the case of a patient with only a tibia broken. It also takes a week or ten days longer to get these patients walking in the plaster.

REDUCTION BY DISTRACTOR AND FIXATION BY PLASTER CAST

If the attempt at manual reduction fails, or if at the outset it is felt that the overlap or displacement is such that there is little prospect of success by manipulation alone, reduction by a distractor should be undertaken. There are a number of good distractors available for the reduction and fixation of these difficult fractures of long bones. With aseptic precautions a sterilized stainless-steel pin, 4 mm. thick, is passed through the tibia above the fracture and another pin through the lower end of the tibia or through the posterior part of the os calcis. The pins are then connected to the appliance. Traction and counter-traction are made by screw adjustment, and, with the aid of some manual adaptation of the fragments as well, a good anatomical reposition of the broken bones can be obtained in almost every case. The procedure is best carried out with the help of the x-ray screen, for by this means the right amount of distraction necessary can be accurately estimated. When correct reposition of the segments has been obtained the apparatus alone will maintain the fixation (Figs. 2–4). To prevent infection occurring between skin and pin, it is a good precaution to smear bipp around the pin at its emergence from the limb and apply a strand of sterile gauze over the paste. A strip of thin felt is next applied to the outer side of the leg in the lower third, and this passes down over the external malleolus, under the heel, and upon the inner side to well beyond the internal malleolus; this felt gives protection to the bony prominence in the region of the ankle. The plaster is then applied direct to the skin and over the thin felt, from the toes to the upper part of the thigh, and when the cast is dry the distractor is removed, leaving the pins in the limb. At the end of ten days walking with crutches may begin, and later on sufficient aid will be derived from a walking-stick. Pins and plaster should be removed in eight weeks. If there is enough consolidation of the fracture, walking may be allowed without the cast; but if the union of the fracture is weak, or if there is pain, a fresh cast with walking-iron should be applied for another three or four weeks. The rate of consolidation depends upon the severity of comminution, the state of health, and the age of the patient.

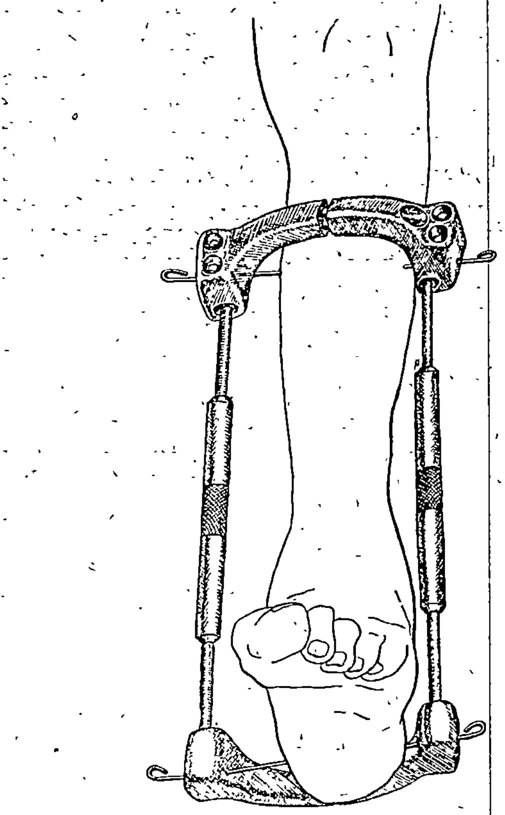

FIG. 2.—A leg with a severely comminuted fracture-dislocation of the lower third of the tibia and fibula. Cuendet's distractor is shown attached to pins transfixing the tibia and os calcis after reduction and fixation of the fragments.

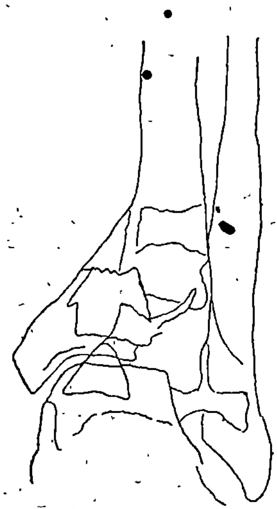

FIG. 3.

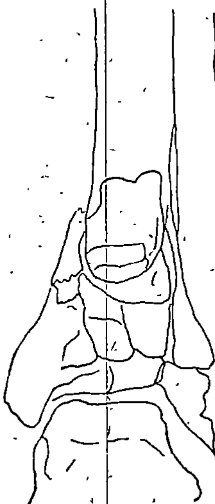

FIG. 4.

FIG. 3.—Tracing of a radiograph of the case illustrated in Fig. 2, before treatment.

FIG. 4.—Tracing of a radiograph of the same case after reduction and fixation of the fragments by the distractor.

Delayed union is apt to follow severe comminution, and particularly if loose devitalized fragments are present. In such cases firm union may not occur for four months or even longer, and demonstrable x-ray consolidation not for five to six months. Again, some may require the protection of a walking-calliper for a while after the plaster cast has been discarded; this particularly applies to the elderly heavy patient with a severe fracture in the lower third of the tibia. Angulation is apt to occur in this type of case even when clinically there is apparent consolidation and immobility of the fragments. Fractures in young children, on the other hand, usually heal soundly in six to eight weeks. All patients after discarding plaster casts should have physiotherapy treatment, directed to improve muscle tone and to get rid of knee and ankle stiffness.

SKELETAL TRACTION AND SPLINTING

Another method of treating fractures of both bones of the leg is by skeletal pin traction combined with a Thomas or Braun splint. A Kirschner wire is inserted through the posterior part of the os calcis and tightened and clamped in a stirrup. The wire can be inserted under local anaesthesia: about 2 c.cm. of a 2 per cent. solution of novocain is injected under the sterilized skin and down to the periosteum of the bone at the point of proposed entrance of the wire. The latter is then driven through the os calcis until the skin begins to bulge on the opposite side. A second injection is now made about the exit of the pin from the bone and afterwards the pin is pushed out through the skin. The limb is placed in a Thomas bed calliper, which is bent to an angle of 45 degrees at the knee and suspended from pulleys attached to an overhead frame; the stirrup is attached to a cord which passes over a pulley, at the foot of the bed, to a weight of 12 lb. or more, according to the amount of traction required to overcome the displacement of the fragments, as indicated by the radiographs. Good correction can be obtained by this method, but it is open to the objection that the patient is kept recumbent, the fracture is not sufficiently immobilized, and there is a tendency towards delayed union. The method is, however, of great value in compound fractures or where it is necessary to keep the state of the limb under observation for trophic or other reasons. In some cases where it is desirable to begin the treatment in a Thomas splint it may be possible, after two or three weeks, to incorporate the limb in a plaster cast.

Compound Fractures of Tibia and Fibula

Compound fractures are a special problem, and they vary from one or two punctures of the skin to complete destruction of the limb, for which amputation is the only remedy. Every compound fracture must be presumed to be potentially infected, and therefore protective inoculation ought to be instituted at once; 1,000 units of antitetanic serum (500 American units) should be given subcutaneously and 4,000 units of gas-gangrene antitoxin intramuscularly. The treatment of the wound will depend on the degree of damage to the soft tissues. Puncture wounds are best left alone and watched; if suppuration occurs free drainage should be provided. Where there are laceration and some devitalization of the part the soiled tissues and skin involved should be excised (débridement). If the skin edges can be brought together without tension this should be done; but if it is not possible the wound should be packed with pure flavine and gauze. Should the wound eventually suppurate flavine and glycerin with gauze packs had best be employed and the leg dressed daily. If there is good alignment of the fragments the limb might be encased in plaster from the toes to the groin and a generous window provided for dressing. If a cast is not possible, or if it is necessary to employ skeletal traction, the limb is best nursed on a Thomas splint. Many compound fractures do well under this treatment, although union of the fragments is delayed. A sinus, however, may persist for several months, the healing of which often follows the shedding of a superficial sequestrum. Very often compound fractures require some calliper protection during the early stages of walking.

Where amputation is inevitable it is best in the early case to amputate through the fracture and provide adequate drainage from the beginning. This procedure, rather than a higher amputation, diminishes the shock, and ultimate healing is often so satisfactory that a secondary amputation for limb-fitting is unnecessary.

In other cases a more conservative attitude may be justified, and by efficient drainage, antisepsis, and possibly administration of sulphanilamide, an unpromising limb may be saved. But if in spite of such treatment there is commencing retrogression with the limb red, swollen, and oedematous, a slowly ascending inflammation and a patient very ill, then amputation becomes a life-saving operation. Even in this type of case amputation at the fracture with very free drainage may be quite enough. But if not enough it very often suffices to tide a patient over a crisis, and a secondary amputation can be planned later with a good prospect of success.

The nineteenth annual report of the National Institute of Industrial Psychology (Aldwych House, W.C.2) records important work of both industrial and educational interest. It is to be hoped that the information the Institute has accumulated and the experience it has gained since its foundation shortly after the last war will be utilized to the full in the present emergency. The section of the report dealing with industrial investigations shows the wide variety of problem with which the investigators are accustomed to deal. Particularly good results are reported in simplifying methods of work and in devising training schemes for new employees. A large part of the Institute's work is concerned with vocational and educational guidance. There was a marked increase in the number of young men sent for testing and interviewing by firms employing or proposing to employ them and in the number of boys and girls dealt with in groups at their own schools. This advisory service is still available, and to meet the needs of school-leavers who have been evacuated the Institute is prepared to send members of its staff to schools in the country.

"THE APPOSABLE THUMB"

SIR WALTER LANGDON-BROWN'S LECTURE

Under the title of "The Apposable Thumb" Sir Walter Langdon-Brown discoursed in his Thomas Vicary Lecture at the Royal College of Surgeons on November 30 on the history of craftsmanship in medicine and the rise of surgery to its proper place. The subject took him to the origin of schools of learning and universities, the separation of philosophy from handicraft (of which the separation of medicine from surgery was a phase) and the intellectual conflicts of the Middle Ages. The lecture was attended by the Presidents of the Royal Colleges of Physicians and of Surgeons and a distinguished company.

The lecturer began his history in almost the darkest of the dark ages, when Theodore of Tarsus arrived in England in 669. Although he was 66 years of age, he proved himself an active reformer and founded a school of learning at Canterbury, at which school our written literature in English may be said to have had its birth. A few years later the monastery at Jarrow associated with the Venerable Bede was consecrated. Jarrow must have been an oasis of civilization in those times. This in turn led Egbert to establish his cathedral school at York. Thus, if one went back far enough, Britain could claim to have planted the seed from which sprang the mediaeval universities. The very names of those universities affected one with a kind of nostalgia—Salerno, Bologna, Paris, Salamanca, Oxford, Padua. They were not founded, but just grew out of the sudden passionate desire for learning in the twelfth century, wandering scholars flocking hither and thither as the reputation of some teacher waxed and waned.

The word *universitas* originally signified not a *studium* or school but a guild formed for self-protection either by teachers or students. A university was and still remained an intangible thing. He sometimes wondered what would happen if a man arrived at Cambridge station and asked a taxi-driver to take him to the university. It would be like arriving at Victoria and asking to be driven to the British Constitution. The rise of Oxford was one of the results of the quarrel between Henry II and Thomas à Becket. As the clergy naturally sided with the archbishop the king ordained that no cleric should cross the Channel except by his permission and that clerics abroad should return or lose their livings. The result was that, exiled from Paris, they crowded in the little *studium* at Oxford. In 1209 the feud between town and gown ended in masters and students three thousand strong deserting Oxford for Cambridge and Reading, and when the quarrel was settled in favour of the university many of the migrants remained in Cambridge, though Reading had to wait until the present century to get its university.

The Ascendancy of Scholasticism

It was Hugh de Balsham, Bishop of Ely, who first took steps to introduce the collegiate system into universities, though for the beginning of the system one must go to Paris. By the middle of the thirteenth century the majority of middle-class students were living in halls under the control of masters. These halls largely disappeared or were absorbed by the colleges, though this absorption was more gradual at Oxford than at Cambridge. Hugh de Balsham founded Peterhouse at Cambridge in 1284, and between 1324 and 1352 seven new colleges at Cambridge came into existence. King's College was founded in 1441 and Queens' a few years later. "It is a strange madness," said Petrarch, "this desire ever to be sleeping in a strange bed," but now the wandering scholars were settling down.

The lecturer next traced the rise of authority in the Middle Ages and the ascendancy of scholasticism which kept control until the Renaissance. He asked what was the attraction of scholasticism to the human mind. It was an attempt to push reasoning by the apparatus of logic to its utmost extreme. This was not an atmosphere in which science or medicine could flourish, though an age which had seen many able minds completely subservient to "the gospel according to Karl Marx" had little reason for sneering at scholasticism. In early times, before the universities existed, the art of medicine was practically controlled by the Church. Even at that early stage any kind of craftsmanship in medicine was looked at askance. It was becoming fashionable to denigrate the Renaissance, but so far as medicine was concerned things were in a far worse state before this rebirth. The universities of Europe, many of which had started as rather revolutionary, anti-clerical institutions, gradually became exclusive. Papal influence seemed to vary directly with the distance of the university from Rome—for example, Paris was more under the papacy than any Italian university. What was it that saved medical science during the two centuries after the death of Frederick II, that liberal patron of Salerno, in 1250? The answer was surgery, which the physicians tried to repress. The lecturer gave an amusing account of the conflict in the University of Paris over the effort to exclude all who worked with their hands. When the surgeons secured the right to attend the lectures, though degrees were denied them, their opponents countered the move by admitting barbers, to which the other side retorted by requiring all lectures to be in Latin, which the barbers could not understand, but this was met by giving the lectures once in Latin and a second time in French!

A Slowly Opening Door

But the Renaissance was at hand. Its harbinger in England was Erasmus, who represented that sort of compromise for which the English were now renowned. The year 1511, when Erasmus was at Cambridge, was an important date in the history of surgery. Those who practised surgery were required to be licensed after due examination. In 1518 the Royal College of Physicians was founded with Linacre as its first President. In 1540 the regius professorship was established. With such a start as this it was disappointing to find how little was achieved. William Harvey made his great discovery, but in fact it had little influence upon the practice of medicine in the seventeenth century. More important than his discovery was his introduction of the experimental method. But the progress of clinical medicine showed an extraordinary time lag. The door that had been opened was not entered at once, and Harvey's injunction to seek out the secrets of Nature by way of experiment was only falteringly followed. The severance between medicine and surgery was maintained by the cleavage between philosophy and craftsmanship.

Gradually, however, during the seventeenth century observation, reason, and experiment penetrated into medicine, modifying somewhat the influence of authority. Two chief aspects in the study of disease became more clearly defined—laboratory experiment and clinical observation—though like two brethren united by a common tie they were apt to disagree. Sydenham was more influenced by the systematic botany of Linnaeus than by the experimental physiology of Harvey. He considered that the first task of the clinician was to reduce diseases to certain definite species. This was the indication of another concept which had continued to be affirmed, denied, and reaffirmed—namely, the entity of disease.

Two events which influenced the practice of medicine were the invention of percussion by Auenbrugger and of the stethoscope by Laennec. From these humble beginnings the whole science of physics obtained an introduction into medicine. Physicians became no longer ashamed to use their hands. Anaesthesia and antisepsis revolutionized surgery, and in the last decade of the nineteenth century clinical pathology added another weapon to the armament against disease. The twentieth century saw the physician so surrounded by apparatus that in its midst the patient was in some danger of being overlooked. Then as a corrective came psychology, at first a kind of reversion to mediaeval methods of thought, but now more observational, and proving of the greatest value to medicine.

Thus the lecturer completed his survey of the long ages from the time when mediaeval craftsmanship found splendid exercise for its talents in pillared Gothic and storied windows, but when to apply experiment and handicraft upon a being having an immortal soul appeared to be like high treason, and when surgery was only to be tolerated as a painful necessity. The Renaissance brought a different attitude to the whole of life, but the new ideas generated seemed automatically to provoke resistance, of which the long-drawn-out refusal to accord surgery its proper place was one example. But now the long struggle had been won, and never again would the birthright of the "apposable thumb" be bartered for a mess of dialectical pottage.

INCOME TAX

EMERGENCY COMMISSIONS IN THE R.A.M.C.

In many cases the income-tax liability of an officer serving in the R.A.M.C. will be a dual one—there will be tax chargeable on his Army pay and deducted therefrom through his Army agent, and there will be liability in respect of the (presumably reduced) civil earnings of his practice or of his share in the practice in which he may be a partner. When an officer receives his commission his Army agents supply him with a form on which he gives such particulars as will enable the War Office assessor to get into touch with the inspector of taxes who has hitherto dealt with the officer's liability. Assuming for the moment that civil earnings have entirely ceased the liaison so established should enable the inspector to see that an appropriate adjustment is made in the local assessment, and to notify the War Office of any allowances—for example, balance of "life assurance" or "child" relief—that may be due from the assessment on the Army pay. The method of calculating that pay is complicated by the system of "allowances," but broadly the principle followed is the one applied to civilian employment—namely, that allowances paid in money are chargeable to tax, but not allowances provided in kind.

Adjustment of Civil Assessment

The adjustment, if any, which should be made in the local assessment on the civil earnings will of course vary with the circumstances of each case. In this connexion the possibility of claiming the special relief provided by Section 11 of the Finance Act (No. 2), 1939, should be borne in mind. That relief applies where the actual aggregate earned income of the financial year is less by 20 per cent.—or approximately 20 per cent.—than the aggregate earned income as assessed, and was explained in some detail in the *British Medical Journal* of October 21, 1939 (p. 821). In spite of this form of relief cases of hardship may occur, as, for instance, where an individual holding an appointment has been seconded for war service without vacating his appointment, with the result that he has in effect two sources of income—the civil source assessable on the previous year's basis and the Service employment assessable as a "new" source in the current year. In cases of demonstrable hardship the officer affected would be well advised to put the facts before the inspector of taxes and ask whether he cannot suggest some equitable basis of settlement. We cannot think that the Board of Inland Revenue could contemplate with equanimity that war service should involve fiscal injustice, and we feel sure that such cases will receive sympathetic treatment.

Serum Sickness.—A process of treatment with heat and alkali will remove from horse serum the factor causing serum sickness in rabbits without unduly impairing antibody content. —Serum Sickness in Rabbits: VII, Method for Removing or Destroying Factor causing Serum Sickness. M. S. Fleisher and L. R. Jones.—*J. Immunol.*, June 1939, **36**, 511.

TREATMENT OF NEUROSES IN THE EMERGENCY MEDICAL SERVICE

The following article, which describes the arrangements made to deal with neuroses in the Emergency Medical Service, has been received for publication.

The probable incidence of psychiatric or neurotic casualties resulting from air raids is a question upon which there is considerable divergence of opinion. It is sometimes anticipated that such casualties will occur in large numbers, but the evidence of those with practical experience of air raids suggests strongly that this view is mistaken. Professor Mira, for example, who was in Madrid and Barcelona during the Spanish War, states definitely that the incidence of neuroses was comparatively small—so small that there was not sufficient employment for the psychiatrists in Spain, some of these having to be transferred to general medical work. Professor Mira's observations will be found in his article "Psychiatric Experience in the Spanish War," published in the *British Medical Journal* for June 17, 1939.

The extent of the problem to be faced is therefore uncertain, and any scheme for dealing with psychiatric or neurotic casualties must be on a basis which will admit of indefinite expansion should circumstances require it, although it is far from certain that these circumstances will arise. Further, any such scheme must take account of the special character of the neuroses, which differ fundamentally from organic conditions in their origin and structure. It should be remembered here, however, that experience in the last war and in the Spanish Civil War showed that a number of patients who had been in the proximity of bursting bombs, and who exhibited symptoms of an apparently neurotic type, proved on examination to be suffering from injury of the nervous system, as demonstrated, for example, by haemorrhage or other changes in the cerebrospinal fluid. The diagnosis of such conditions from the neuroses is clearly a matter of the first importance.

When this diagnosis has been made, however, the handling of the neuroses proper requires essentially different methods from those suitable for wounds and organic injuries. The central fact which has to be borne in mind is that we are concerned here with conditions in which psychological factors play a predominant part. For this reason the development and duration of neuroses are greatly influenced by the manner in which cases are treated at their outset. If they are inefficiently handled at this stage not only may their course be prolonged unduly but the incidence of neuroses in the population may be greatly increased by suggestion and contagion: the potency of factors of these kinds was strikingly pointed out in the article by Professor Mira already mentioned. "When a man did not return to his post after a nervous breakdown his comrades were quick to notice it, and there was a tendency for more neuroses to appear. . . . It was our experience that you can always fill your psychiatric beds, no matter how many you decide to have; the supply creates the demand." Hence the policy of evacuating casualties as quickly as possible down the line, while suitable for organic injuries, has to be substantially modified so far as neurotic cases are concerned. Indiscriminate evacuation of such cases might easily lead to a grave increase in neurotic disorder.

The scheme elaborated by the Ministry of Health for dealing with neuroses which may occur under air raid conditions has been constructed on the basis of the foregoing considerations. The arrangements for the London area will be described in some detail. A similar organization has been built up in provincial areas.

Arrangements for the London Area

The special arrangements for dealing with neurotic casualties are of course closely linked with the main Emergency Hospital Scheme in the area. The structure of this scheme is now generally known, but the aspects relevant to the present subject may be briefly summarized as follows. London and the contiguous areas of the home counties are divided into ten Sectors, each radiating from a central area comprising one or more of the teaching hospitals. Each Sector contains a large number of hospitals, which are so organized that casualties arriving at first-aid posts or casualty hospitals within the Sector, and which cannot be dealt with other than temporarily at this level, will be evacuated to hospitals further afield in the same Sector.

This procedure, while admirably adapted to the rapid and appropriate disposal of organic injuries, requires considerable modification in its application to neurotic cases. First, in many of the cases success is dependent upon early treatment being obtainable near the site of onset. Secondly, if cases of simple fright and mild neuroses are immediately evacuated to hospitals further down the line the accommodation required for organic cases under the conditions of a severe air raid might be unduly strained. Thirdly, owing to the psychological factors underlying neurotic disorder this procedure might lead to a great increase in the incidence of such disorder. Fourthly, it is undesirable that neurotic cases should be treated in the same wards and under the same conditions as organic cases, as this again may tend to accentuate and prolong neurotic illness. Lastly, more severe neurotic cases require special methods and expert care, which may not be available in general hospitals.

It is therefore essential to secure that simple neurotic cases are dealt with adequately "in the front line"—that is, at first-aid posts and casualty hospitals, from which the large majority may be returned to their own homes after any necessary preliminary treatment; next, that only those cases which in the opinion of an expert require more prolonged treatment are sent down the line, facilities being provided for the careful sorting out of such cases; and, finally, that cases so sent down go to special hospitals, where the staff and methods suitable for these cases are available.

In order to secure these ends the following machinery has been established. Each Sector has been divided into four or five areas, and a neurologist or psychiatrist (including in the latter term "medical psychologist") has been attached to the hospitals of each area. The duties of this officer are: (*a*) to make himself acquainted with the topography of his district; (*b*) to get in touch with the various hospitals comprised in that district, and to ensure the smooth working of the neuroses scheme; (*c*) to establish, with the aid of the Group Officer, out-patient departments in one or more of these hospitals, where neurotic conditions can be treated, and to which general practitioners may send cases for which specialist aid is required; (*d*) to decide which cases need the more prolonged and specialized treatment to be obtained in the special neurological hospitals. In general, cases can be sent to these special hospitals only on the advice of the neurologist or psychiatrist. In the event of a local air raid any further specialist staff required will be drafted in from other districts.

In order to ensure adequate handling of neurotic conditions at the "front-line" level, instructions have also been issued to the medical personnel of first-aid posts (published in *British Medical Journal Supplement*, September 2, 1939). These instructions emphasize that in cases of simple fright, and in the majority of mild neuroses, all that is required is sympathetic but firm handling, opportunity for temporary rest, with or without sedative drugs, and then the return of the patients to their own homes. Such patients may be advised, if it is thought necessary, to report to their general practitioners or to attend the special out-patient departments established in their district. More severe cases will be referred by the officer in charge of the aid post to a casualty hospital, where they will be dealt with in the manner already described.

Four special neurological hospitals have been organized at various places around London, but all situated at least ten miles from the central area. These hospitals, staffed entirely by neurologists and psychiatrists, are designed for the treatment of those patients whose condition is too severe to enable them to be sent to their own homes or to be dealt with adequately as out-patients. The neurological hospitals also provide mobile units which can be sent to neighbouring areas to supplement, in the event of a local air raid, the neurologists and psychiatrists attached to those areas. Two of the special neurological hospitals (at Mill Hill and Sutton) have been organized by the Maudsley Hospital, which has in effect been divided into these two units. The remaining neurological hospitals are situated at Isleworth and at Maidstone, and a fifth hospital is projected in Essex. A special hospital has also been established near Watford to deal with cases requiring more prolonged psychological treatment.

In the event of further accommodation being required than the special hospitals are able to furnish, it is proposed to provide neurological units in association with the base hospitals more remote from London.

Provincial Areas

Arrangements similar to those of the London Area have been made in each of the provincial areas, though of course modified in accordance with the circumstances and needs of each area. In particular, the aim of providing special neurological hospitals in which the patients will be under expert care has been followed throughout. About twenty such units have been established in the provinces, each of which can receive patients from neighbouring towns or from a more extensive district.

A pool of neurologists and psychiatrists who are under contract for service has been prepared from which specialists can be dispatched immediately after an air raid if their services are required to supplement those locally in charge of arrangements.

TOXIC GASES IN INDUSTRY: PHOSGENE AND ARSINE

The Department of Scientific and Industrial Research has issued two further leaflets in the series describing standard methods for the detection of poisonous gases produced in industrial processes, dealing with phosgene (carbonyl chloride) and arsine (arsenic trihydride or arseniuretted hydrogen) respectively.

In the leaflet on phosgene (Methods for the Detection of Toxic Gases in Industry, Leaflet No. 8, published by H.M. Stationery Office, price 2s. 6d. net) it is pointed out that this gas is made specially for use in certain industrial processes, particularly in the dyestuffs, organic chemical, and pharmaceutical industries. It is also used in the manufacture of several metallic oxides, and may also occur as a decomposition product of trichloroethylene and of carbon tetrachloride (used, for example, in some forms of fire-extinguishers). The gas is much more deadly than chlorine. Atmospheres containing concentrations of phosgene only just detectable by smell or lacrimation, and consequently easily "tolerable," may prove fatal. There is a risk of serious lung injury from exposure to a concentration, by volume, of one part in 30,000 for as short a period as two minutes, and the maximum output permissible for prolonged exposure is one part in 1,000,000.

Arsine is dealt with in Leaflet No. 9 (price 2s. 6d. net). Some of the situations in which it may be encountered in dangerous concentrations are works employing electrolytic processes or in the manufacture of zinc chloride and sulphate and the smelting of arsenical ores of iron, lead, zinc, cobalt, etc. It is also encountered in dyestuffs, electroplating, galvanizing, hydrochloric acid and sulphuric acid works. Arsine smells faintly of garlic, and the smell may easily pass unobserved. No reliance, therefore, should be placed on the absence of such an odour as an indication that a suspected atmosphere is safe. There is evidence also that repeated exposures to very low concentrations result in a cumulative effect, with possibly severe poisoning as a result. There does not appear to be any limiting concentration at which this gas can be regarded as harmless for daily exposure, and continuous work should never be permitted in an atmosphere in which the presence of arsine can be detected by the tests described in the leaflet. Exposure to a concentration of one part, by volume, in 20,000 for one hour is dangerous, and a concentration of one part in 100,000 for twelve hours is fatal.

Reports of Societies

INDUCED PYREXIA

A meeting of the Medical Society of London took place on December 11 under the chairmanship of Mr. ZACHARY COPE, when the subject for discussion was "Induced Pyrexia."

Fever Treatment of G.P.I.

Dr. F. J. NATTRASS said that his principal experience of the method was in the treatment of general paralysis of the insane. In his view the electrical method of producing fever had great advantages over the infective method (for example, malaria). The fact that so many different methods had proved effective, though in varying degrees, suggested that the fever alone was the essential element in all these forms of therapy. It could no longer be contended that there was anything specific about malaria; it was only one of the agents for producing high and sustained fever.

The instrument he had employed for the production of short waves was a small radiant heat cabinet, the chief advantages of which were the low cost and the fact that a continuous record of rectal temperature could be maintained. He had also had some experience of inductothermy. Almost all methods could give good results if properly used. The chief factors to ensure success were a thorough knowledge of the system chosen and the closest observation and care of the patient during treatment. But, with such reservations, the published figures appeared to show that the results of fevers produced by physical agents were superior to those produced by malaria, and the mortality was considerably lower when physical agents were employed. He quoted some Ministry of Health figures from which it appeared that where special experience was assisted by organized arrangements the death rate directly attributable to benign tertian malaria was seldom more than 3 or 4 per cent., but where these precautions were not taken the case mortality had been as high as 10 or 14 per cent. During the past four years he and his colleague S. F. Evans had given 213 fevers to cases of general paralysis of the insane, with no deaths from the treatment. Treatment by electrical heat was less formidable for the patients than malaria and did not make them ill. They recovered quickly from the fever and if necessary could go out of hospital next day. After the first or second fever herpes labialis was common, but it was of no practical importance.

The general principle in treatment should be to persist until a maximum clinical response had been obtained. As a rule it was apparent at an early stage of treatment whether or not the patient was responding, but gradual improvement might continue for months after the cessation of the course of fever. About ten fevers were generally advised, but his experience had led him to believe that if the level and duration of the fever were adequate a shorter course was sufficient. His present practice was to give from four to six fevers of 106°, each for eight hours. Pyrexial treatment must be supplemented by full specific treatment, especially by tryparsamide and bismuth, but in general it had been found too dangerous to inject the drugs during the height of the fever. The fever soon caused a fall in the cell count and protein of the cerebrospinal fluid, but the change in the Wassermann reaction and in the Lange curve was very slow. Just enough sedative should be given to keep the patient reasonably comfortable without reducing consciousness to a point where drinking was difficult. It was important to maintain proper water intake during fever to compensate for loss by sweating. It should be made clear that not all cases of general paralysis of the insane were suitable for electropyrexia. The patient must be capable of a certain amount of co-operation, or at least be non-resistant. It might well be that malaria was still the method of choice for very excited or severely demented patients.

Gonorrhoea and Other Diseases

In gonococcal infections, Dr. Nattrass said, fever was usually reserved for resistant cases, and those with local extension of the disease in the male or female organs, also for the treatment of gonococcal arthritis. The treatment of such cases was in fact the most notable achievement of fever therapy. He was not competent to judge whether fever had been superseded by the new chemotherapy with sulphonamide compounds; he thought the matter was *sub judice*. Prolonged experience had shown that a temperature of just above 106° was near the upper limit of safety for application to the human subject. Lower temperatures than that might cure gonococcal infection, but only the higher temperatures cured the larger proportion of cases.

Apart from general paralysis and gonorrhoea, benefit by fever had been established or claimed in a number of diseases. Cases of gummatous meningitis resistant to chemotherapy had sometimes improved. In primary and secondary syphilis the results were better when fever was combined with chemotherapy, and much experimental work was proceeding on the subject. No case had yet been made out for the routine use of fever in early syphilis. In asthma the effect of treatment was difficult to assess. Prolonged remission or even permanent disappearance of asthma and especially of the status asthmaticus might follow fever incident to pneumonia. In the two largest series of reported cases of asthma, one of forty-four and the other of fifty, it was reported that 50 per cent. experienced remission of attacks for periods varying from a few days to a year or more. The authors were judicious in their claims, and made it clear that ultimate relapse was usual, although relief could often be obtained by a second series of fevers. In chorea, in some cases the movements were promptly checked by fever, and there was evidence that a short course reduced the total duration of the illness, while the presence of carditis was not a complete contraindication to fever therapy. At the same time he doubted personally whether fever was generally indicated in chorea.

Results with Inductothermy

Dr. **George Graham** described some work carried out at St. Bartholomew's Hospital, at first with Neymann's diathermy technique, but afterwards with the inductotherm and a heat-insulating bag. The bag formed a sort of waterproof quilt above and below the patient, whom it entirely enclosed, save for the neck opening, with the help of zip fasteners. Temperatures (rectal) were taken every quarter of an hour until they reached 104°, and then every five minutes until about 105° was reached, when the current was turned off. During the fever the patients were given as much fluid as they liked to drink, and sometimes they consumed 3,000 c.cm. a day. A fan playing on the face made conditions more comfortable. Morphine (1/4 gr.) was given about a quarter of an hour after the fever had started. As to the results, he mentioned five cases in which the symptoms and pathological findings were those of general paralysis of the insane; they had all done very well indeed under fever therapy. The Wassermann and sigma reactions had changed very little, but the cerebrospinal fluid cells and protein showed a considerable fall. The patients, with few exceptions, developed bad herpes widely distributed over the face, in some cases compelling a cessation of treatment.

In gonorrhoeal arthritis he had used the treatment in cases in which there were large swollen joints, and they had done very well. In one case after four fevers, although the joint condition cleared up, gonococci remained in the urethra, and a long treatment with diathermy was necessary before they finally disappeared. He believed that the treatment was useful in very severe asthma, and he quoted two cases. In one of them—a man who had required at least 80 minims of adrenaline a day—death took place eventually from lobar pneumonia, but there was no doubt that he had been made much more comfortable over a long period through being given fever. In the other case, that of a man who required 20 minims a day to keep him comfortable, the fever stopped the asthma altogether. In patients who had occasional attacks of asthma it was uncertain whether benefit followed fever therapy or not.

He had employed inductothermy in two cases of chorea, one a very severe one, and as a result of his experience he would use the treatment in all cases of chorea, save in those of young children under the age of 8 or 10 years. Cases of subacute infective arthritis or rheumatoid arthritis had been treated by induced pyrexia at the Mayo Clinic, and about 10 per cent. were reported completely arrested and 30 per cent. very much improved. Dr. Graham had himself treated some eleven cases of subacute infective arthritis. Those which were in the early stage of the disease had responded well, but if the disease had been present a long time, with already some fixation of the joints, no great amount of good was likely to be done. The patients felt much better on the day following treatment, having less pain and increased joint movement, but within three or four days the pain returned, though not to the same degree, and the limb became more stiff. Four or five fevers had been given to these patients, after which they were allowed to leave hospital, and some of them had gone on improving, but his opinion was that it would be well to give them more fever. He had also treated three patients suffering from spondylitis, and they had done very well as regards immediate relief of pain. He had studied the sedimentation rate in these cases; it went up considerably when treatment started, and afterwards settled down. Here again it was true that the earlier such cases were treated the better the result.

Beneficial Effect of Accompanying Fever

Mr. **Zachary Cope** said that this method of treatment seemed to be a criticism of common clinical practice. The first measure taken in a number of diseases, when the patient had fever, was to give him an antipyretic drug. Possibly the physicians had been wrong in trying to reduce fever as the first line of treatment. The temperature might come down, but the patient was not better, and was deceived into going about again before he ought to do so. In such cases the antipyretic drug was a delusion and a snare in cutting short the fever which was helping him to get well. He wondered whether the introducers of the discussion knew of any drugs which acted on the heat-producing centre, bringing about a fever of adequate amount but causing no serious harm.

Dr. C. B. **Heald** suggested that not hyperpyrexia but pyrexia, with temperatures of about 102°, and not given at weekly intervals but every day over a short period, might be effective in arthritis of a chronic type, with a suspicion, though no proof, of a gonorrhoeal nature. In some cases in which this method had been applied the same effect was obtained as with hyperpyrexia, but without any of the distress. Apparently if one got somewhere near the heat breaking-down point, and repeated it again and again, a clinical benefit was forthcoming which was not obtained in a series of hyperpyrexias separated by an interval of days.

Mr. **Johnston Abraham** had found the induction of malaria rather troublesome because one could not tell for ten days or so whether it was likely to serve its purpose, and once or twice, in his experience, it was not possible to stop malarial recurrences afterwards. He believed that the treatment of gonococcal infections by sulphonamide compounds had put the Kettering hypertherm out of action for the time being, but some 10 per cent. of gonococcal infections would not clear up at all under sulphonamide, and, moreover, there were always relapses even up to seventy days after apparent clinical cure by chemotherapy, so that a certain residuum of cases always remained in which hyperpyrexia was indicated.

Mr. **Williamson-Noble** mentioned that cases of secondary glaucoma sometimes yielded very good results on short-wave applications.

In his reply Dr. **Nattrass** said that he had had no experience of moderate pyrexia in arthritis, but one American worker had testified to symptomatic benefit following the use of hot baths. He did not think, however, that such measures could cure gonococcal arthritis; hyperpyrexia was needed for that. Dr. GRAHAM, replying to a question whether the treatment might be used in cases in which there was acute rheumatic fever, said that Neymann had stated that in the treatment of cases of chorea rheumatic endocarditis was not a contraindication. He himself had had only one case in which there was acute rheumatic fever. There was a definite systolic murmur at the apex. Since the hyperpyrexial treatment she had been very well indeed, and there had been no return either of chorea or of endocarditis; no murmur was now perceptible.

LIQUIDATING THE LOUSE

At a meeting of the Royal Society of Tropical Medicine and Hygiene on November 16, with the president, Sir RICKARD CHRISTOPHERS, F.R.S., in the chair, Professor PATRICK A. BUXTON read a paper on the louse. In his introductory remarks the lecturer said the paper and references to current literature were brief, since a full account of the insect was now in the press.[1]

The body louse and the head louse, he said, should be regarded as biological strains of a single species, *Pediculus humanus*. Lice transmitted such diseases as epidemic typhus, trench fever, and relapsing fever. In the civil population a considerable proportion of school children were infested with head lice. In the war of 1914–18 trench fever and skin complaints associated with *Pediculus* remained major causes of admission to hospital up to the end of the war.

Collective Biology

It was important to know what proportion of people were infested and whether they harboured few or many lice, also what was the constitution of the louse population itself—that is, the proportion of adults to young and males to females. Populations were dynamic, not static, and they were always increasing or decreasing, irregularly or according to the season or other factors. The louse belonged to an order of insects (the Anoplura) in which metamorphosis was slight, the larva being a small edition of its parents. Moreover, adult and larvae lived in the same place and fed only on the blood of human beings. Head and body lice and their eggs were found on or near the surface of the body and beneath the clothes, where the temperature and humidity were remarkably constant. Lice could be counted in garments or on the head, or they could be bred experimentally in gauze-bottomed containers held against the skin. Basic facts obtained under good experimental conditions by the latter technique showed that: (1) the adult female lived thirty-four days, laid no eggs on the first two days or the last, and on other days laid nine eggs—that is, a total of 279; (2) the eggs had a mortality of 30 per cent., this stage lasting nine days; (3) the larvae had a mortality of 40 per cent., this stage lasting nine days. Assuming that the adult progeny were male and female in approximately equal numbers and that every female was fertile, it was possible to construct tables and graphs showing daily births and deaths, total number living, etc. Under favourable experimental conditions viable females might exceed 1,000 on the sixty-first day. If conditions were less favourable, as they might be on a person able to achieve a partial control of the insect, lice could still multiply rapidly. On the assumption that the average female lived only twenty days, that she laid only six eggs a day, and that 80 per cent. of her offspring died without reproducing themselves, the descendants of a single female even then would amount to 1,000 viable females on the eighty-ninth day.

Actually, counts on the hair or on the shirt demonstrated that with both head and body lice small populations of from one to ten lice were commonest, and that counts beyond 100 were rare. This suggested that populations frequently started were exterminated, or that they were kept at a low level by human interference or by some other factor which was effective when the population was less than 100. Seasonal changes need consideration. In the Mediterranean head and body lice were rarer and less generally distributed in the hot dry summer than in the cold winter, and in such countries as Northern India and the north of Nigeria lice were rarer in the hot dry weather before the rains than at other times of the year.

Methods of Control

Though many methods had been recommended in the past for destroying lice no work had been done on this subject for twenty years, and many new insecticides known to be of value against other insects had never been tested on *Pediculus*. In discussing the subject of control it was best to consider head, body, and crab lice (*Phthirus*) together, as what killed one killed the others. On the other hand, the destruction of lice and eggs on the surface of human beings and their destruction on garments and blankets presented separate problems. If improved methods of controlling lice were required the most promising things to investigate were (1) the effect of the newer organic fumigants on lice in clothing and blankets; (2) the possibility of controlling body and head lice with powders or liquids containing rotenone and substances which occurred with it; (3) the possibility of "proofing" garments for at least some days with the halogenated cresols. As the military experience in the war of 1914–18 proved, one could thoroughly "delouse" a large body of men, but they became reinfested as soon as they went up the line again. The most important problem, on the military side, was to find a means of disinfesting a soldier without undressing him or taking him away from work, or as an alternative to "proof" him and his clothes so that they would not become infested.

The various ways of controlling lice included mechanical methods, the effects of temperature, and the effects of such contact insecticides as cresol and phenol, organic poisons like paraffin or kerosene and xylol, vegetable oils such as eucalyptus. With contact insecticides used on the head it was generally advisable to cover it with a bathing cap or towel for an hour and then wash the hair. Though *Derris* and other plants containing rotenone were extensively employed in veterinary practice against lice on domesticated animals they had not been tested on man. Fumigants included sulphur dioxide, hydrocyanic acid, carbon bisulphide, carbon tetrachloride, and naphthalene.

Dr. V. B. WIGGLESWORTH discussed the psychology of the louse. Lice were said to leave a patient with fever. Why was this? Was it due to a higher skin temperature, which repelled these insects, or was it due to a moist sweating skin associated with fever? The behaviour of the louse must be studied systematically and in detail to answer such a question.

Mr. KENNETH MELLANBY, Ph.D., had been studying certain published estimates of the degree of lice infestation in this country. In one northern city the medical report of the education department stated that only 1 per cent. of the children were infested, but records from a children's hospital in the same city disclosed a high percentage with head lice. The head of a child under 1 year was not suitable for lice, but children of from 2 to 4 years of age were almost as heavily infested as older children going to school. There was a higher incidence in girls owing to their longer hair. There also appeared to be minimal and maximal degrees of infestation at different periods of the year. Actually the figures were very disconcerting. In at least one industrial city in this country at one time of the year almost half the children were found to be lousy; this implied that during the course of the whole year very few children escaped. He had found that 70 per cent. alcohol, which was not particularly irritating to the skin, was effective against head lice in children. Three or four fluid ounces of the spirit were used. The hair was made wet and an alcohol compress was then applied under a rubber bathing cap for an hour or longer. Colonel W. BYAM asked Professor Buxton whether, when working with chemicals for the destruction of lice, he took into account the effects of these agents on their excreta. In trench fever, for example, the excreta were infinitely more important in the spread of the disease than the louse itself, and the excreta remained dangerous for long periods after the lice had disappeared from garments and blankets. Mr. G. H. STUART-BUNNING emphasized that the main reason for our being troubled with lice in this country was ignorance of the populace on this question. The best way to kill the louse was to educate local authorities, parents, and children.

---

[1] Buxton, Patrick A. (1939). *The Louse*. London: Edward Arnold and Co.

Professor Buxton, in reply, agreed that the communication from Mr. Mellanby about his northern city was very disturbing. The official figure was 1 per cent., but the actual figure on admission to hospital was about 30 per cent. During the last three months the experience on evacuees gave ground for thinking that some such figure must be common in many parts of the community. There was urgent need on the civil as well as on the military side to devise better methods of control and to bring these methods into practical use. The faeces of lice were important channels of transmission of the rickettsiae of both trench fever and epidemic typhus. But it was highly improbable that most methods successful with the insect would disinfect faeces. Cresols might do both.

Correspondence

Regional Hospital Organization

Sir,—The article on regional hospital organization in your issue of December 9 (p. 1151) must be welcomed as calling attention to the necessity for clear thinking, which is now more than ever vital in the cause of an efficient hospital service. It is feared by some that better organization and some measure of control by the State would dry up the sources of private philanthropy, but there is reason to think that this would not be the case, for better organization would enhance the value of contributions to the hospitals in this country.

Your correspondent omits any reference to the method of finance which obtains in many of our orthopaedic hospitals. It has been evolved precisely because the difficulty of finding the funds for the maintenance of hospitals is so much greater than that of obtaining the necessary capital for building. At the hospital with which I am connected the capital sums required for building have been raised on a voluntary basis, but the maintenance is provided by the payments for the services rendered to patients. This does not mean that the patients themselves, in any but a minority of cases, provide the cost of treatment. It does mean, however, that this cost is met by various public authorities—education and child welfare committees, public assistance committees, private and insurance companies, and voluntary bodies. This enables the hospital to concern itself with its own running and improvements without having the anxiety of a steadily increasing debt. There are undoubtedly shortcomings and difficulties in this system, but without it many hundreds of orthopaedic cases would have been left untreated. It presents a typically English compromise and allows co-operation between different authorities and people interested, in a way which would otherwise be difficult, if not impossible. (It may be said that orthopaedic cases can be more readily dealt with under this system than can the more acute and emergency cases, but this is a question of degree, not of principle.)

I am writing this letter because I feel that in future planning every proved method of dealing with hospital problems should have careful consideration.—I am, etc.,

Nottingham, Dec. 11. S. Alan S. Malkin.

Treatment of Wounds by Closed Method

Sir,—I would state at once that my experience in the treatment of open fractures by the closed method has been confined to civilian types of injury and almost exclusively to patients treated within a few hours of their accident. The results in a large number of patients have been such that I was in no way surprised to learn from Dr. Trueta that the method is also eminently successful for war injuries.

Mr. E. T. C. Milligan (*Journal*, December 9, p. 1160) lays stress upon a mechanical principle that must be realized if we are to appreciate the detailed principles underlying this method of treatment and if we are to persuade those who still hesitate to use the closed plaster in the treatment of open fractures. The treatment rests upon the main principle of re-establishing and conserving the vital quality of the damaged tissues. After the surgical débridement we are assured by active bleeding that the outflow of circulating fluid is adequate, but to maintain life an effective circulation is essential. The return flow through venous and lymphatic channels is equally important, for if this is impaired stasis, oedema, and even death may result. There is no clinical test to prove at operation that the return flow in the damaged area is adequate, but we know the factors upon which this return flow depends. One of importance is the normal tension in limiting membranes such as skin, aponeurosis, fibrous sheaths, and fascia. The open wound has released this physiological tension. In so far as it is safe to do so, that tension should be replaced; the safest method is the application of a closed plaster. The application of this plaster is as important a technical step as any in the surgical procedure, for it must hold the reduction of the fracture and supply this necessary even pressure; too tight a plaster is dangerous, too loose a one ineffective. The plaster itself should be of the quick-setting type. One that sets in a few minutes not only allows speed of work but lessens the possibility of movements during the setting stage with the occurrence of rucks and unevenness in the cast. For those fractures below the knee associated with gross muscle and bone damage it is difficult, if the first plaster has to be changed before any sort of union is present, to hold the original reduction. If too much traction is applied the fragments are distracted; if not enough is applied they angulate; a quick-setting plaster helps in this difficulty.

One final point regarding this treatment. The smell of open wounds under plaster is unpleasant to us while the patient is in hospital, but if treatment is continued in the small homes of the working class the smell becomes intolerable to both the patient and his family. A few drops of chlorinated eucalyptus dropped on the plaster several times a day helps to keep such families together.—I am, etc.,

Richmond, Surrey, Dec. 10. William Gissane.

Treatment of Air Raid Casualties

Sir,—The principles of the treatment of air raid casualties as expounded by Dr. Trueta are at the moment receiving—quite rightly—wide publicity in the medical world, and it seems an opportune one to ask ourselves if all the principles laid down by Dr. Trueta are in fact sound. In this letter I wish to deal with one principle alone—namely, the speedy removal to hospital at all costs of the injured in an air raid.

If the injured man can be on the operating table within fifteen or twenty minutes so much the better, says Dr. Trueta, but always presupposing, in my view, that he has been adequately dealt with *en route* to the hospital, that he has been carefully lifted on to the stretcher, which, in its turn, has been carefully lifted into the ambulance, which is modern, fully equipped and manned, and driven by a trained ambulance driver, then I agree with Dr. Trueta that speed is not only safe but essential. Alas! how many cases are going to be so lucky, for I think that the importance of adequate stretcher-bearing, expert ambulance driving, and careful and gentle handling of the injured has not been sufficiently brought home to the public by the profession.

What in actual fact will be the fate of most of the badly injured—and, if my picture is not very heartening, it is as near the true picture as can be—is that the injured man will be picked up by untrained people, heaved and pushed on to a stretcher, jacked up into an ambulance (which more often than not will be a converted grocer's van, inadequately sprung, lighted, and equipped), and driven by someone who has little or no conception of how to drive a car with injured aboard. Then, if he is still alive and conscious, the moment at which this ambulance starts its 40 m.p.h. dash to hospital will be the one at which the injured man will pray that he was neither. In the River Emergency Service we shall embark most of our injured on to our ambulance ships from other ships and disembark them at points convenient for evacuation either to the C.C.S. or to the sector hospitals, and during the time they are in the ship I propose to do everything possible by means of splints, dressings, etc., to alleviate their sufferings.

I maintain that, haemorrhage apart, the principle of speed in surgery is fundamentally wrong even under the most favourable conditions, and dealing with the injured in the streets or elsewhere is but a branch of surgery. I should like to have the views of some of our senior surgeons with practical experience of war conditions on this matter.

Finally, if some of Dr. Trueta's other views are correct, all first-aid posts which are not attached to hospitals should be abolished. This is a view contrary to that adopted by the authorities in London, and it is of the utmost importance from the medical, as well as from the financial, angle that this matter should receive all the publicity possible.

If criticism from a general practitioner who has not had recent experience of treating injuries comparable to those received in air raids seems presumptuous, nevertheless it is justified if it calls forth an answer from those who are best qualified to give an opinion on the important points which he has raised.—I am, etc.,

London, S.W.3, Dec. 13. R. PROSPER LISTON.

Treatment of Gas Gangrene

SIR,—During 1915–16 I had the good fortune to be acting as surgical dresser to the late Sir Herbert Waterhouse in Russia, where gas gangrene was a frequent complication of gunshot wounds. Many of the wounded had spent several days *en route* to the C.C.S. or the base hospital, and fully developed gas gangrene of the limbs required immediate amputation by the guillotine method. In some cases the infection had invaded the abdominal wall, the thorax, or the neck, making amputation impossible. Sir Herbert Waterhouse treated such cases with generous incisions, followed by the rubbing of powdered crystals of potassium permanganate into the wounds. This led to violent reaction with the emission of heat and steam, and the treated surfaces became covered with a charred coagulum. This separated after a few days, leaving a granulating surface which ultimately healed.

During the recent correspondence upon the treatment of gas gangrene this method of treatment has not been mentioned, so that I venture to bring it forward as a method that can be adopted in apparently inoperable cases.—I am, etc.,

Sherborne, Dec. 8. J. WHITTINGDALE.

Bipp

SIR,—This Rutherford Morison method of the treatment of war wounds was so successful in the last war that I trust it will not be forgotten in the present. To Dr. Austin Priestman's letter (December 9, p. 1164) I would add the important closure of the wound afterwards by large stitches, which wound need not be dressed for ten days. The slight exudate of bipp would look like pus, but the temperature shows this is not so.

The cleansing of the wound by 1 in 20 carbolic, the washing with methylated spirit, the application of the bipp, and the closure of the wound with stitches seem to be similar to Dr. Trueta's closed plaster method described in the *Journal* of December 2 (p. 1073), except that there need be no removal of damaged tissues, only cleansing and fixing in position.

I did a hundred consecutive cases after the Somme offensive of 1917 in the Wharncliffe War Hospital and obtained ideal results, as all were healed in from ten to fourteen days with no pain and no painful dressings, which is very important, as the shock is too severe to be disregarded.

As one who suffered from painful face wounds requiring many dressings, and from my experience later as a surgical specialist, I urge that this method be not forgotten.—I am, etc.,

Chesterfield, Dec. 11. K. B. MACGLASHAN

Endotracheal Anaesthesia

SIR,—Having read the summary upon the advantages and disadvantages of endotracheal anaesthesia by Drs. Rosalind M. P. Milne and J. Ross Mackenzie in your issue of December 9 (p. 1136), I am left with the impression that in spite of the overwhelming preponderance of advantages over disadvantages given by them they are rather averse to endotracheal anaesthesia except in special circumstances, and are definitely hostile to nasal, particularly blind, intubation under any circumstance.

To my mind and in my experience the most important factor in the achievement of good anaesthesia is the establishment and maintenance of a perfectly free airway. This factor can only be obtained with certainty in every case by the introduction of an intratracheal tube. Surely the routine application of a method which establishes a perfect airway in every case needs no defence upon scientific grounds.

The routine application of laryngeal intubation in anaesthesia is, of course, only justified if the intubation can be performed without trauma and without dangerous or unpleasant sequelae. That this can be done is shown by the report of Drs. Milne and Ross Mackenzie upon their 1,253 cases, none of which exhibited any unfavourable sequelae. The complete lack of unfavourable sequelae in this series is remarkable in view of the methods employed, and can only indicate a high degree of skill and care in the performance of the intubations. I am convinced that the surest way to avoid trauma is to reduce instrumentation to a minimum, or, better, to eliminate it altogether by adopting the "blind" technique of nasal intubation introduced by Magill. Once the knack is acquired, provided that the nasal passages and, if one prefers it, the larynx have been desensitized and devascularized by means of spraying with either cocaine 10 to 20 per cent. or percaine 2 per cent. with adrenaline and the nasal tube efficiently lubricated, "blind" intubation can be performed in almost every case with an absolute minimum of trauma. I do not agree that complications are more frequent after nasal intubation; they are entirely dependent upon faulty technique, and their incidence is exactly proportional to the degree of skill exhibited by the anaesthetist, whether the route be oral or nasal.

The choice of tube is a very important factor in the technique of endotracheal anaesthesia, and calls for a nice degree of judgment which is only acquired by practice. The tube should be sufficiently small to pass through the nose without the use of force, and should be sufficiently big to fit the larynx snugly. The snugly fitting tube passed through the nose is held steadily in place and does not move, thus eliminating the trauma to the delicate membranes with which it is in contact and which is occasioned by the movement and rubbing of a smaller tube; moreover, it discourages the constant regurgitant stream of irritating vapour which occurs around a smaller tube, also the inspiration of mucus between the tube and the wall of the larynx. With a well-fitting tube the only times at which trauma may occur are during introduction and removal; it is important, therefore, that a sufficient depth of anaesthesia to abolish the laryngeal reflex be instituted before either of these acts is performed.

If oral intubation by direct vision is to be performed the Magill tube, which was designed primarily for nasal intubation, is not the tube of choice, since its curve renders introduction more difficult than that of a straight tube.

Drs. Milne and Mackenzie rightly stress the great advantage conferred by the intratracheal tube in eliminating the dead space of mouth and pharynx. This is of particular importance in the maintenance of nitrous oxide and oxygen anaesthesia, where an accurate control of the gaseous mixture is so essential. It should, however, be stressed that the dead space is not eliminated by the loosely fitting tube advocated by Drs. Milne and Ross Mackenzie unless the pharynx is tightly packed with lubricated gauze around the tube—a procedure which is not devoid of the risk of trauma and which is rendered unnecessary by the adoption of a larger tube.

I have assumed that in their summary Drs. Milne and Ross Mackenzie have referred in the main to anaesthesia by inhalation rather than by insufflation. The latter method, which except in special circumstanes is now little practised by anaesthetists, requires an intratracheal tube of lesser circumference than the rima glottidis, or a second tube, to facilitate the escape of gases delivered to the lungs under pressure.

In conclusion may I say that, while recognizing certain definite contraindications to the passage of an intratracheal tube, I cannot remember one instance in the routine use of intratracheal anaesthesia when the advantages of perfect control of the anaesthesia, the feeling of safety against all emergencies, the smoothness of the anaesthesia, and the minimum amount of what we must never cease to regard as noxious agents required to produce the optimum level of anaesthesia were not of equal benefit to the patient, the surgeon, and myself; whereas I can remember any number of instances when I have had cause to regret that I had not passed an intratracheal tube.

I am in complete agreement with Professor Macintosh when he advises all who would practise anaesthesia to familiarize themselves with the technique of intubation before interesting themselves with the newer anaesthetic agents. I am convinced that the problem of providing mass anaesthesia in war hospitals at home or abroad, should the need arise, will find its solution largely in the routine use of intratracheal tubes rather than in the use of this or that agent.—I am, etc.,

Bournemouth, Dec. 9. S. F. DURRANS.

SIR,—In their interesting paper on endotracheal anaesthesia published in the *Journal* of December 9 (p. 1136) Drs. Rosalind M. P. Milne and J. Ross Mackenzie are, I think, inclined to lay too much stress on the difficulties attending a method which, from all points of view, is so very often essential to the safety of the patient. Writing as a laryngologist who has of necessity had to intubate his own patients before operation and with an experience going back twenty years, when the now obsolete Kuhn's flexible metal tube was employed, I am confident that blind intubation if properly performed is a quicker and therefore a better method than that carried out by direct vision by means of an endoscope. Blind intubation presupposes a certain easily acquired tactile education.

It is advisable to apply (under guidance of the left index finger) some 10 per cent. cocaine solution by means of a small piece of gauze held in a McKenzie-type laryngeal forceps as soon as the patient is "under" and a few minutes before inserting the rubber tube. This latter can with advantage be suitably curved and braced by inserting through its whole length a piece of flexible copper wire covered (especially at its ends) by bicycle valve tubing bound to the wire in places by thread. To facilitate its rapid withdrawal and introduction the end of the rubber-covered wire as well as the end of the tracheal tube are dipped in liquid paraffin just before use. I have modified Magill's introduction forceps so that the distal end takes a downward dip for about one and a half inches above its actual grasping terminal, which latter is, of course, in the plane of the vocal cords and when closed embraces the tracheal tube with its enclosed wire. The proximal part of the forceps—that is, that part which is outside the patient's mouth—is deflected laterally and downwards, so that the hand of the introducer is removed from his own line of vision. After localizing the arytenoid eminences and the epiglottis with the left index finger, the lower end of the stiffened tube grasped by the forceps is brought between the epiglottis and the finger and, during an inspiration, can be very easily introduced into the trachea. Slight cervical flexion with extension at the atlanto-occipital joint will facilitate introduction. Though employing this method for many years I have only once known a vocal granuloma to occur, and in that case a Kuhn's metal tube had been used.

In nasal introduction with an unstiffened tube I find that the tube very often finds its way straight through the cocainized larynx if advanced during inspiration. If this fails it can readily be passed by the use of the left index finger and forceps as above described. Not only gas and oxygen but, by the use of a connecting tube and funnel, chloroform mixture or (by using a larger-size funnel) pure ether can be readily administered in this way.

By employing the method of introduction described one only requires "simple apparatus and portable agents," and considering the facility with which it can be carried out as well as its comparative safety and frequent desirability, if not necessity, I think the "claims of the undergraduate" will be better served when, as I feel sure will be the case in the near future, a practical knowledge of anaesthetic administration will include a practical knowledge of endotracheal anaesthesia.

I feel sure that Drs. Milne and Mackenzie did not mean to be taken literally when they advised the use of a gauze pack "saturated" with liquid paraffin for the purpose of occluding the supralaryngeal region. I have found gauze squeezed out of normal saline to be effective for this purpose—but a word of caution. It is easy for such a plug to be overlooked at the end of operation, and in one of my patients such an oversight necessitated a "crash" tracheotomy after the patient was back in bed. Incidentally, it is always advisable when giving endotracheal anaesthesia to have at hand a catheter with its distal end cut straight across so that adventitious secretion blocking the tube can be quickly aspirated.—I am, etc.,

Cork, Dec. 15. J. BOWRING HORGAN.

Psychological Casualties in War

SIR,—Dr. T. A. Ross urges the sifting out from recruitment of psychopaths. It is amazing that such a need should still exist. Dr. W. Mayer-Gross (and others who, like myself, are listed to deal with mental casualties) wants an efficient method of ensuring early contact between therapist and patient. Dr. A. C. D. Telfer wants psychological treatment centres; and so on.

I have been in communication with the Central and Local Emergency Committees, the Ministry of Health, the War Office, and the Group Officer of the Hospital Emergency Service. The general response is, "Be a good chap and wait until something happens; try So-and-so—they may know something." So I am still in the dark as to where, how, and with whom I am expected to work when casualties arrive.

There are psychological advisers to the Services and Ministry who presumably know what is being aimed at in Service and civilian spheres. Would it not help those of us who stand and wait if we were informed by those advisers (by letter or at a meeting) as to their plans, metropolitan and provincial? It is fifteen months since I was asked by telegram to be available for public service as a psychiatrist and I am still waiting for instructions.—I am, etc.,

Norwich, Dec. 11. R. LOUIS ROSE.

SIR,—You were good enough to publish recently (October 14, p. 764) an article in which I reported the type of psychiatric material seen at a London hospital in the first weeks of war. It may be of interest to consider the subsequent history of this clinic in view of the many letters appearing in your *Journal* with regard to the expectation of neurosis and psychosis in the civil population should air hostilities be intensified.

The first period—that on which I reported—in the early part of September put the hospital in the position of serving an unusual number and type of patients, as the railway terminus near by was crowded with a specially selected group of population—fugitives from the threat of bombardment. Subsequently the hospital has served its peace-time population somewhat depleted by evacuation—an evacuation which may have selected and removed many potential neurotics, thus possibly falsifying any attempt to compare war and peace figures for this clinic. For this and other reasons assumptions based on the figures of such a clinic can be no more than suggestive. They may, however, be of interest. In the first few days the hospital was attempting to carry on its usual out-patient and casualty services while reorganizing at the same time on a new basis, and I find I cannot trace all the notes for that period. However, the loss of notes is non-selective and need not falsify proportions.

	September	October	November
Cases precipitated by stresses attributable to the war situation ..	11 (55%)	3 (25%)	3 (14%)
Cases precipitated without relation to war stress	9	9	18
Total	20	12	21

The falling off of war stress as a precipitating factor as the war passed from an "acute" to a "chronic" phase seems to be suggested by these small and, no doubt, inadequate figures. The cases included are all cases not previously seen at this clinic, and are "new" in the sense that the breakdown, though in some cases merely a relapse, was of recent origin. Psychotic and neurotic cases are included.

I should find it hard to believe that any large increase in the number of accidents in industry would not lead to a proportional increase in post-traumatic neuroses. The stress of accident falling on more people would consequently fall on more potential neurotics, who might thereby be caused to break down. Should a larger stress than normal fall upon the population as a whole one would surely expect a larger number of neurotic and psychotic breakdowns to occur. The threshold has, as it were, been lowered. That the figures for the last war can tell us anything of value about the possible effects of this war upon civil populations is doubtful. They tell us little enough that is reliable about these effects upon the Forces. Probably we are looking not at a single process but at two, which taken together tend to obscure or cancel out each other. There is in the clinic of which I write a very distinct falling off of old cases. Whether these have recovered owing to war employment or have merely departed to the country or stayed at home I cannot at the moment say. But their disappearance has kept the clinic numbers down to approximately their pre-war level. Such a process on a larger scale might obscure an increase in the number which would otherwise be apparent.

The only conclusion which seems obvious from the discussion of psychiatric conditions of the last war is that the data are so conflicting and unreliable that they are of little value save to suggest that they should be more carefully collected in this war.—I am, etc.,

St. Mary's Hospital, London,
W.2, Dec. 4.
GEORGE PEGGE.

SIR,—This correspondence has come to embody the principal sins of which controversialists can be guilty, including the old unconscious device of attributing views to me which I have not advanced.

If Dr. A. T. M. Wilson (December 9, p. 1161) had read the entire correspondence with his usual care he would not have had real doubt that I was concerned with civilian psychiatric casualties, and that I had made the suggestion (and not entertained the "belief" which Dr. G. R. Hargreaves (p. 1161) seeks to father upon me) that these might not after all be particularly numerous on the grounds that (*a*) there was no evidence of such an occurrence among civilians during the last war (the assertions of regius professors, if not supported by fact, are not evidence, *pace* Dr. A. C. D. Telfer, December 2, p. 1111); (*b*) that even in the Spanish War, according to Dr. Mira, psychoneurotic and similar forms of breakdown did not increase; and (*c*) that there may be reasons even (cf. Dr. Weatherly's observations, p. 1019) for thinking that they might diminish.

I am grateful to Dr. Wilson and to Dr. Hargreaves for drawing attention to the number of people receiving pensions for neurotic disabilities after the last war, because the deductions that may be made, while not necessarily those which Dr. Hargreaves would evidently draw, are of considerable importance for those faced with casualties among civilians. Dr. Hargreaves's talk of the "appalling" number of such psychoneurotic casualties shown in the pension statistics suggests an attitude of just the kind I had in mind when I spoke of creating hypochondriasis in the population. Was it so appalling? It amounted to only 2 per cent. of the troops that survived the war. According to the views advocated by a number of people in peace time this is less than the ordinary incidence of psychoneuroses and allied conditions among the general population. Was it unavoidable that there was even this number? Is it not conceivable that the hastily devised measures for treatment and the methods of assessment of pensionable disability may not have added to rather than limited the number of such chronic casualties? As Professor Mapother once said, there were not a few who "bought a dream book," and with its aid perpetuated illnesses which otherwise might have ceased from neglect or from a different line of treatment. The possible effect of the mere existence of a pension scheme has to be very carefully considered in the case of civilian casualties, especially in a community where in peace time—as Dr. T. A. Ross has emphasized in a similar context—it had become possible to obtain legal redress for even witnessing an accident.

Obviously it is unwise to minimize the importance of foreseeing this problem in all its aspects, but nothing is gained by exaggerating the position by misreading the meaning of previous experience and, on the basis of this, setting up "psychological centres" staffed by enthusiastic but inexperienced people. Let the existing clinics reorganize themselves as efficiently as possible under war conditions; let them be closely attached to the hospitals where casualties in general are to be treated; and let medical staffs in general be taught that neuroses arising in such conditions, if properly handled, are likely to be short-lived and that the treatment should be simple. Let us also remember that in the conditions which may occur during air raids it may be that doctors are not more qualified than many others to deal with the states of minds that will arise, since the example of courage will usually be the main thing, in the early stages at least. Hurry the frightened person to a doctor at the very start, and he will be apt to conclude that he is unnaturally ill rather than quite naturally frightened.—I am, etc.,

Anaesthesia in War Time

SIR,—I hope you will be able to afford me space on this subject. My experience is vast in anaesthesia and in surgery, having for twenty-five years been the general (using the term "general" to cover all the surgical specialties) surgeon in charge of a hospital of 500 beds, and myself the only surgeon for all major surgery, operating usually from 9 a.m. till 5 p.m. seven days of the week, and personally supervising every anaesthesia. My anaesthetist was a dispenser trained by me from 18 years of age. He used from 100 to 150 lb. of chloroform in the year with a Junker inhaler. There was no more competent man living at his job. In that time we had three deaths—one an adenomatous goitre and two persistent thymus gland cases, which latter I learned are very characteristic. My anaesthetist watched the breathing, having the stomach region exposed for that purpose, and the corneal reflex. The slightest irregularity in breathing he would call my attention to. If these two facts are looked after—to keep the corneal reflex just under control and to see that the breathing is regular—I feel that for war or most other general surgery chloroform is one of the very safest anaesthetics, granted that it is pure and free from ethyl chloride.

For those in search of anaesthetic adjuvants—basal anaesthetics, new drugs—I commend the old ones which we know and which we know how to handle—morphine and alcohol—and they will find them far less dangerous than any other and just as efficient; there will be fewer coroners' inquests than after barbiturates.—I am, etc.,

Clogher, Co. Tyrone, Dec. 5.
HENRY SMITH.

SIR,—The section on chloroform in our article on "Anaesthesia in War Time" (*Journal*, December 2) was in no way meant to suggest that avertin and chloroform should be combined, but that on theoretical grounds the danger of ventricular fibrillation could be avoided by the use of basal anaesthetics generally. *We consider that when possible chloroform, alone or in any combination, should be avoided.* We have used it, however, following avertin in bronchoscopy and have seen this sequence used in amputation of the breast where diathermy was employed. In our article we stressed the dangers of delayed chloroform poisoning. Nevertheless, we do not consider there is a greater danger of acute yellow atrophy of the liver from the combination of avertin and the small supplementary dose of chloroform which then suffices to depress the patient to the required depth of anaesthesia than there is if chloroform alone is used, since here a very much larger dose of this drug is necessary to achieve a similar depth of anaesthesia.—We are, etc.,

Department of Anaesthetics, R. R. Macintosh.
Radcliffe Infirmary, Oxford, Dec. 16. Freda B. Pratt.

Sir,—Dr. J. B. H. Holroyd's letter in your issue of December 9 shows a complete misapprehension of the value of the conjunctival and corneal reflexes in measuring the depth of anaesthesia. The light touch, the *tactus eruditus*, employed by an anaesthetist cannot, and in point of fact does not, cause any damage whatever, while it gives valuable information about the need for more, or less, anaesthetic. There is no call whatsoever for the barbaric method of "sticking fingers into patients' eyes"—no more than we would employ a sledge-hammer to elicit knee reflex. There is no known case of eyes having been injured by "corneal attacks by anaesthetists." When a patient is "under" and has become unconscious he is blind, and there is therefore no corneal reflex obtainable: this can be found by lifting the upper eyelid and observing the presence or absence of reaction to light without in any way touching or damaging the eye. Surely every anaesthetist knows this.—I am, etc.,

X-ray Examination of Militiamen

Sir,—If I am not yet too late to make a contribution to this discussion I should like to bring forward one aspect of it which has not yet been considered.

All over the country are men anxious to serve, among whom are a certain number of sufferers from pulmonary tuberculosis. With misguided patriotism these men are apt not to disclose their true history to the medical examiners, with the result that, lacking universal screening, many are missed clinically and passed into the Services, where most will at least become pensioners and at worst not only accelerate their own deaths but probably cause those of others as well.

In my own area, with just over a thousand on the register, I have learnt in various ways of six who have been accepted for service, and I have no doubt that there are others who have not yet come to my knowledge. Two were called up as reservists. The first is an early and sputum-negative case, whose most recent film taken in January of this year shows soft infiltration in the left apical and subapical regions, with a fresh patch in the fourth intercostal space when compared with his previous film taken in May, 1938. The second is a slight quiescent case from a household where there has been one death from the disease and another positive-sputum case still alive. His most recent film, taken on May 10, 1937, shows hard mottling at the left apex and in the right lower lobe, with thickened pleura at the right base. This man is now in France. One joined a Territorial anti-aircraft battery shortly before the outbreak of war. His latest x-ray photograph, taken in February of this year, shows multiple calcified foci in the right upper zone with a third-stage cavity one inch in diameter just below the right clavicle. His sputum was positive until 1937, but was negative when last examined in February last. Three were volunteers. The first had tuberculous peritonitis starting in 1934, and in early 1938 developed a lung lesion in the left mid-zone. A period of sanatorium treatment caused this to resolve, and his lungs were clear on his latest film, taken in August this year. There is still some doubt, however, about the abdominal condition being completely arrested. The second had an extensive dry pleurisy on the left in August, 1938, and films taken then and later show fibrosis and calcification involving most of the right upper zone, and, while this is apparently stationary, the added strain of service conditions may easily bring about a breakdown. The third was a recent discharge from sanatorium, in good general condition but with upper-zone infiltration of both lungs, bilateral cavitation, and a positive sputum. He passed the medical examination and was only prevented from joining the R.A.F. by his father approaching the medical officer of health the day before he was due to leave for his unit.

Although the authorities are apparently not prepared to face the expense of x-ray examination for all, surely arrangements could have been made for them to have complete lists of all men known by the tuberculosis authorities to be suffering from pulmonary disease of such a nature and extent that service with the forces was contraindicated. This would have ensured that at least the group of which I have written would not have slipped through their medical net, to become in many cases a further burden on our national expenditure.—I am, etc.,

A. Scott,
Wolverhampton, Dec 8. Clinical Tuberculosis Officer.

Eye Injuries from Gas

Sir,—In his interesting article on ophthalmic injuries from mustard gas (*Journal*, December 16, p. 1181) Mr. John Foster gives me credit for an experimental work which showed that the effect of gas on the cornea is instantaneous. This important work was done by Brevet Colonel L. T. Poole, who kindly permitted me to use his findings for my paper at the Aberdeen Meeting, and it is to him and not to me that the credit must be given.—I am, etc.,

London, W.1, Dec. 16. Arnold Sorsby.

Carcinoma of the Stomach

Sir,—The many good results which surgeons nowadays obtain from operating on early cases of carcinoma of the stomach make its immediate diagnosis of great importance. The difficulties have been stated by Sir James Walton carefully from his long experience (*Journal*, December 9, p. 1127), and, if I may say so, from the aspect of a physician very fairly.

It will be agreed that carcinoma of the stomach can be broadly divided into two groups: Class A, with a short history of dyspepsia not exceeding a few months and with achlorhydria; and Class B, with long history of dyspepsia, usually extending over ten or more years, and with normal gastric acidity. With regard to Class A, there is little dispute that the condition is carcinoma from the onset of the symptoms. Why, then, is it mistaken for gastric ulcer? I find that in many cases these patients give, initially, a history which may be said to be characteristic of gastric ulcer. As Walton says, one should be more than suspicious of gastric ulcer commencing after the age of 40. On careful questioning and going round and round the history, one finds that it gradually ceases to be so similar to that of gastric ulcer, with the symptoms of which the patient is often familiar. To treat these cases as gastric ulcer is an error in diagnosis, not a question of treating gastric ulcer medically too long. But the diagnosis is not always so simple as it might seem later in the course.

I am in agreement with Walton as to the rarity of gastric ulcer commencing after the age of 40, but I cannot go so far as to say that dyspepsia after 40, with a clear past history, is due to carcinoma of the stomach unless the contrary can be definitely proved. The cases of carcinoma which fall into Class B are more difficult to interpret. In this group there is a long history of dyspepsia over many years with a short final period of a different type of symptom, due to the development of carcinoma. How can the long period of the initial symptoms be interpreted? We may accept it that some lesion of the stomach becomes carcinomatous, but is it justifiable to assume that the lesion is a gastric ulcer? Walton refers to these cases as having a history *suggestive* of a past ulcer; quite rightly he does not say *characteristic* of an ulcer. I do not deny that an undoubted gastric ulcer may develop into carcinoma, but in my experience, and I gather also in Walton's, these cases are very rare. Of his 112 patients who gave a previous history suggestive of gastric ulcer, only ten fulfilled his requirements of carcinoma developing from a gastric ulcer. I have long been puzzled by the indefiniteness of the symptoms in these cases and by the rarity with which characteristic features of gastric ulcer develop in spite of the long period of their histories. In some cases the diagnosis of previous gastric ulcer is only made when the carcinoma is finally found.

Walton gives four requirements for accepting that the carcinoma has started in a gastric ulcer—namely, the history suggestive of past ulcer; the presence of free hydrochloric acid; a lesion at operation simulating a chronic ulcer; and a microscopical report indicating that this was the nature and origin of the growth. How should one interpret the aetiology of the cases which fulfil only the first two requirements? I would suggest that there is a lesion of the stomach other than ulcer which after many years' duration may terminate in carcinoma with a normal acidity. So far few of these cases have been watched with the modern knowledge of chronic gastritis, incomplete as it is, and with the advantages of gastroscopy, in the earlier stages of their history.

Is this lesion a form of chronic gastritis? We are here considering gastritis which produces symptoms and is associated with a normal acidity, and not the atrophic gastritis which may lead to carcinoma of the type referred to above as Class A. If the lesion is chronic gastritis we should not have at our disposal medically a method of treatment substantially different from those at present in use, and surgery would have none. It definitely affects the argument, partly based on these cases, that physicians are to blame for treating gastric ulcer too long, and that if only adequate surgical treatment had been performed earlier the carcinoma would have been prevented. These patients, when they die from any cause in this stage, would at necropsy be found to have neither ulcer nor carcinoma, and hence would not be included in investigations on the relation of gastric ulcer to carcinoma. The aetiology of this group is an important question to settle, and it may need several years of observation. In the meantime I would suggest that in only a minority of these cases, with a long history of dyspepsia and a normal gastric acidity, is carcinoma secondary to gastric ulcer, and that some other lesion is at fault. It may still remain true in these cases that the development of carcinoma should have been recognized when it was operable, but the error is one of diagnosis at that point and is not connected with the previous treatment.—I am, etc.,

London, W.1, Dec. 12. H. LETHEBY TIDY.

SIR,—The survey of this subject which Sir James Walton has written in the *Journal* of December 9 is most comprehensive and timely, for not only does it cover the many aspects of this disease, but also it should serve to impress those who treat gastric conditions in the earlier stages with the necessity for obtaining an accurate diagnosis of the existing gastric pathology. It is only in this way that the question of the existence of carcinoma of the stomach may be decided at the most opportune time for successful treatment. Sir James's wide experience in the treatment of gastric conditions in general vests his statements with the hall-mark of authority, and the points which he stresses should be noted by all. It is, therefore, in no spirit of criticism that this letter is written, its object being to raise certain points which the gastroscopic examination of the gastric mucosa has demonstrated, and which have a most important bearing on the subject.

Mention is made by Sir James as to the value of gastroscopy in the early diagnosis of gastric carcinoma; but his remarks suggest that its application is limited, and that there is a danger of valuable time being lost by frequent gastroscopies being carried out before a positive diagnosis could be made with certainty. I am sure that all experienced gastroscopists would join issue with this contention. The routine use of the gastroscope in the investigation of gastric pathology has shown again and again that an early carcinoma was present when the history of the case was inconclusive and when careful radiological examination had failed to reveal its presence. Furthermore, it is most unusual for an experienced gastroscopist to require frequent examinations in order to establish a diagnosis of carcinoma. As is similar in conditions of other organs of the body, certain cases are frankly carcinomatous; other cases are not; while the intermediate or indeterminate group will vary in number according to the experience and ability of the investigator concerned.

It is a practical fact that the presence of a large palpable tumour in the stomach makes gastroscopy unnecessary and inadvisable, not only on account of the difficulty of making a thorough examination of the stomach, but also on account of the very real danger of damaging the friable stomach wall present in cases of this nature. It is, therefore, in early cases of suspected gastric carcinoma that gastroscopy is so helpful. With the flexible gastroscope it is a safe procedure and associated with very little discomfort to the patient. The examination can be carried out quickly and inexpensively, and in the vast majority of cases the findings are conclusive, as Sir James Walton himself has experienced at the London Hospital.

But it is not only with regard to early and accurate diagnosis that gastroscopy is assisting the gastric surgeon. By the correlation of the appearances of the gastric mucosa and abnormal gastric functions, both motor and secretory, and careful inquiry into the patient's previous history, especially with reference to the existence of any severe or prolonged infective state, a much greater knowledge of gastric pathology and of the aetiology of gastric conditions is being developed as more and more evidence is obtained by gastroscopic examination—a knowledge based on the sounder foundation of fact rather than empirical hypothesis. The term "gastritis," which for so many years has been applied to a variety of stomach conditions without any great common feature, for want of a better classification, has now taken on a very real and definite meaning; and the part played by long-standing atrophic changes of the gastric secretory mechanism in the production of a gastric carcinoma and certain blood diseases can now be assessed with greater and greater accuracy.

I have seen many carcinomas of the stomach, particularly primary malignant ulcers, in the pyloric and pre-pyloric regions of the stomach without any visible evidence of alteration in the gastric mucosa of the pyloric antrum, body, or fornix. Although microscopical changes in the form of round-cell infiltration might conceivably have been present in the submucosa of these particular stomachs, the fact remains that by all gastroscopic standards there was no fragment of evidence to justify the opinion that atrophic or hypertrophic gastritis was present or that the gastric mucosa was other than normal. Furthermore, it should be noted that in these cases there was no diminution in the gastric acidity.

It is a fact, which is not appreciated sufficiently, that the gasric mucosa is a highly specialized and functioning secretory organ under the control of a most carefully balanced nervous mechanism; and just as the highly specialized parenchyma of the kidney is liable to damage during acute generalized infective states, so also is the gastric mucosa. It is no mere coincidence that in the investigation of cases of achlorhydria associated with greater or less degrees of atrophic gastritis, particularly in younger subjects, it is always possible to obtain a history of some very acute infective disease during their lifetime; the onset of gastric symptoms has dated from the period following convalescence. I have the record of twenty-seven cases which will form the basis of a paper to be published shortly. Not every case of scarlet fever gives rise to nephritis, nor is the stomach always involved during the course of an acute infection. The main point is, however, that the atrophic changes in the gastric mucosa are *secondary* rather than primary; and while it is agreed that carcinoma may develop somewhere on an atrophic gastric mucosa, it may and frequently does develop somewhere on a normal one. In the terminal phases, when the growth is well established or when the early establishment of pyloric obstruction has brought the patient to operation, atrophic changes in the gastric mucosa will invariably be present, but here again the atrophic changes are secondary. Thus a carcinoma of the stomach may develop in a gastric mucosa which shows no naked-eye appearances of atrophic gastritis or other type of inflammation of the gastric mucosa. As the condition advances atrophic changes will develop and arise from the effect on the gastric mucosa of the general wasting and toxic absorption associated with malignant disease in general. Carcinoma of the stomach may also arise in a gastric mucosa which has already undergone atrophic changes as a result of previous damage from whatever cause during the course of the patient's lifetime. It cannot be assessed at the present time whether the former type is less malignant than the latter or whether there is any difference in the character of the growth or location in the stomach.

I cannot agree that the recognition of atrophic gastritis is an indication for advising a partial gastrectomy on the grounds that a carcinoma of the stomach might develop at some future date. It is advisable, however, that known cases of atrophic gastritis should be examined gastroscopically from time to time if the development of a carcinoma is to be recognized as early as possible. Nor does this apply to cases of atrophic gastritis alone, no matter what figures are quoted, and in reality figures mean very little when compared with the true end-results of treatment. The successful issue of any case of gastric carcinoma will depend on the period of its existence when it is first recognized or treated. If all cases of persistent gastric dysfunction were submitted to an efficient gastroscopic and radiological investigation the ravages of this horrible condition could be controlled to a much greater degree than exists at the present time.

For those who are engaged in the study of gastric disease the questions of aetiology, pathology, and symptomatology will always have a profound interest; but to those whose duty it is to visit the sick in their homes or to attend them in consulting rooms there should be but one object when dealing with a gastric case with persistent symptoms: "Is this case one of carcinoma?" In the past radiological evidence has not been sufficient; now gastroscopy can offer so much. Should it, therefore, be reserved only for the difficult case, or should it become the routine method of investigation?—I am, etc.,

Bournemouth, Dec. 13. LLOYD OLVER.

Cause of Peptic Ulceration

SIR,—In appreciation of Dr. James Ronald's interesting article on the value of therapeutic measures in duodenal ulceration Sir Adolphe Abrahams in his very elegant letter (*Journal*, December 2, p. 1112) reiterates the fact that peptic ulcers heal up when the patient is confined to bed for three weeks and agrees with Dr. Ronald that hyperchlorhydria cannot be responsible for the causation of peptic ulcer since he has demonstrated that ulcers have healed in cases in which the acid index has actually risen during the period of healing. Agreement is mutual in the fact that a carefully selected but extended diet does not detract from the healing process, but indeed materially assists by giving greater strength to the patient in place of the semi-starvation usually imposed upon these unfortunate people.

From this it may be concluded that neither the presence of excess of acid nor the taking of a generous diet interferes with the healing of the ulcer, so it is therefore certain not to have been caused by either the one or the other. Bearing these findings in mind, the act of lying in bed in the recumbent position must play a direct part in the healing process. To what, then, is this due? Sir Adolphe, among other things, suggests that peptic ulcer may be influenced if not actually caused by mental worry, and that the three weeks in bed acts as a soothing factor to the nervous system and thus promotes healing.

This does not coincide with one's usual experience, because three weeks of physical inactivity is not likely to relieve the anxieties of a mentally worried business man but rather to add to his mental trouble; moreover, it is an undoubted fact that many of these cases relapse within a variable but usually short period of time after the patient resumes his ambulant activities. It therefore appears that the recumbent position assumed in bed is a causal factor in the healing process. Since the ulceration is in the stomach or in the duodenum one naturally turns one's thoughts to the connexion between the recumbent position and its influence upon these parts. When it is remembered that the ulceration takes place during the time the patient is ambulant and heals up when he is confined to bed the suggestion that posture is a possible causative factor is forced upon one, since the confinement appears to be the *sine qua non*.

For a number of years I have had the opportunity to observe from a radiographic point of view the stomach, duodenum, and other abdominal organs of patients suffering from peptic ulcer and have also had the privilege of treating a large number of these cases.

It is, I think, universally agreed that peptic ulcer is nearly always situated in much the same locality in the stomach or duodenum—in the stomach upon the lesser curvature near the pyloric end, and in the duodenum at the junction of the first and second parts of that organ. Radiographic examination reveals the fact that nearly all of these patients suffer to a greater or less degree of middle-line or right-sided colonic ptosis. The fall of the colon when the patient is in an erect position imposes a pull upon the greater curvature of the stomach through the fused omentum. This pull upon the stomach is resisted by it. The stomach is fixed at two points—at the cardiac end and at the junction of the first and second parts of the duodenum; the line of maximum pull is therefore upon the lesser curvature between these points, and is observed to be in the position where gastric ulceration usually takes place—near the pyloric end of the lesser curvature, where the curve can often be seen to be almost an acute angle—and in the case of duodenal ulcer at the junction of the first and second parts where duodenal ulcer is usually seen. At these points mechanical circulatory obstruction takes place with subsequent ulceration. When the patient assumes the recumbent position this drag is relieved by the influence of gravity upon the abdominal organs, which resume their normal position, and the mechanical interference with the circulation no longer exists.

This will explain the initial causation of ulceration by the assumption of the erect position and its healing in recumbency, and its subsequent recurrence, if steps be not taken to prevent it, when the period of recumbency is ended. It will also explain why excess of acid is not its causation nor a restricted diet a factor of hindrance to its healing, but will, I submit, bring forward the suggestion that the causation of peptic ulcer is a mechanical interference with the circulation due to the drag of gravity upon an uncorrected colonic displacement.—I am, etc.,

London, W.1, Dec. 6. CHRISTOPHER KEMPSTER.

Sternal Puncture in Lymphatic Leukaemia

SIR,—Dr. M. C. G. Israëls's article on the value of sternal puncture in the diagnosis of atypical cases of lymphatic leukaemia (*Journal*, December 9, p. 1132) is of much importance, but his series of five cases does not include an example of the most puzzling and most easily overlooked variety of the disease.

I refer to those aleukaemic cases in which symptoms and signs of severe anaemia dominate the clinical picture, while the blood shows severe (usually orthochromic) anaemia, without signs of blood regeneration, and intense leucopenia. The picture is that of aplastic anaemia, and no enlargement of lymphadenoid tissue can be detected. I recently (by the courtesy of Sir Maurice Cassidy and Dr. Meek of Mill Hill) saw such a case in a man of over 60 who had no signs of lymphatic leukaemia. Admittedly there was a certain amount of controversy concerning some of the mononuclear cells in his blood, as I contended that a few were lymphoblasts, whereas another haematologist who had seen the films would not agree that these rather large cells were immature types. There was one point that militated against a diagnosis of aplastic anaemia—blood transfusion caused only the most transient rise in the number of red corpuscles, so that it seemed certain that haemolysis was occurring.

The diagnosis became clear when films of material from sternal puncture were examined, because about 30 per cent. of the cells were large mononuclear elements with coarsely reticulated nuclei in which nucleoli were easily visible. These cells, which were regarded as being lymphoblasts, did not give the oxidase reaction. The case was, then, one of aleukaemic lymphatic leukaemia (aleukaemic lymphadenosis) of the type that used to be known as the medullary form of pseudo-leukaemia. It is in cases such as this that sternal puncture is of outstanding value for diagnosis, and it is probable that, if this small operation were carried out on all cases suspected of being examples of aplastic anaemia, more diagnoses of aleukaemic (medullary) leukaemia would be made.

Dr. Israëls mentions that he has seen lymphocytosis in the marrow in "glandular-fever- and aplastic-type anaemia," but he does not say that he has ever seen infiltration of the marrow with many lymphoblasts in these diseases. It is of course possible that some of the "aplastic-type anaemia" cases were really examples of medullary pseudo-leukaemia.

It is high time that a monograph in English should deal with sternal puncture, but one fears that the times are not propitious for such a venture, for even publishers must live.—I am, etc.,

London, W.1, Dec. 13. A. PINEY.

Test for Vi Antibody

SIR,—In your review of the memorandum on typhoid fever[1] issued by the Ministry of Health (*Journal*, December 2, p. 1124) you took note of the statement that the modification of the Widal reaction suggested by me, in which the blood is tested for Vi antibody, is not yet regarded as a practicable procedure for routine detection of carriers. It is evident that the memorandum had been prepared at a time when the technique of the Vi agglutination reaction was not yet fully described. A full description was published a year ago,[2] so that the statement in the memorandum is now out of date.

A standard agglutinating Vi serum and a preserved suspension representing a pure reagent for the Vi antibody are now available. The former has been made at the Lister Institute, and the latter is being prepared from Bhatnagar's[3] Vi strain by Lieutenant-Colonel R. F. Bridges at the Oxford Standards Laboratory of the Medical Research Council. The two reagents are obtainable from the Standards Laboratory, and the test for Vi antibody has thus become a practicable routine procedure.—I am, etc.,

Lister Institute, London, S.W.1, Dec. 12. A. FELIX.

"Lady Nicotine"

SIR,—Referring to the annotation "Lady Nicotine" in the *Journal* of December 2 (p. 1098) the following short piece of research work may be of interest:

While serving in the last war as a lieutenant in the R.A.M.C. I found myself in charge of a ward of some twenty-four Australians and New Zealanders convalescent from typhoid. Most of them had been there week after week running pulses over 100 a minute. The Red Cross brought round cigarettes at, I believe, 7.30 a.m. each day, and the patients smoked almost without stopping till 7 or 8 p.m. As there seemed to be no reason for the tachycardia, I was bold enough to knock off smoking for the whole ward for a week, and, with a little persuasion, obtained the co-operation of the men in the matter. At the end of the week there was only one pulse over 100, and nearly all of them were quite normal.

My own experience with functional and psychological conditions of many kinds (I was seeing between 5,000 and 6,000 a year at the end of the war and for a time after) has convinced me that cigarette smoking tends to increase or produce insomnia, restlessness, and irritability, while pipe smoking, if severely indulged in, seems to produce depression. It is naturally impossible to formulate a rule on the result of one case, but I well remember a barrister who week after week made no progress but remained depressed; he was an inveterate pipe smoker. At last I persuaded him to give up smoking, which he did by rapid reduction of the number of pipes smoked each day, and he went straight ahead and got well.

The large gifts of cigarettes now being sent out to the troops may be very doubtful benefits, both from the standpoint of health and of actual physical condition for military service, for plenty of athletes give up smoking during training.—I am, etc.,

Chorley Wood, Dec. 11. CLAUD F. FOTHERGILL.

Desmoid Tumour of the Abdominal Wall

SIR,—In your issue of September 16 (p. 606) Mr. E. W. Bintcliffe describes a case of large desmoid tumour of the abdominal wall. My interest lies in his difficulty in closing the gap left by the removal of the tumour. In 1924 I operated upon a similar case in which a gap in the muscular wall of about three inches diameter was left by the excision. To fill this I used a method which I had devised for the closure of unusually large herniae—the swinging into the gap of the tensor fasciae femoris with nervous and vascular supply preserved intact (*Brit. J. Surg.*, 1924, **12**, 28). The result was completely satisfactory. The woman has had a child since and the abdominal wall has remained sound.—I am, etc.,

Auckland, New Zealand, Nov. 22. KENNETH MACKENZIE.

Lymphatic Leukaemia

SIR,—In reading in the *Journal* of December 9 (p. 1132) Dr. M. C. G. Israëls's article on lymphatic leukaemia I found myself at a loss to know on what grounds he arrived at a diagnosis of lymphatic leukaemia in Case IV—a platelayer aged 55 who complained of lassitude, etc. In this case the blood count was 2,480,000 R.B.C. (described by Dr. Israëls as "a moderate anaemia") and the colour index 1.08. Would a general practitioner be considered as committing an unpardonable diagnostic error in thinking this to be a case of pernicious anaemia and prescribing intramuscular and/or intravenous injections of some such preparation as neohepatex? May the improvement ascribed in this case to iron and arsenic therapy not merely be an intermission in pernicious anaemia?

I should also like to know why the anaemia of Case I (R.B.C. 2,570,000) is described as "a moderate anaemia" and that in Case II (R.B.C. 2,470,000) as "a rather severe anaemia." I would also ask Dr. Israëls if the increased cellularity of the marrow in Case V is not rather a slender reason for regarding it as a lymphatic leukaemia when the Wassermann reaction is positive. Why should this not be regarded merely as an anaemia secondary to syphilis?—I am, etc.,

Wrexham, Dec. 12. A. WESLEY HILL.

Treatment of Varicose Ulcers

SIR,—Dr. Stuart McAusland being the head of a well-known ulcer clinic in the north, I feel a natural diffidence as a general practitioner in replying too dogmatically to his criticisms (*Journal*, December 9, p. 1164) of my letter on the treatment of varicose ulcers in the *Journal* of November 25. However, in the circumstances I feel bound to make the following observations:

1. The leg ulcers preceded by a definite interval the appearance of the boils in the groin and axilla.

2. As regards syphilis, admittedly no Wassermann was done, but the patient did not show any of the usual stigmata of syphilis, and the ulcers were excessively painful and cleared up rapidly on the institution of the (non-antisyphilitic) treatment described in my letter.

3. The rationale of the occlusive bandage treatment is, I believe, (*a*) the cutting off of the blood supply to the ulcer, thereby inducing it to heal; and (*b*) the mobilization, in response to the imprisoned septic products, of the patient's defence forces. With regard to (*a*), this treatment in the case of callous indolent ulcers with only a little serous discharge exuding from them, and with floors which are showing signs of attempting to granulate, is no doubt quite effective. I admit that I have cured some obstinate ulcers in this way, but when there is much septic discharge it seems to me to be bad treatment to keep it pent up in the tissues. If the contrary is the case, what is the object of ever incising an abscess? As regards (*b*), how, with the circulation and vitality of the part already impaired by the varicose condition, can the defence

[2] Felix, A. (1938). *J. Hyg.*, **38**, 750.

[3] Bhatnagar, S. S. (1938). *British Medical Journal*, **2**, 1195.

forces be stimulated by the presence of a considerable quantity of imprisoned pus and micro-organisms? Far more likely that they would be hopelessly outnumbered, as I am convinced in numerous cases (including the one described in my letter) that they actually are.

May I add, in conclusion, that a number of practitioners with whom I have from time to time discussed this question hold views similar to mine.—I am, etc.,

Leamington Spa, Dec. 11. J. R. A. Davies.

Virtues of "Brown" Bread

Sir,—Dr. Geoffrey Taylor's proposal in your issue of November 18 (p. 1022) that the British Medical Association "urge the Government to bring in measures to encourage, if not to enforce, the eating of brown bread by everyone, at least during the war," overlooks a number of important facts. First, not all "brown" bread is rich in vitamin B, for the vitamin is contained in the wheat germ, and "brown" bread often differs from white bread only in containing bran. Secondly, the general use of brown bread would eliminate an important source of animal feedstuffs, which are converted into animal foods consumed by man and containing vitamin B. There would be no net gain and there would probably be loss in the amount of vitamin B available. Thirdly, in a considerable number of cases the roughage in brown bread is irritating to the colon, and is probably a contributory factor in producing colitis. Fourthly, diets of the people of India are so restricted and otherwise poor in vitamin B owing to lack of animal foodstuffs that it is legitimate to advocate consumption in India of bread containing the germ of whole wheat. But it does not follow that McCarrison's work can be used to support similar measures in England.—I am, etc.,

Geneva, Nov. 30. E. F. Penrose.

Sir,—I should like to endorse the opinions already expressed in your correspondence columns on the value of whole-meal flour, by which I mean flour which represents the whole of the wheat berry. I conceive it to be the duty of the whole profession to urge the use of this flour upon the nation at the present juncture. That the general public are ready to take up the question I have ample proof in the mass of correspondence with which I have been flooded following a letter to the *Times* on November 21.

In order to buy back from the millers that which should never have been taken out the public have to pay six or seven times the cost of the wheat germ in order to recover the vitamin and mineral content in the shape of patent foods. Since writing to the *Times* I have discovered one firm which supplies flour representing the whole wheat berry; the address is: Messrs. John Wright (London), Ltd., 98–102, Bermondsey Wall, London, S.E.16. I did not know that such flour was obtainable previous to my original letter to the *Times*, and used to have bread made for my own household from wheat germ and whole-meal flour according to a recipe originally taken from correspondence in the *Journal* some time ago, which I would suggest should be republished for the information of those interested.—I am, etc.,

Lancaster, Dec. 11. C. J. Stocker.

Sir,—Your correspondent, Dr. Arthur King, of December 9 (p. 1164) states that in England the "colour prejudice" against brown bread is most pronounced among the poor and uninformed. If he were a housewife he would know the reason why—that brown bread is more expensive than white. Until this fantastic state of affairs is remedied there is little hope of inducing the "poor and uninformed" to eat brown bread instead of white. Individual denunciation is of little avail in such a case, but suitable action by the British Medical Association might well reverse the situation.—I am, etc.,

Cardiff, Dec. 11. M. Grace Eggleton.

Tuberculosis in the Last War

Sir,—Your article entitled "A Nation in Good Health" (December 16, p. 1191) seems misleading in its statement that "tuberculosis notably declined during the [last] war." It is true that the number of fresh notifications of the disease received in 1913 was higher than in any subsequent year, but this perhaps is to be explained as the first effect of the Tuberculosis Regulations (1912), which enlarged the basis of notification by including non-pulmonary disease. During the period 1914–18 the death rate from tuberculosis substantially increased, and the downward tendency that had been observed for several decades was reversed. In 1918 the standardized death rate for pulmonary tuberculosis was higher than that touched twenty-five years previously. Similar increases were seen in other belligerent countries. That this was a consequence of the war is shown by the fact that the death rate fell rapidly after 1919. Tuberculosis is pre-eminently a disease which flourishes under the conditions of war.—I am, etc.,

London, W.C.1, Dec. 18. Harley Williams.

Obituary

With the death of Dr. **Keith Robertson** on December 8, aged 61, the burgh of Greenock has lost one of its best known and highly esteemed practitioners. He had been in active practice till a month before. A native of the town in which he spent his active life, he was the son of the late Dr. J. K. Robertson. He graduated M.B., Ch.B. at Edinburgh University in 1901, and proceeded M.D. four years later. After graduation he served for a term as house-physician in Glasgow Royal Infirmary. Later he took charge of about 400 cases of small-pox under the Greenock medical officer of health during an epidemic. Shortly after this he settled in general practice in Greenock, and became attached to the Eye Infirmary, where he was assistant surgeon for many years. But throughout his career his chief interest was in ear, nose, and throat work. In this connexion he assisted the late Dr. Robert Fullarton till 1920, when on the latter's retirement he assumed charge of the Greenock Ear, Nose, and Throat Institution. Here he gave splendid service, and under his direction the work was greatly developed. At the time of his death a new and commodious hospital for ear, nose, and throat cases was nearing completion, and he was eagerly looking forward to the improved facilities to be provided there. For several years he was medical officer for diseases of the ear, nose, and throat to Renfrewshire Education Authority. Dr. Robertson served for a time in Greenock Royal Infirmary as assistant surgeon, and was at the time of his death honorary consulting surgeon for diseases of the ear, nose, and throat. From 1907 he held the office of medical officer to Sir Gabriel Wood's Mariners' Asylum. He was an active member of the British Medical Association, and for three years (1934–7) was chairman of the Renfrewshire and Buteshire Division. He was also one of the original members of the Scottish Otological and Laryngological Society. The St. Andrews Ambulance Association had in Dr. Robertson an active worker, and he also took part in training V.A.D.s. Lately he was engaged in A.R.P. work. Dr. Robertson will be greatly missed by his colleagues and a large circle of patients. He was earnest and conscientious in all he undertook, and gave of his best to all who called for his services, rich and poor alike. He was deeply attached to Trinity Church, where he had been an elder for twenty-nine years.

Dr. **Martin Randall**, who had long practised with great success at Wimbledon, died in retirement at Haslemere on December 7, aged 71. He studied first for the teaching profession, and took the B.A. of London University in 1887; he then turned to medicine and entered University College Hospital Medical School, taking the English Conjoint diplomas and the

M.B. with first-class honours in 1892, the M.D. in 1894, and the F.R.C.S. in 1895. At University College he had been assistant demonstrator of anatomy and Atkinson Morley surgical scholar. After qualifying he was house-surgeon at U.C.H. and at the Bristol General Hospital. On his retirement from practice in 1931 Dr. Randall was made an honorary consulting surgeon by the Nelson Hospital, Wimbledon, where he had been a member of the active staff since its foundation; and University College, London, elected him one of its Fellows. He joined the British Medical Association in 1893. By his fellow practitioners Dr. Randall was held in high esteem and affection. One of them writes: I came to know what a lovable and fine character he possessed: so capable, so curiously shy and retiring till you gained his confidence; the blue eyes with the searching and steady glance expressed his character—honesty, loyalty, uprightness. He was a born surgeon, resolute, careful, and thorough, with sound judgment and hands to carry out his purpose as a fine craftsman.

Universities and Colleges

UNIVERSITY OF OXFORD

At a Congregation held on December 16 the following degrees were conferred:

D.M.—*L. T. Ride.

B.M.—E. J. L. Lowbury, A. N. Guthkelch, J. C. Hill, E. J. Wood, H. M. Balfour, J. C. Ryle, R. W. Tibbetts, I. C. B. Pearce, E. Smith, J. J. Brenner, K. F. Wilsdon, *D. H. Swayne, D. H. Davies.

* By proxy.

UNIVERSITY OF CAMBRIDGE

The Vice-Chancellor has appointed Sir Augustus Moore Daniel, K.B.E., M.B., Hon. Litt.D., of Trinity College, formerly Director of the National Gallery, to be Rede Lecturer for the year 1940. The place and subject of the lecture will be announced later.

UNIVERSITY OF BRISTOL

J. S. W. Little has been approved at the examination for the degree of M.D.

UNIVERSITY OF ABERDEEN

At a graduation held on December 13 the following medical degrees, etc., were conferred:

M.D.—Esther Hendry (awarded commendation for thesis).

M.B., Ch.B.—I. A. Angus, A. G. Beattie, J. H. Begg, G. R. Bernard, R. S. Dewar, W. F. Dickie-Clark, F. A. Forbes, E. Fowler, J. C. Fraser, J. Gauld, C. W. Hossack, A. L. Hughes, G. E. Johnstone, M. J. Mackenzie, J. G. Moir, Elizabeth J. B. Orr, R. W. Panton, C. W. Petrie, W. F. Russell, J. H. Scott, A. C. B. Singleton, K. Smith, G. P. Wallace, A. M. Watson, W. G. R. Wilson, C. C. Wright.

D.P.H.—R. M. Gordon, J. Warrack.

UNIVERSITY OF EDINBURGH

A graduation ceremonial was held in Examination Hall B on December 15, when the following degrees, etc., were conferred:

M.D.—L. W. Brown, Captain R.A.M.C. (*in absentia*), W. N. Campbell (*in absentia*), A. H. Crichton, †J. N. Davidson, ‡L. V. Knutson, ‡R. A. H. Krynauw (*in absentia*), A. U. MacKinnon, Lieutenant R.A.M.C. (*in absentia*), J. H. D. Millar, Lieutenant R.A.M.C. (*in absentia*), P. T. Northover, ‡Beatrice A. S. Russell (*in absentia*), *A. C. White, ‡J. F. Wilson, Captain R.A.M.C. (*in absentia*).

M.B., Ch.B.—J. R. Allan, J. L. Anderson, R. Barrie, N. C. Baskett, Elizabeth G. Batters, F. W. Belford, I. R. Bindman, G. M. F. Bisset, J. Breckenridge, L. S. Bruce, B. Carr, D. Crichton, B. G. Daly, S. W. Davidson, A. R. Duff, R. M. Ellison, P. M. Fea, W. M. Ferguson, J. S. Fraser, W. A. Glen, W. M. Grant, J. H. Higgins, A. R. Hodgson, M. Homayun, E. L. O. Hood, W. Huey, W. W. Hutton, Helen S. Lauder-Thomson, N. G. Lindsay, R. N. Littlewood, C. T. MacDonald, H. J. M'Pherson, F. K. Matheson, W. C. Menzies, W. B. Nelson, J. Robertson. A. F. Rutherford, J. L. Shanks, J. L. Sinette, G. H. Stuart, W. B. Thorburn, Thelma G. Townson (*in absentia*), K. R. H. Wardrop, J. L Washington.

D.P.H.—I. A. G. MacQueen.

Ph.D. (Faculty of Medicine).—S. C. Das (*in absentia*).

* Awarded gold medal for thesis. † Highly commended for thesis. ‡ Commended for thesis.

QUEEN'S UNIVERSITY, BELFAST

The following candidates have been approved at the examination indicated:

M.B., B.Ch., B.A.O.—J. J. Black, J. McAnallen, W. E. C. McCullough, R. K. McElderry, W. J. McLeod, D. Rooney, Henrietta H. Scott, T. M. Shannon, C. D. Stewart, R. H. Trinnick, W. L. Uprichard.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At an ordinary meeting of the Council, held on December 14, with the president, Mr. Hugh Lett, in the chair, a resolution of condolence was passed on the death of Mr. Wilfred Trotter. The Council accepted with grateful thanks the offer of Mr. Herbert Olivier to present to the College a replica of his portrait of Mr. Wilfred Trotter.

It was decided to alter the time of the Hunterian Lectures to be given in 1940 from 5 p.m. to 3 p.m.

It was reported that the special trustees of the Prophit Trust had renewed the cancer research studentships of Dr. L. H. Gray and Dr. C. A. P. Wood for the year 1940.

Diplomas

A diploma of Membership was granted to Harry Vernon Reeves.

Diplomas of Fellowship were granted to the following thirty-one candidates:

N. A. Miller, R. Parkinson, M. P. Morel, P. W. Houghton, H. H. F. Barns, C. G. Rob, J. C. Coates, J. Ll. D. Roberts, J. S. Horn, R. L. Lamming, C. J. Longland, A. J. Heriot, S. H. Raza, Alice J. M. T. Barnes, W. P. Greening, C. P. Sames, D. M. Thomson, P. A. Menon, S. S. Anand, J. R. Barbour, A. C. Belfield, J. O. Corbin, K. Das, D. M. Douglas, K. T. Goldswain, B. C. Hardy, J. W. Horsley, C. J. D. Langton, J. F. Lipscomb, Riyaz-I-Qadeer, T. F. Rose.

Diplomas in Anaesthetics were granted, jointly with the Royal College of Physicians of London, to the following twenty-three candidates:

R. D. N. Bisset, F. K. Boston, Dorothy M. Braddock, I. G. Braddon, Elizabeth M. Corbin, T. F. Crowley, Charlotte S. Dafoe, E. W. Dunkley, G. H. Ellis, F. G. Ethiraj, Margaret Forbes, G. P. Fox, H. Gillies, P. Glazer, C. A. Hayes, A. L. St. A. McClosky, W. M. Maidlow, Beryl M. Mason, B. M. Phillips, T. B. Pitts, N. F. Sahor, R. N. Sinclair, B. N. Sircar.

Medical News

At the reopening ceremony of Paris University, which took place in the presence of M. Albert Lebrun, President of the French Republic, and M. Yvon Delbos, Minister of National Education, Sir Humphry Rolleston and Dr. Philip Roy, formerly Minister of Canada at Paris, were made honorary doctors.

Sir Bernard Docker has accepted the invitation of the Council of the British Hospitals Association to become its chairman in succession to Sir Harold Pink. He has been closely identified with the interests of the voluntary hospitals through his association with the Westminster Hospital, London, and the Birmingham Children's Hospital.

A meeting of the general purposes committee of the International Society of Medical Hydrology was held in London on November 17 to deal with emergency measures made necessary by the war, and also by the death of the society's chairman of council, Dr. E. P. Poulton. By the unanimous vote of the members present and of all those abroad who could be reached by post, Dr. J. Barnes Burt was elected chairman of council until such time as the whole council could meet, and the general purposes committee was strengthened by the appointment of four additional vice-chairmen, all in countries "neutral" in the present conflict. It was further resolved that the cash balance remaining should be set aside for reconstruction of the society after the war, and the general secretary was given indefinite leave of absence without pay and instructed to close the London office. This has now been done and the society's address will be, until further notice, that of the hon. treasurer, Dr. G. D. Kersley, 6, The Circus, Bath.

Mr. S. Ingleby Oddie, who graduated M.B., C.M. at Edinburgh in 1891 and afterwards practised at the Bar, retired on December 18—his seventieth birthday—after twenty-seven and a half years' service as coroner in Central London. At a farewell ceremony Mr. Oddie said that nearly 50,000 deaths had been reported to him, and he had held inquests on 20,000. He was the last coroner to be appointed by the Dean and Chapter of Westminster and the last coroner for the City and Liberty of Westminster, a franchise coronership abolished in 1930. Sir Bernard Spilsbury spoke of Mr. Oddie's skill in the examination of witnesses, and stressed the importance, in large towns particularly, of having coroners with a thorough medical training.

Sir Sidney Clive, recently Director of Personal Service at the War Office, is directing a Red Cross commission in France. He has consulted the Adjutant-General and the Director-General of the Army Medical Services of the B.E.F. so that the Red Cross war organization may undertake those duties which are allotted to it.

The American officers of the international congress have decided that in view of the present world situation it is advisable to postpone to an indefinite date the fifth International Congress of Paediatrics, which was to have been held in Boston, Massachusetts, U.S.A., on September 3, 4, and 5, 1940.

Mr. Godfrey Heathcote Hamilton will retire from the secretaryship of the National Hospital for Diseases of the Nervous System, Queen Square, W.C., at the end of the year, having served the hospital for nearly thirty-eight years.

With the exception of Strasbourg all the French medical faculties reopened on October 18. Of the 28,000 doctors in France 77 per cent. have been mobilized, and only 6,000 doctors are kept for civilian practices.

The King's Medal for the best shot in the Canadian Army has been won for the sixth time by Captain D. T. Burke, of the Canadian Army Medical Corps, who won the King's prize at Bisley in 1924 and tied for it in 1929.

Dr. Alfred Fröhlich, formerly professor of pharmacology in Vienna University, whose name has been given to the adiposo-genital syndrome, has been appointed pharmacologist to the May Institute for Medical Research of the Jewish Hospital, Cincinnati.

Professor Angel Roffo, director of the Cancer Institute of Buenos Aires, has been made an Officer of the Legion of Honour at a ceremony when the French Ambassador presented him with a cheque for 100,000 francs for the foundation of a fund for the study of cancer.

M. van den Meulebroeck, the successor of the heroic M. Max as Burgomaster of Brussels, is a medical man.

The Department of Scientific and Industrial Research has now published No. 10 of its leaflets on Methods for the Detection of Toxic Gases in Industry, to which reference has been made in these columns from time to time. The present leaflet is devoted to chlorine (H.M. Stationery Office, 3d.). The greatest risks of exposure to chlorine gas are during its manufacture and use in industry, and generally as the result of accidents in which large quantities of the gas escape from cylinders or other containers.

During 1938 the mortality rate in the New York City hospitals for contagious diseases fell to 1.8 per cent., the lowest to date. In 1937 it was 2.2 per cent. This figure compares favourably with a 4 to 6 per cent. mortality in general hospitals. There were 2,109 cases of whooping-cough admitted to hospitals in 1938, or more than for any year in the last two decades. Of all the cases of diphtheria notified to the Health Department in 1938, 43.7 per cent. were hospitalized, while 31 per cent. of the scarlet fever cases, 8.4 per cent. of the measles cases, and 16.1 per cent. of whooping-cough patients were sent to city hospitals.

According to official statistics the population of Japan on October 1, 1938, was 72,227,700, or 969,000 more than in the previous year. The most populous city is Tokio, with 6,457,000 inhabitants.

Medical Notes in Parliament

On December 14, before Parliament adjourned for the Christmas recess, the Royal Assent was given to the Postponement of Enactments (Miscellaneous Provisions) Act, which provides that the House-to-House Collections Act will come into force on March 1. An Order in Council approving amendments of the Regulations of the Dental Board of the United Kingdom has been presented to Parliament.

Milk Consumption

On the motion for the adjournment, on December 14, Mr. Tom Williams opened a debate on milk prices. He said the Milk Marketing Board had asked the Central Milk Committee to agree to an increase and 4d. a gallon had been mentioned. Such an increase must reduce consumption and the working classes would suffer. After five years of operation the Milk Marketing Board had increased the price by 2½d. per gallon, or, allowing for the distribution margin, 2.65d. per gallon. The Government should use the machinery and finance, if necessary, to keep the price within the purchasing power of the people.

Mr. W. S. Morrison said all parts of the House agreed on the need, in war even more than in peace, for securing an adequate supply of milk at reasonable prices. If war conditions were superimposed on peace-time commercial practice it would be necessary for the Government to assume responsibility for milk policy during war time as regards production, price, and distribution. There had been since the war no rise in the price of liquid milk for ordinary consumption in spite of a short supply of feeding-stuffs. Liquid milk consumption had declined, and one reason was that the milk-in-schools scheme was dislocated. Milk which in peace would have been sold for the scheme at prices like 1s. a gallon had been diverted to butter at 7d. a gallon. The Ministry of Food decided that an increase in the producers' returns was justified, but was anxious to avoid a general rise in the retail price of liquid milk. The Ministry would make a temporary grant to the Milk Marketing Board in January, February, and March, to be passed to producers, on condition that the existing level of retail prices for liquid milk was maintained for the present. The grant would only be on milk sold for liquid consumption.

Mr. Haden Guest considered that there should be a programme of milk production, with a view to consumption, over the next three years. On the milk policy would depend the national reserve of child life. He cited the pioneer work of Dr. Harriette Chick, and the Report on the Physiological Bases of Nutrition prepared by an expert committee appointed by the Health Committee of the League of Nations. The scientific case for the increase of milk consumption was irresistible.

Dr. Summerskill said the Government, if the policy outlined that afternoon was followed, would not encourage the consumer to buy more milk. Professor Mottram had said that, if the health of the people was to be maintained in war, the consumption of milk should be increased. She asked whether the Government had taken steps to maintain the quality of the milk supplied. The most important customers of the Milk Marketing Board—the children—had been removed from the towns to the country, where there were no pasteurization plants. Dr. Elliot on a previous occasion had not denied that children in the country were drinking infected raw milk. Many of them would die from a death less spectacular than bombing but one which was insidious and certain. The Milk Bill which Dr. Elliot had introduced last Christmas had shown, though it was later dropped, that the Government held the views she had expressed.

Lord Apsley stated that an Edinburgh professor told him pasteurized milk so lacked nourishment that children fed on it became more liable to disease for that reason. If pasteurized milk were placed in a cup and a fly put a foot into it the milk would react to a tuberculin test. Only fresh good-grade A milk was of benefit to children. Dr. Guest said the Milk Marketing Board had reported that an experiment on 6,000 children with pasteurized and non-pasteurized milk showed the nutritional difference was insignificant. Mr. Montague said that by organizing the distribution of milk more cheaply a means could be found of increasing its consumption in the average poor family. The debate then ended and the House adjourned till January 16, unless required to assemble earlier for urgent business.

Domiciliary Treatment of War Casualties

On December 12 Mr. Denville asked the Minister of Health what precise agreement he had made with the British Medical Association in respect of the temporary domiciliary medical service which he proposed to establish for civilians who sustained war injuries in this country; and why no other medical organization like the Medical Practitioners' Union had been asked to co-operate. Dr. Elliot replied that he had arranged, in co-operation with the British Medical Association, that free domiciliary treatment should be available to war casualties in cases where further treatment was required after attendance at hospital, a fee of 16s. a year being paid to medical practitioners who gave this treatment in respect of any casualty not entitled to medical benefit under the National Health Insurance Acts. In accordance with established practice he consulted the British Medical Association as representing the general body of the medical profession.

On the same day Dr. Elliot also told Mr. Denville that details of the temporary domiciliary medical service for civilians, other than insured persons, who sustained war injuries when hospital treatment was not necessary or was impracticable would appear in a forthcoming memorandum. The scheme would apply to the whole of Great Britain, although there might be differences of detail in Scotland. It would be administered by his Department in England and Wales, and by the Department of Health in Scotland.

Unaccompanied Children: Doctor's Payments

On December 12 Mr. Groves asked the Minister of Health whether he would reconsider the arrangements relating to medical services whereby the remuneration of medical practitioners was dependent on a local emergency medical committee disbursing Government funds on such basis, whether capitation or attendance, as might be found convenient to the committee; and whether his Department, as responsible for the provision of the medical services, would deal with the expenditure and have it properly certified by the Exchequer and Audit Department. Dr. Elliot said he saw no reason for varying the arrangements made for the medical treatment of unaccompanied children evacuated under the Government scheme. The total amount payable for this service was determined by his Department on the basis of the number of unaccompanied billeted school children as indicated in returns received from local authorities, and the payment by the Department was subject to audit by the Exchequer and Audit Department. The distribution of the amount for each area among the doctors was dealt with by the Local Emergency Medical Committees, who would be required to send in periodical accounts which would be available for inspection by the Exchequer and Audit Department.

Increase in Unemployment Assistance

In the House of Commons on December 12 Mr. Assheton moved that the draft Unemployment Assistance (Determination of Need and Assessment of Needs) (Amendment) Regulations, 1939, should be approved. The regulations, he explained, increased the present rates by 2s. a week in the case of a man and wife, 1s. in the case of a member of the household of 16 years and over, and by 6d. of a child under 16. The rate of a person living alone would be increased by 1s. 6d. a week.

Mr. Grenfell said that the regulations contained no provision for improving the standard of living of the unemployed. No household dependent on these allowances, particularly where there were a number of young children, would be able to provide the standard of diet advocated by the British Medical Association or Sir John Orr. There would be 1,000,000 persons who could never get sufficient to eat or clothe them, or obtain decent housing accommodation. Dr. Edith Summerskill said that the Government concession was totally inadequate. She was a member of a local authority which administered many institutions for children, and when they were buying food in bulk for something like 200 or 300 children, in every instance with an eye to giving these children a nutritious diet, they could not cater for them at a cost of less than 6s. 6d. a week each for food alone. Was the Minister going to continue this system, or could the House hope that in perhaps a few months' time he would realize that it was in the best interests of the State to look after the next generation?

The draft regulations were approved.

Emergency Medical Service

Sir Ernest Graham-Little asked on December 14 what was the number of members of the honorary staffs of the voluntary hospitals who accepted the new conditions outlined by Dr. Elliot on November 23, and the number who returned to take up their duties as regards conduct of out-patient and other specialist departments and systematic education of medical students in the voluntary hospitals. He also asked whether the offer of transfer to this new scheme from any form of agreement previously accepted in individual cases covered those members of hospital staffs who were receiving the second grade of salaries for whole-time service. Dr. Elliot replied that to December 14 337 specialists and consultants had accepted the offer. He could not say how many of these returned to their normal duties. That was a matter with which he was not officially concerned. It was not suggested by the professional committee consulted that the offer of transfer should extend to members of the Emergency Medical Service receiving the second grade of salaries for whole-time service.

Sir Ernest argued that the reply which Dr. Elliot gave on this subject on November 23 had been understood to extend the offer of transfer to all voluntary staffs who had accepted full-time engagements. Dr. Elliot said he would again examine his answer. He would not evade carrying out any undertaking which he had given.

On the same date Sir Ernest Graham-Little further asked whether, in view of the necessity for maintaining the most experienced available surgical skill in London, where the first and most critical effect of any air attack must be expected, Dr. Elliot would revise the arrangements by which nearly all the most experienced surgeons awaited the expected casualties in centres remote from London. Dr. Elliot said the present arrangements, which were made in general agreement with the profession, provided for the bulk of the surgical treatment required by London air raid casualties being given by the more experienced surgeons at hospitals on the periphery of, but not necessarily remote from, London, and for the rapid transfer of the patients to these hospitals. These arrangements were designed not only to secure the most efficient treatment of the patients but also to avoid undue risk to highly skilled and irreplaceable personnel. He thought it undesirable to revise them further for the present. He was aware that a Spanish surgeon, in a recent lecture at the Royal Society of Medicine, had emphasized the primary importance of immediate surgical attention of the highest quality for air raid casualties. Plans for dealing with the matter were well advanced, but a hospital in the centre of a bombarded town was not always the best place to bring casualties.

Tuberculosis in Monmouthshire

Dr. Elliot's attention had not been called to a statement of the medical officer of health for the county of Monmouthshire to the effect that persons suffering from tuberculosis are dying because of the failure of the Welsh National Memorial Association to provide the requisite hospital accommodation.

He told Mr. Jenkins, however, on December 14 that the list of tuberculous patients for Monmouthshire, including Newport, awaiting admission to residential institutions included a large proportion of cases of the advanced hospital type. It was hoped to devote a proportion of the beds in the new hutted hospitals to reducing the waiting lists in the coming year, and he was keeping the whole matter under review.

Cancer Mortality in Wales and Monmouth

Dr. Elliot told Mr. Jenkins on December 14 that he had seen Press reports of a meeting of the Cardiff Public Health Committee at which a report was made to the effect that the mortality rate from cancer was rapidly increasing in Wales and Monmouthshire, and that the Welsh Board of Health and the regional commissioner had both refused to take any action for the establishment of a radiotherapeutic institute for the treatment of cancer. Dr. Elliot added that the Welsh Board of Health called a meeting of the local authorities concerned last year to discuss the provision of a radiotherapeutic institute for South Wales. It had not in any way discouraged those authorities from establishing such an institute. It was primarily for the authorities themselves to proceed with proposals for this purpose. Statistics of deaths from cancer, both in England and in Wales, had shown a continuous increase in recent years. Steps had been taken even during the present war to forward plans for dealing with this disease under the recent Cancer Act.

Bed Accommodation in Voluntary and Municipal Hospitals

Mr. Pritt asserted on December 14 that the number of emergency beds provided by the London County Council and other municipal authorities under the Emergency Hospital Scheme was much in excess of those provided by the voluntary hospitals, but that the former were not provided with anything like the same proportion of extra doctors and surgeons. Dr. Elliot replied that the number of beds available in municipal institutions was naturally larger than in voluntary hospitals. The proportion of medical staff enrolled in the Emergency Medical Service to casualty beds was higher in the voluntary hospitals than in the municipal hospitals, but in the latter the medical staff available for casualties included also a number of doctors in the employment of the local authority but not enrolled in the Emergency Medical Service. No useful conclusion could be drawn from a comparison between the respective proportions of beds to medical staff in the two types of hospital The medical staffing of a hospital included in the Emergency Hospital Scheme was governed by medical needs, and depended on factors such as the probable use and the arrangements with affiliated hospitals.

Notes in Brief

In October 1,500,000 gallons of milk were supplied in England and Wales for the milk-in-schools scheme, being over 60 per cent. of the rate of consumption before the war.

Plans were made in England and Wales for the evacuation of up to three million persons; some 1,230,000 persons took advantage of the scheme. It was estimated on December 14 that about 540,000 had returned to the evacuation areas.

Mr. W S. Morrison states that the largest producers vitaminize all their margarine, both cheap and dear

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

In England and Wales the more important notifiable diseases were rather less prevalent than in the previous week, with the exception of measles and acute poliomyelitis. In Scotland, on the other hand, there was an increase in the notifications for diphtheria, dysentery, cerebrospinal fever, erysipelas, and primary pneumonia. The incidence of dysentery had fallen in recent weeks, but rose last week from 28 to 41, of which 18 were in Edinburgh (11 last week), 8 in Dundee, 7 in Glasgow, and 4 in Aberdeen.

Whereas Scotland is correspondingly free from whooping-cough and measles, both diseases are prevalent in England and Wales. The counties most heavily affected are: Glamorgan 358 (Swansea 142, Rhondda 94, Caerphilly 84); Warwick 168 (Birmingham 7, Leamington 42, and the districts of Southam 39, Tamworth 35, and Shipton-on-Stour 20); Cumberland 155 (Workington M.B. 97, Ennerdale R.D. 21); Yorks (West Riding) 153 (Baildon U.D. 35, Thorne R.D. 64); Lancaster 146 (Blackpool 35, Blackburn 11, Manchester 11, Liverpool 9, and widely scattered in both urban and rural districts); Durham 116 (fairly evenly distributed in the five county boroughs and urban and rural districts); Gloucester 117 (Gloucester 51, Cheltenham M.B. 39, Bristol 20). On the other hand, in London there were only 9 cases (Bermondsey 3, Battersea 2, Lewisham 2, Islington 1, Shoreditch 1), in Leicester 8 (none in Leicester City), in Notts 5, Berks 2, and none in the counties of Hertford, Hunts, Norfolk, Soke of Peterborough, Rutland, Suffolk East and West, Cardigan, and Radnor. It is seen that, generally speaking, the expected measles epidemic has not yet made its appearance in the big cities, but the presence of multiple foci all over the country is likely to result in rapid spread at an early date.

Whooping-cough occupies third place in order of prevalence; in contrast with measles it remains typically an endemic disease of large towns and urban communities, rarely acquiring the explosive epidemic character of measles; occasionally, however, an unexpected prevalence is encountered, especially in isolated communities of the closed or semi-closed sort. Large numbers were notified during the week in: Birmingham 43, London 28, Eastbourne 26, Blackburn 25, Swansea 25, Beaconsfield 15. In Liverpool and Manchester only 6 cases were notified in each, and in seven counties no notifications were recorded: Anglesey, Caernarvon, Merioneth, Montgomery, Radnor, Rutland, Soke of Peterborough.

League of Nations Epidemiological Report for 1937

The *Epidemiological Report* for 1937 deals mainly with the incidence and mortality of the acute infectious diseases in the principal countries of the world, and the corrected figures of the rates of births, general mortality, and infant mortality in thirty-five countries. A special table gives details of the death rate according to age and sex in recent years and the corresponding standardized general mortality rates. England and Wales compared favourably as regards typhoid fever (which is generally regarded as one of the most sensitive single indices of the health of the community) with most other European countries; the figure of 1,186 (specific mortality per 100,000 inhabitants, 0.5) is much smaller than that for the previous year but rather greater than in 1935. High figures were recorded in Italy 32,131 (11.8); Poland 17,490; Hungary 10,144 (10); Czecho-Slovakia 7,461 (6.3); Rumania 7,379 (8); Greece 6,266; and Germany 3,051 (0.8). Figures in parentheses are specific mortality rates per 100,000 inhabitants. The latest data from the U.S.S.R. are 61,334 cases in 1936, and from Spain 16,354 cases in 1935. In most countries the third quarter of the year has the worst typhoid fever record.

Diphtheria was comparatively common in England and Wales, although there were fewer cases than in Germany per head of population—64,341 (7.2) against 146,773 (10.9)—and mortality was much lower. The situation here compared unfavourably with other large countries—for example, Italy 28,596 (6.3), Poland 21,084, and France 19,187 (3.2). Scarlet fever was less prevalent in England and Wales 95,735 (0.8), Germany 117,544 (1.9), France 18,728 (0.7), and Italy 16,302 (0.7), but more prevalent in Poland 24,896 and in Scotland 20,493 (2.5). Both diphtheria and scarlet fever were most prevalent in the last quarter of the year in the majority of countries. Among European countries acute poliomyelitis was prevalent in Italy 2,740 (0.8), Germany 2,723 (0.5), Sweden 1,931 (6.8), Switzerland 1,494 (4.2), and Denmark 1,243 (3.6), compared with England and Wales 864 (0.3), France 592, and Poland 158. In the United States of America there were 9,511 (1.1) cases in 1937, in Canada 3,880 (1.8), and in Australia 1,979 (1.7).

No. 48

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended December 2, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for : (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for : (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases ; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. of reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The Telephone Number of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The Telegraphic Addresses are
EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*
SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Doctúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Achlorhydria and Condiments

Dr. L. I. Hardy writes: Can any of your readers inform me whether the practice of taking condiments at meal times is more prevalent among the natural achlorhydrics than among the rest of the population, and whether this can be carried on by them with impunity for many years?

Crataegus oxyacantha

Dr. Frank Bodman (Bristol) writes: Mr. A. E. Sawday (December 9, p. 1172), in effect, asks when should a dose be defined as homoeopathic. It might appear that there was some arbitrary level of dilution below which all doses could be called homoeopathic. In actual practice this is not so. In some subjects the pupil dilates to extreme dilutions of atropine, but this is still a physiological effect and not a homoeopathic action. Crataegus given in 45-minim doses a day produces in hyperpietics a fall in blood pressure. This may be described as a physiological effect. Crataegus given in 1 to 5 minim doses to patients suffering from reduced pulse pressure raises the pulse pressure. This is its homoeopathic action. In the case of crataegus the margin between the physiological range and the homoeopathic range of action probably is very small. In the majority of drugs the gap between the two actions is much larger.

Income Tax

Married Woman—Employment of Domestic Staff

"E. A." is a married woman holding a public health appointment. Owing partly to the illness of her husband she has to employ a housekeeper and a children's nurse to set herself free for her professional duties. Can she claim any deduction for these expenses?

⁂ No. It was ruled in the case of Bowers *v.* Harding (concerning a schoolmistress who employed a domestic servant) that such expenses were not incurred in the performance of the duties of the office, and therefore could not be deducted.

Property in Scotland

"A. B." used to occupy some premises, part of which were sublet. He has now left, and the whole of the premises is let in sections. The premises have been revalued by the rating authorities on the basis of the rents payable less rates borne by "A. B.," and the result is a substantial increase. The points mentioned below arise.

⁂ While "A. B." was actually in occupation of a part of the premises their annual value was to that extent a matter of estimate. It is not uncommon for an increase to occur when the estimate is displaced by an actual letting. The division of the rating into two sections is permissible, and lends itself to the allowance in due course for empty periods; it may therefore be accepted. If the rents are collected at frequent intervals some deduction from the full amount for the year is usually made. The fact that certain fixtures and fittings are included in the rents should be explained and a deduction claimed—33⅓ per cent. of the capital value would probably be the maximum allowance. With regard to the income tax, Schedule A, if the tax paid by way of deduction from "A. B.'s" trust income is likely to cover his whole liability, the inspector of taxes will no doubt arrange on request for the Schedule A tax to remain in abeyance until the end of the financial year—or if not the whole at least a substantial part of it.

Superannuation—Payment of Premium by Employer

"D.P.H." holds an appointment in a sanatorium, but not under a local authority. The governing body have arranged that "D.P.H." shall take two units in the B.M.A. Pension Scheme, and that they will pay for one of the two units so long as he is in their employment. The income tax authorities claim to regard that payment as assessable income in "D.P.H.'s" hands.

⁂ That view appears to be legally correct on the basis that "D.P.H." is liable to pay for both units, and that payment on his account by the employer is equivalent to payment by him. The corollary to acceptance of that proposition, however, is that "D.P.H." is entitled to the life assurance relief on *both* units—and we gather that the authorities are prepared to accept a claim on that basis. (The compulsory levy in the case of local authority employees rests on an entirely different legal basis, and the deductions made are dealt with as if they were expenses of the employment.)

LETTERS, NOTES, ETC.

Hypersomnia after Accident

Mr. Norman Porritt, M.R.C.S., L.R.C.P. (consulting surgeon, Huddersfield Royal Infirmary), writes: The following account of excessive sleepiness after an accident, and of its treatment by benzedrine, was thought worth recording. The patient is a healthy-looking, well-nourished man, 81½ years old, who does not look his age. For as long as he can remember he has had a sleep after his midday meal. On December 22, 1938, he fell backwards down a short flight of stairs and struck his head violently against the wall at the bottom of the stairs. At the beginning of 1939 he began to be unaccountably sleepy, until at length he was overcome by sleep after breakfast and slept till lunch time. Though he had his afternoon sleep he found it difficult in the evening to keep awake till bed time, when he slept all the night. His urine had a specific gravity around 1020 and was free from sugar and albumin. One estimation of his blood urea showed it to be within normal limits. He is not a big eater, especially of meat. His bowels move daily without aperients. When awake he is mentally bright and active. As no flaw was found in his health to explain the condition his somnolence was diagnosed as narcolepsy due to old age and the fall he had. On August 2 he was given half a milligramme of benzedrine three times a day; on August 4 he was just as sleepy, and the dose was increased to one milligramme three times a day. By August 14 there was no sleepiness till bed time. He had a better appetite and was brighter. Since August 17 sleepiness has been less marked and less trying. Half or one milligramme of benzedrine on odd days dissipated it. by November 23 the sleepiness had vanished, the patient having taken no benzedrine since September 15. When he took 1 mg. three times a day for three days he said he felt "doped," his walking powers were weakened and his brain befogged.

Supplementary Food Rations for Invalids

Dr. M. Fishman (London, N.W.2) writes: The following communication has been received from the local Food Control Committee: "For the present no arrangements are being made to provide for special or supplementary rations for invalids owing to the limited number of commodities which are being rationed and the adequacy of supplies of alternative foodstuffs." This ruling, unless modified, will cause unnecessary hardship among invalids. I believe in the last war arrangements were made for invalids to receive supplementary rations on medical certification.

Disclaimer

Dr. H. Gordon McGregor (Hove) writes: May I request the hospitality of your columns in order to disclaim any responsibility for an article which appeared in an evening newspaper for December 7 under my name? My original article was published by the *Practitioner* last month, and reappeared, to my astonishment, in the evening press with full case notes. I understand that there is no power of preventing a free press from "lifting" articles in this regrettable manner, or likelihood of obtaining even the common courtesy of a formal request before they do so.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY DECEMBER 30 1939

THE PAINFUL SHOULDER*

BY

PHILIP D. WILSON, M.D.

New York City

(WITH SPECIAL PLATE)

Shoulder pain may be due to a host of causes, and in order to transfer the discussion of this subject from an abstract to a specific basis I submit the following analysis of diagnoses from 168 personally studied cases seen during the last five years. This list is presented with due apology for its shortcomings and with the full knowledge that it represents nothing more than the experience of an individual surgeon. Its only merit lies in the fact that it includes all patients seen during this period who complained primarily of the shoulder, and that it gives an indication of the variety of conditions that must be included in the differential diagnosis.

TABLE I.—*Showing Analysis of Diagnoses of 168 Personally Studied Cases of Shoulder Pain*

	No. of Individual Lesions	Totals for Different Groups
I. Region of shoulder:

Study of this table shows that lesions of the subacromial bursa accounted for eighty-nine, or 53 per cent., of the 168 cases. The other pathological lesions occurred in a scattered manner, with the exception of the fractures and dislocations, which were included only for the sake of completeness. In the space at my disposal I cannot attempt to consider all the various causes of shoulder pain; consequently attention will be devoted only to the more common ones.

Lesions involving Subacromial Bursa

Some objection may be made to the differentiation of lesions causing shoulder pain on the basis of whether or not they involve the subacromial bursa, and it may be claimed that a better classification could be obtained upon a pathological basis. The exact nature of several of the pathological processes is, however, obscure, and it seems to me that they can be best understood in relation to the anatomy and function of the subacromial bursa.

This bursa serves to remove friction and to permit the greater tuberosity of the humerus to rotate inwards under the acromion process in movements of abduction and rotation of the shoulder. It is a synovial sac about one and a half inches in diameter whose base is fixed to the superior capsule of the shoulder-joint and to the greater tuberosity of the humerus, and its roof to the proximal portion of the deltoid muscle, the coraco-acromial ligament, and the acromion process. The peripheral portions of the bursa are loose and redundant, and thus permit the floor of the bursa to glide under the roof during the different movements of the shoulder. Normally the layers of the bursa are approximated, but enough fluid is secreted to keep them moist and lubricated. When the two layers become adherent movement of the shoulder is greatly restricted (Fig. A).

---

* Read in opening a discussion in the Section of Orthopaedics and Fractures at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

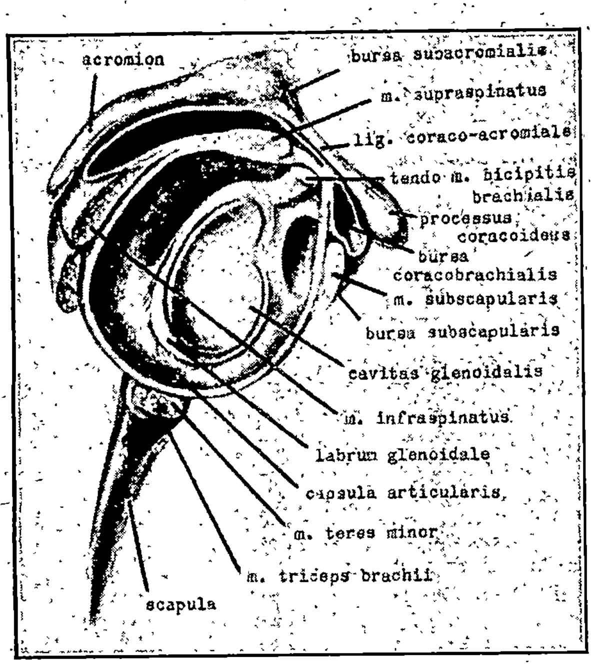

Fig. A.—Specimen showing relations of subacromial bursa, capsulo-tendinous cuff, and shoulder-joint after removal of humerus.

Inflammation of the subacromial bursa occurs practically always as a consequence of a lesion involving neighbouring structures. Codman (1934) states: "I now feel that an attempt to describe bursitis as an entity would be equivalent to attempting to describe peritonitis as an entity. It is not a structure where disease starts, so much as a structure which limits disease in the adjacent structures by temporary adhesions causing fixation of the parts." Just as it would be a mistake to-day to make a diagnosis of generalized peritonitis without attempting to describe its cause, so it would be a mistake to make a diagnosis of subacromial bursitis without first defining its origin.

In the subacromial bursa the source of most of the pathological changes is the structure forming the larger part of its floor. This is variously designated as the superior capsule of the joint, the supraspinatus tendon, and the musculo-tendinous cuff. It is in reality a composite structure made up of the short flat tendons of the subscapularis, supraspinatus, infraspinatus, and teres minor muscles, which blend with the capsular ligament and with each other at a point about one inch proximal to their bony insertions to form a conjoined tendinous and capsular cuff whose fibres are indistinguishable from each other. Again I quote from Codman, who says: "I may summarize by saying that owing to the peculiar mechanics of the shoulder the avascular and inert supraspinatus tendon is the most vulnerable part of the joint, and that inflammation in it is apt to be painless until the adjacent subacromial bursa is involved, which, being abundantly supplied with vessels and nerves, produces the symptoms of which the patient complains." It should be pointed out, further, that, owing to the relatively unstable architectural arrangement of the shoulder-joint with its large humeral head and small glenoid cavity, this tendino-capsular cuff is called upon to bear a great deal of strain and is exposed to injury either from repeated minor insults in daily use or a single more serious trauma. Meyer (1931) pointed out the high frequency of attritional changes involving the tendino-capsular cuff and long tendon of the biceps found upon routine examination of many cadavers. It is probable that these changes play a large part in the genesis of many painful lesions of the shoulder.

The more common lesions involving the subacromial bursa are the following: (1) calcareous deposits (calcifying tendinitis); (2) periarticular adhesions (tendinitis); (3) rupture of supraspinatus tendon.

Calcareous Deposits (Calcifying Tendinitis)

There seems to be much confusion in respect to the part played by calcareous deposits in causing shoulder pain. This is doubtless due to the fact that calcification in the shoulder is not infrequently revealed by *x*-ray examination when the patient is completely free from any complaints in this region. Indeed, in the case of a patient complaining of a painful shoulder the *x*-ray examination of the normal side may show an even larger calcified mass than on the affected side. Again, there is an extreme variability in the severity of the symptoms which may be difficult to understand unless one has had the opportunity of exposing these lesions by operation and of observing at first hand the differences in the pathological appearance.

The deposits almost invariably originate in the tendino-capsular structure, and although they may be seen in the subscapularis, infraspinatus, or any other location, the favourite situation is in the supraspinatus tendon close to its point of insertion. Elmslie (1932) reported finding the calcareous material in a cavity in the greater tuberosity in three cases, but this is unusual. The characteristics of the deposits vary. Sometimes they may be found as uncoalesced collections of dry, gritty, sand-like particles without any surrounding hyperaemia (Plate, Fig. 1), and at others as confluent cavities filled with soft greyish material having much the same consistency as toothpaste and surrounded by zones of intense inflammatory reaction (Plate, Fig. 2). On some occasions in order to remove them it is necessary to excise the entire diseased portion of the tissue, on others only to prick the roof of the cavity and drain it like an abscess. Chemical analysis of the material has been made and the results reported by many observers, including Moschcowitz (1915), Codman (1934), and Elmslie (1932). The examination of material removed from several of my own cases agreed substantially with theirs. It is composed chiefly of calcium phosphate and calcium carbonate in non-crystalline form. In a case recorded by Codman calcium oxalate was present, but this substance was not reported by others. On microscopical examination the material is seen to consist of small ovoid colourless bodies of variable size, exhibiting a marked Brownian movement. It is insoluble in alcohol and ether. The murexide test for uric acid is negative. The Liebermann-Burchard test for cholesterol is sometimes positive and sometimes negative.

All cultures made from these deposits, including both those reported by others and those in my own cases, have proved negative. There is no scientific evidence, therefore, to support the contention that the deposits are of infectious origin. Similar deposits have occasionally been found in other regions of the body, particularly in and about the tendinous attachments of the gluteus medius and minimus muscles, the flexors carpi ulnaris and radialis, muscles, and the tendo Achillis. Worthy of note is the observation that all of these structures have the common characteristic of being dense fibrous tissues with slight, if any, vascularity.

Method of Deposit Formation

Microscopical examination of different specimens shows that the deposit is first laid down in small punctate areas deep in the tendinous fibres. Gradually these enlarge, coalesce, and work their way to the surface of the tendon. Milgram (1939) recently called attention to the occurrence of large round cells in the tendon whose cytoplasm gradually became swollen and lost its staining properties. This change seemed to be followed by precipitation of calcium—at first in the periphery of the cell, but gradually spreading until the entire cell became calcified. Whether these were cells of the wandering type or connective-tissue cells that had undergone pathological change had not yet been determined. Reasoning from what is known of calcifying processes in other structures, and particularly in the walls of blood vessels, the most tenable theory would seem to be to regard these deposits as the result of degenerative changes in dense avascular fibrous tissue not unlike that seen in arteriosclerosis. Attrition rather than injury would seem to play the principal part, but the process can probably be best described as a calcifying tendinitis.

Symptoms of Calcifying Tendinitis

Whether or not the deposit gives rise to painful symptoms would seem to depend upon its having enlarged sufficiently to approach the tissue layer beneath the bursal wall, which, being richly supplied with vessels and nerves, is capable of reacting in the usual inflammatory manner and of transmitting painful stimuli. Inflammatory reaction may result in absorption of the deposit, or in certain instances the material may actually rupture into the bursal cavity, where it sets up an intense but usually short-lived inflammation, finally resulting in absorption. When the deposit lies deep in the tendinous structure it causes no symptoms. As it enlarges the overlying tissues become thinned and it causes a localized hyperaemia or swelling. At this stage the patient will begin to complain of a painful catch in the shoulder on certain movements, usually those of abduction and external rotation, in which the painful area is compressed between the greater tuberosity and the acromion process. Other motions are free and painless. *X*-ray examination will usually reveal a small rather discrete calcareous deposit, lying as a rule in the region of the supraspinatus tendon close to the greater tuberosity, but it is to be emphasized that there is more variation in the anatomic location than generally supposed. This is the subacute stage, and it may persist for many months with slight, if any, change.

Other patients with or without previous shoulder symptoms of the subacute type may be awakened in the middle of the night with acute pain, which very quickly becomes excruciating. Such patients show extreme apprehension of the slightest movement of the shoulder and are unable to co-operate upon examination. It may appear hot and slightly swollen, and is exquisitely tender upon palpation. There may be a slight elevation of temperature and a moderate leucocytosis. The *x*-ray examination at this time will often reveal a mass of calcareous matter filling the bursal cavity and sometimes extending downwards over the greater tuberosity. Large doses of morphine may be necessary in order to give relief. This is the acute stage.

I have had the opportunity of observing the actual pathological condition in several of these acute shoulders at operation. In two cases there had occurred a rupture of the calcareous matter into the bursal cavity. The bursal wall was congested, and upon opening the sac it was found to be filled with fluid containing white calcareous substance and fibrin. After removing this substance a small cavity could be seen in the floor of the bursa from which it had escaped. In other cases the bursal wall was found reddened and adherent over the deposit, and upon puncturing these tissues the calcareous matter spurted out in a liquefied state with much the same appearance as pus escaping from an abscess cavity.

Treatment of Calcifying Tendinitis

Formerly the only alternatives in the treatment of calcifying tendinitis were rest and physical therapy or surgical excision. Of the various physical agencies that have been tried the most benefit has been obtained from properly administered diathermy. I have seen demonstrated many cases in which complete relief of symptoms and disappearance of the deposits upon *x*-ray examination had followed promptly after a series of such treatments (Titus, 1929). In contrast, I have seen similar cases in which no improvement was obtained by this method. I have also observed patients in whom the symptoms were relieved and the deposits disappeared without any treatment other than rest. I am therefore unable as yet to accept the claims of benefit from diathermy as fully proved.

The results of surgical excision of the deposits are definite, and the relief conferred upon patients with the acute type of symptoms is so immediate and great that there is much to recommend it. On the other hand, with the subacute type of symptoms few patients are sufficiently disabled to be willing to undergo even this mild procedure. Particularly is this so in the case of women, to whom the thought of a disfiguring scar is objectionable.

Fortunately we now have the method of aspiration and irrigation by needle to accomplish the same result as by operation, only with less trauma (Plate, Figs. 3 and 4). Porritt (1931) was one of the first to indicate the usefulness of this method, but Patterson and Darrach (1937) published the most comprehensive series of cases. They used two needles, one inserted from the anterior aspect and the other from the lateral aspect directly into the deposit. Salt solution was forced in by syringe through one needle and allowed to escape through the other. They made no claims for complete removal of the deposits by this method, although that result was achieved in a few instances. They did state, however, that pain was relieved and function restored, either immediately or within a few days, and that absorption of the calcareous matter followed within a period of a few weeks (Table II).

TABLE II.—*Showing a Summary of Cases treated by Irrigation (By courtesy of Dr. R. L. Patterson)*

Treated by irrigation		63
Acute (seven days or under)	48	
Subacute (under one month)	8	
Chronic (over one month)	7	
Histories of previous attacks		17
Roentgenograms showed calcium shadows		48
Average period of economic disability:		
Acute	4.8 days	
Subacute	7.0 „	
Chronic (when relieved)	10.14 „	
Results:		
Complete relief of symptoms		57
Infections		0
Limited motion in shoulder		2
Operation necessary after irrigation		2
Pain and limited motion still present		2

NOTE.—Only one of the six cases included in the last three groups was acute.

I have had the opportunity of observing the results obtained by Patterson in many cases treated by this method at the Hospital for the Ruptured and Crippled, and am in a position fully to confirm his earlier conclusions. I have also employed this method of treatment in some of my own cases. In the acute cases the relief that may be obtained is striking, and it is a cause for gratification that we now have at our command a method that is capable of affording immediate, and generally permanent, relief from such severe pain. Failures result in a few cases when one has been unsuccessful in reaching the calcareous deposits with the needle, but the procedure should then be repeated, employing *x*-ray localization in order to guide the needles. Recently Milgram (1939) stated that it was unnecessary to employ saline irrigation, and that he had obtained just as good results by direct needling and aspiration. He believed that the essential factor was to puncture the deposit and open channels through which capillaries might penetrate, a process that would be followed by absorption.

Relief may also be obtained by puncture and irrigation in the subacute cases. All depends upon being able to reach the deposit, and greater skill comes with greater experience. Accurate localization of the deposit by preliminary *x*-ray examination in two planes is necessary. In a few cases deposits of dense, almost bone-like, consistency may be encountered which do not respond to this method of treatment. In such cases operative excision may still remain the procedure of choice.

Reviewing the twenty-five cases of calcifying tendinitis that occurred in the series, I find a preponderance of the male sex, which accounted for sixteen, or 64 per cent. In respect to age, the peak of the incidence was 46 to 50 years, with almost as many in the 41–45 year and 51–55 year periods (Fig. B). There was practically an even distribution between the left and right sides, with three bilateral cases. Nine cases were classified as acute and sixteen as subacute. Of the acute cases three were treated by operation, three by needling and irrigation, and the remainder by immobilization with sling and circular bandage and by local heat. All recovered within a period of seven to ten days, but those treated by puncture and irrigation made the most rapid and spectacular improvement. Of the sixteen subacute cases three were treated by puncture and irrigation with relief, two by diathermy, and the remainder expectantly, since their symptoms were minimal and did not cause disability. The final results in these cases are unknown.

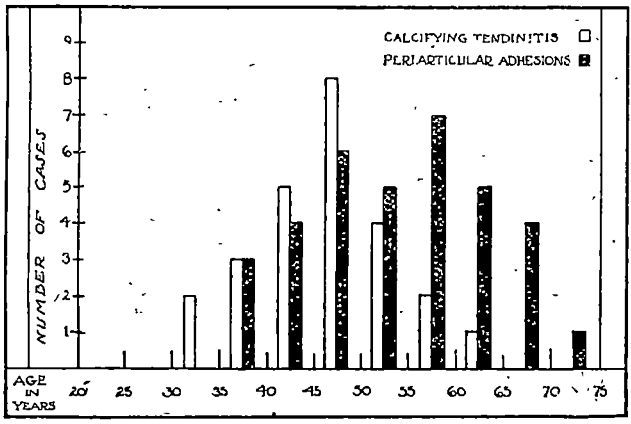

FIG. B.—Graph showing comparative age incidences of twenty-five cases of calcifying tendinitis and thirty-five periarticular adhesions. (One case of periarticular adhesion is not included, as the patient's age was not obtainable.)

Periarticular Adhesions (Tendinitis)

Periarticular adhesions account for even more cases of shoulder pain than do calcareous deposits. In my group of cases they numbered thirty-six, compared with twenty-five of the latter. The age incidence appeared to be a little older, as may be seen from a glance at the graph, although this observation is not confirmed by the figures given by Codman (1934). The males outnumbered the females twenty to sixteen. The left shoulder was affected twenty-one times, the right seventeen times, and in two cases the condition was bilateral.

Little is known of the exact pathological process, and the nature of the condition can only be deduced from the clinical evidence. The symptomatology is so characteristic, however, that there can be no doubt that we are dealing with a separate disease entity. The patient is not usually seen until the condition is already well established. He generally gives a history of having noticed a slight painful catch in the region of the shoulder and upper arm for a period of several months. Gradually he has become aware of an inability to perform certain tasks or to participate in certain sports because of stiffness in the arm. Night pain, often awakening him after he has fallen asleep, is a common complaint. Frequently it radiates down the arm to the hand, but without being localized to any nerve distribution.

Physical examination fails to reveal any swelling or definite point of local tenderness, although there may be generalized sensitiveness about the shoulder. Tests of movement, however, invariably show marked restriction of both active and passive abduction and of rotation. If the shoulder girdle be fixed in order to limit the motion to the scapulo-humeral joint the range of abduction may not exceed 35 to 45 degrees. When one forces the movement pain is elicited. The *x*-ray examination is usually quite negative, although in a few of my cases several flecks of calcium deposit were shown. In addition we know that when this condition is treated by forcible manipulation, as advocated by Sir Robert Jones and others, there occurs a loud sound of snapping adhesions, followed immediately by a complete freeing of the shoulder movements. From this and the negative *x*-ray findings the condition has been ascribed to the formation of adhesions about the joint. No evidence of arthritis has been found. Where these adhesions are located has never been definitely discovered. I have operated upon several patients with this condition and explored the subacromial bursa, with rather disappointing findings. In only one case was the bursa obliterated by adhesions. In two cases the appearance of the bursa was fairly normal, although it seemed small, and there may have been adhesions at the redundant free edges. In one other case the bursa appeared normal, but the tendino-capsular cuff lying beneath it was of a uniform red colour, indicating an extensive hyperaemia, and I am led to believe that this was an early case with the inflammatory process still present and active. Codman has reported similar findings. With my finger in the bursa I manipulated three of these shoulders and felt the snapping of adhesions in the capsular structure beneath my finger and anteriorly in the region of the subscapularis tendon.

I am of the opinion, therefore, that the adhesions lie in the substance of the tendino-capsular structure, whence they may extend, to involve either the underlying or the overlying tissues. The process probably starts as a tendinitis, which subsides, leaving a thickened inelastic capsule adherent beneath to the edges of the articular cartilage and above to the adjacent soft tissues. As to whether this tendinitis is a true inflammatory process due to low-grade infection as suggested by Dickson and Crosby (1932), or whether it is still another manifestation of the attritional and degenerative changes to which this structure is particularly liable I have no direct evidence. I can say, however, that most of the cases treated by me have recovered without any particular attention to foci of infection and that their recovery time compares favourably with that of the cases reported by Dickson and Crosby, in which all infectious foci were eradicated.

Treatment of Primary Tendinitis

In respect of treatment, it should be emphasized that by no means all of the cases of stiff or frozen shoulder are due to primary tendinitis. Many, according to the history, are clearly due to adhesive processes secondary to injury of the soft structures or to calcifying tendinitis. This differentiation is important, because the secondary cases respond well to local heat, massage, and active and passive movement, whereas in the primary cases this treatment is generally ineffective.

In discussing the subject of primary adhesive tendinitis Codman maintains that it is a self-limited disease and that all cases finally recover, with or without treatment. He is inclined to explain this to the patient and to leave the decision to him as to whether or not he will undertake treatment. While it is probably true that many of the patients will eventually recover without treatment, I do not share Codman's confidence that this will invariably be the case. Even if it were so, the length of time required would be too great in view of the amount of pain many of the patients suffer. My own procedure is to begin with physical therapy, consisting of local heat, massage, and pendulum exercises. If night pain is severe the arm is immobilized with a sling and circular body bandage when the patient is in bed. During the day active use with the arm at the side is encouraged, but motoring, lifting, and participation in sports are banned. If after a trial period of about two weeks no improvement of motion or diminution of pain has been noted some other procedure should be adopted. This usually means a choice between manipulation under anaesthesia or recumbent treatment with the arm suspended in abduction. Manipulation has given good results in my hands and has not resulted in complications, although I have seen cases of others in which the shoulder had been dislocated. During the manipulation the adhesions should be completely freed and massage and exercises should be started immediately. I do not favour the use of a splint, but I make it a rule to keep the patient recumbent in order that abduction exercises may be performed without the counter-effect of gravity.

Manipulation, however, is only too often followed by a difficult and painful period in which it is a question whether one will be able to maintain the newly acquired freedom of movement. I have been impressed by the fact that much of the original restriction of movement is due to irritation and muscle spasm, and that if this can be overcome the adhesions can be made to yield. To accomplish this result adhesive traction is applied to the upper arm with the elbow in right-angle flexion and the forearm suspended from an overhead frame, the patient being recumbent. The shoulder is generally maintained in a position of right-angle abduction, but several times a day the line of pull is changed so that positions of hyperabduction and of adduction may also be obtained. Not until the patient is able to maintain these extreme positions for considerable periods without pain—generally after seven to fourteen days—can the usual physiotherapy be started, and even then it is important at other periods to reattach the traction and suspension apparatus. Often at this stage the part-time use of an abduction splint can be substituted. Gradually the shoulder is allowed more and more freedom, and the frequency and amplitude of the exercises are increased until complete recovery is obtained.

Of my own thirty-six cases fourteen responded to physiotherapy alone, ten were treated by manipulation with nine recoveries, three were treated by traction and suspension with complete relief, and nine were untreated.

Summary

A series of 168 personally studied cases of shoulder pain is analysed.

Pathological processes are discussed in relation to the anatomy and function of the subacromial bursa.

The more common lesions involving the subacromial bursa—calcareous deposits (calcifying tendinitis), periarticular adhesions (tendinitis), and rupture of the supraspinatus tendon—are reviewed and their treatment described.

Leaflet No. 11 in the series issued by the Department of Scientific and Industrial Research on methods for the detection of toxic gases in industry deals with aniline vapour (H.M. Stationery Office, 3d. net). Aniline exists in small quantities in coal tar, but is produced industrially almost exclusively by the reduction of nitrobenzene. It is chiefly used as a starting-point in the manufacture of dyestuffs and to a less extent in other chemical industries. Its pleasant smell in no way suggests the dangers resulting from its presence in the atmosphere. It has been shown that cases of acute aniline poisoning arise by absorption through the skin by splashes either directly on the skin or indirectly through the clothing. Its immediate toxic effect is on the blood, and the symptoms which characterize it are a blue-grey discoloration of the lips, ears, and cheeks. Depending on the intensity of the concentration, shortness of breath, rapid feeble pulse, nervous excitement not unlike drunkenness, may occur later. With a concentration of one part in 140,000 slight symptoms may occur after several hours' exposure, while with concentrations of one part in 10,000 to one part in 6,000 serious disturbance occurs if the atmosphere is inhaled for more than an hour.

TREATMENT OF HAEMORRHOIDS*

BY

W. B. GABRIEL, M.S., F.R.C.S.

Surgeon, Royal Northern and St. Mark's Hospitals

(WITH SPECIAL PLATE)

The choice of treatment of haemorrhoids depends so much on examination and an accurate estimation of the condition presented in each particular case that I should like to say a few words on these preliminaries.

Distinction between Internal and External Haemorrhoids

The distinction between internal and external haemorrhoids is of the first importance. Internal haemorrhoids arise from the columns of Morgagni as the result of dilatation and engorgement of the internal haemorrhoidal plexus, and are covered by mucous membrane which is at first of the normal bright pink colour. This colour may be changed by superficial inflammation, ulceration, or sloughing. Later, as the result of repeated prolapse and surface irritation, a large internal pile often shows an overgrowth of squamous epithelium over its lower pole. It may be noted that we see exactly the same change quite commonly over the mucous membrane of the appendix when exposed as an appendicostomy. An internal pile may thus become considerably covered by squamous epithelium, and therefore when prolapsed it somewhat resembles on superficial examination an external skin tag, but the groove which originally marked the muco-cutaneous junction, due to the attachment of the terminal fibrous expansion of the longitudinal muscle, persists in most cases and thus separates it quite clearly from an external pile.

As opposed to this an external pile is covered by skin *ab initio*, whether it is in the stage of an acute thrombosed external pile (anal haematoma) or a soft anal skin tag. Under certain conditions, however, an external pile must be carefully inspected to discover its true nature. Thus an acute haematoma may be seen at the stage when the skin has become ulcerated so that blood and clot are being discharged, and it has on cursory inspection a superficial resemblance to a prolapsed internal pile. Again, if a large mass of external thrombosis and oedema is present careful examination is often needed to detect the lower pole of a prolapsed and thrombosed internal pile in the same quadrant, which is really the "villain of the piece." The anal margins must be separated and perhaps some traction in a lateral direction applied to the haematoma, when the lower pole of the thrombosed internal pile, if present, will at once be seen.

Treatment of External Piles.—Excision of a solitary tense anal haematoma under local anaesthesia is the most common, and a very satisfactory, anal operation. A large conglomerate type of anal haematoma is best treated on expectant lines. Skin tags at the anal margin may subside with lead lotion compresses, but if large should be excised under local anaesthesia. When associated with prolapsing internal piles (intero-external type) a formal haemorrhoidectomy is the best treatment.

Degree of Internal Haemorrhoids

The treatment of internal haemorrhoids is intimately linked up with a correct assessment of the degree of prolapse. Ernest Miles (1919) divided piles into three stages.

Primary, being the earliest stage, in which bleeding takes place at defaecation: the pile may just become grasped by the anal sphincters during the act of defaecation, but no prolapse outside the anal margin occurs.

Intermediate, when the pile protrudes through the anal orifice at defaecation and then becomes reduced spontaneously when the expulsive effort has ceased. Some bleeding still occurs, but may be less than before owing to some fibrosis taking place in the substance of the pile, together with some thickening of the mucous membrane.

The final stage is reached when the prolapse is still more pronounced and does not become spontaneously reduced at the end of defaecation; the pile remains in the prolapsed and engorged state, and digital reduction is needed after each act of defaecation. Sometimes such a pile is irreducible by reason of mere bulk, massive thrombosis, or sphincter relaxation. Even after being properly reduced, recurrence of prolapse takes place subsequently on slight provocation, such as coughing, sneezing, any lifting effort, walking or standing for any length of time, or even passing flatus.

These three stages are now more commonly known as the first, second, and third degrees. It is essential to recognize the symptoms associated with piles of the third degree: mucoid discharge and bleeding into the clothing during the day are common complaints in addition to the necessity for digital replacement.

Routine Diagnostic Methods

Inspection, digital examination, and proctoscopy are required in all cases. The patient should be asked to strain down as the proctoscope is withdrawn in order that the full degree of prolapse may be seen, and very often a bleeding point is revealed as the piles become engorged.

The presence of fibrosis in an internal pile, so that it is palpable to a finger, is evidence of recent or old thrombosis. Large prolapsing piles can almost invariably be rolled under the examining finger, and if the process has advanced to the stage of formation of a fibrous polyp this can readily be felt and can usually be hooked down until it prolapses outside the anus. A pulsating branch of the superior haemorrhoidal artery can sometimes be felt in relation to one or more of the primary internal haemorrhoids, and is a clear indication of the need for a ligature operation.

Other associated ano-rectal conditions must be accurately diagnosed. Fissure in ano is one of the most important, and if present may have considerable influence on the choice of treatment. Of the many other conditions which may coexist with haemorrhoids it is necessary to mention the not infrequent association of carcinoma of the rectum: hence a high digital examination and sigmoidoscopy with this in mind should be done in all cases.

The choice of treatment is necessarily much influenced by finding a pelvic tumour of uterine or ovarian origin, and in men prostatic enlargement often introduces a difficulty in deciding on the right line of treatment. Abdominal conditions such as cirrhosis will affect treatment. In many cases I have seen a troublesome degree of piles in patients who were taking intensive alkali treatment for duodenal ulcer, and this combination is a difficult one to treat.; so also is any degree of haemorrhoids in patients with chronic cardiac or pulmonary disease. The general state of patients must always be carefully gone into, particularly if surgical treatment is proposed.

As a statement of the practice of St. Mark's Hospital I will now describe three treatments for internal haemorrhoids, each of which has a useful and in fact an essential place when applied to the right type of case.

---

* Read in opening a discussion in the Section of Surgery at the Annual Meeting of the British Medical Association, Aberdeen, 1939.

Palliative Treatment

Small internal piles associated with a generalized congestion of the lower rectum are not infrequently seen, particularly in stout subjects who may be liable to hepatic congestion and constipation. Medical treatment directed specially towards limiting the intake of meat and alcohol is of great value; the free drinking of water and barley-water will help constipation and enable aperients to be drastically cut down. I am anxious to stress the common tendency among the general public to take aperients unwisely and to excess: drugs such as salts, calomel, phenolphthalein, and some herbal teas undoubtedly produce irritating watery stools, and when these are voided there is a considerable amount of straining and rectal congestion. Women are very liable to these troubles, which often start during pregnancy.

Palliative treatment is necessary for an attack of prolapse with thrombosis. The more the local sepsis, with ulceration or sloughing, the greater the need for palliative treatment. I am strongly opposed to surgical treatment at this stage, and although this is a matter upon which some controversy exists I shall hope to convince you that surgery in the stage of septic thrombosed internal piles is unnecessary; it is apt to result in delayed healing and chronic post-operative ulceration, which may take months or years to clear up.

The most essential item in palliation is for the patient to be in bed: the foot of the bed may be raised upon blocks, or the buttocks be slightly elevated on a pillow. An attempt should be made to reduce the prolapsed pile or piles, and in most cases this can be done with gentle but firm pressure with the forefinger, aided by some dry gauze or cotton-wool. A firm pad of gauze moistened in lead lotion is applied and kept in position by a T-bandage. If the piles cannot be reduced, as sometimes happens when there is a massive degree of thrombosis with much external oedema, the anus is shaved, the patient confined to bed, and compresses of 1 in 2,000 perchloride, eusol, lead lotion, or dettol lotion are applied every three or four hours. This treatment can be carried out effectively in the patient's home; and in the hospital class I have been struck by the excellent results obtained provided the patient realizes the importance of staying in bed. On these lines the thrombosis quickly resolves, ulceration heals, and external oedema disappears; in fact, after a week's efficiently applied palliative treatment the majority of patients are able to begin getting up and about again. Only in the worst cases, with smelly sloughing piles, is longer treatment up to two or three weeks required in bed. A perianal abscess forms occasionally, and for such surgical drainage must be given.

When thrombosis has resolved, digital and proctoscopic examination will show if further treatment is required. In many cases nothing further has to be done. For some, injections are advisable, and in a few it is clear that large prolapsing piles remain and a ligature operation is necessary for cure: in no case should this be done within six weeks after an attack of prolapse and thrombosis.

Injection Treatment

The objects of injection-treatment are twofold: (1) to produce a chemical thrombosis in the internal haemorrhoidal plexus, and, following this, (2) a sclerosis in the submucous layer which will fix loose, redundant mucous membrane to the inner muscle layer and by fibrosis draw up the pile so that it no longer prolapses or becomes grasped by the sphincters.

The solution which is used at all the out-patient clinics at St. Mark's Hospital is 5 per cent. phenol in almond oil, with 2 grains of menthol to 1 oz. (Albright's solution). This is injected into the submucous layer by a technique which is now so well known as not to need detailed description. The following points might be mentioned.

SELECTION OF CASES

The ideal cases for injection are first-degree piles: a single small vascular pile can almost invariably be cured by a single injection. Second-degree piles are less favourable, for although bleeding can usually be stopped and prolapse improved so that the patient becomes symptom-free, recurrence after a variable time is not infrequent. Third-degree piles, particularly those which show an overgrowth of squamous epithelium at the lower pole and those with a marked external skin tag in relation (intero-external piles), are not suitable for injection, and as a general rule a ligature operation should be performed in these cases. Associated conditions such as anal fissure, a fibrous polyp, proctitis, or any inflammatory condition such as abscess or fistula are contraindications to injection treatment.

AGE AND OCCUPATION

Patients are commonly seen with piles of the second degree verging upon the third degree, and the choice of treatment may reasonably be influenced by age and occupation. In subjects under 30 years of age it is impossible to guarantee permanent cure by any method, including operation, and for this reason injection treatment is the method of choice in young subjects, with the object of postponing the need for operation until middle age. Late second-degree piles have a better chance of responding well to injections when the patient is engaged in some professional or sedentary occupation. Men doing hard manual work are often better treated by operation with a view to permanent cure rather than be subjected to disturbance of their work by repeated attendances for injections, which in the end may prove disappointing.

TECHNIQUE

It is essential to use a sufficiently long proctoscope and inject the phenol in oil into the submucous layer at the upper pole of the internal haemorrhoids. No pain should be caused by the injection, and if a patient complains of pain during or soon after injection it is certain that either the puncture has been too low down or a complicating fissure is present. There is no set routine for distributing the injections, but the constant arrangement of the three primary piles (left lateral, right anterior, right posterior) must be recognized. If one internal pile is more prominent than the others, particularly the right anterior, I find it is best to inject this alone at the first session and deal with the remainder at subsequent sessions. If one pile is seen to be bleeding, this should be chosen for the first injection.

The amount injected is usually 2 or 3 c.cm., and sufficient should be used to produce a smooth rounded swelling in the submucous layer, slightly pale but not white. In the case of a pile with a good deal of mucosal laxity it is often advisable to inject rather more, say 3 c.cm. into the upper end, and a further 2 c.cm. through another puncture slightly lower down.

When a pile is particularly vascular and bleeds freely from its lower pole, an injection of a stronger solution of phenol is valuable: for instance, 6 to 8 minims of 20 per cent. phenol in glycerin and water can be injected into the substance of the pile, using Graeme Anderson's syringe, either at the same time as the submucous injection high up (double-injection method) or at a later session. Subsequent injections are given at weekly intervals, and when a firm submucous induration has been produced in the three primary internal haemorrhoidal areas (as judged by digital examination and by direct touch with a probe through a proctoscope) the treatments should be discontinued. Re-examination is reasonably made after an interval of four to eight weeks, and then if the condition remains satisfactory the patient may be discharged. He should be advised to report at any time in the future if a recurrence of bleeding or prolapse should be noted.

RESULTS

The results of injection treatment, when done efficiently with proper doses at the correct level, depend upon the stage reached by the haemorrhoids at the beginning of treatment. For first-degree piles there is a high percentage of cures; in the second degree the results are less favourable, there being fairly commonly a recurrence of prolapse within three to five years; in the third degree there is at the best some amelioration in prolapse for perhaps three to twelve months, but any sort of permanent cure is unlikely to be achieved. A *single* third-degree pile, particularly when situated in the right anterior quadrant, sometimes does remarkably well, and by a series of repeat injections every year or so I have been able to keep many such patients very comfortable over a course of years.

Statistics in regard to the proportion of cures in the three degrees of haemorrhoids are very difficult to arrive at, and I believe my colleague, Mr. E. T. C. Milligan, has some interesting figures to present in this connexion. To mention some mass statistics, Kilbourne (1934) reviewed more than 25,000 collected cases, and estimated that recurrence took place in at least 15 per cent. within three years: it is not unfair to assume that this 15 per cent. was probably constituted by third-degree piles which were tentatively treated by injection.

To conclude this section I should like to summarize these few important points:

1. Cases for injection must be carefully selected, chiefly with the object of excluding third-degree piles.
2. Cases must be uncomplicated by other ano-rectal conditions.
3. The technique of injection is not easy, and much care must be taken to give adequate doses of the phenol-in-oil solution at the correct level—that is, at the upper pole of the pile and slightly above the level of the ano-rectal ring.
4. Complications are due to errors in technique; pain is due to the injection being placed too low down; chemical necrosis is due to a too superficial injection, overdosage, or injection into sclerosed tissue. Abscess formation is extremely rare, and is due to a combination of the above faults.

Operative Treatment

Operative treatment is the method of choice for the permanent cure of internal piles of the third degree, particularly those of the intero-external variety—that is, a prolapsing pile with a related skin tag in the same quadrant. Operation is indicated also when piles are complicated by a fibrous polyp, a fissure, a fistula, or any other rectal lesion which also requires surgical treatment for cure.

CHOICE OF ANAESTHETIC

In my opinion the ideal anaesthetic is a local infiltration of the external sphincter with 1 per cent. procaine by Hirschman's technique, supplemented by a subcutaneous injection of the solution at the anal margin in relation to the three primary piles. This form of anaesthesia gives perfect relaxation and is very rarely followed by any urinary difficulty; for instance, I have operated on a man aged 86 and a woman of 87 by this method; neither patient had to be catheterized after operation and both made a perfect recovery.

The next best form of anaesthesia is a low spinal injection, which also gives a perfect anaesthesia for the operation, but is followed in 5 to 10 per cent. of cases by a troublesome headache, and retention of urine is more common. General anaesthesia is seldom used, and its avoidance has contributed largely to post-operative comfort, for straining and vomiting have been practically eliminated by the use of local or spinal anaesthesia.

CHOICE OF OPERATION

It would appear that the operation for cure of haemorrhoids has now become more standardized, and I submit that Whitehead's operation, the clamp and cautery method, excision and suture over a clamp, and many others should all be relegated to the past. Even Salmon's ligature operation, which was practised by Salmon, Allingham, and their successors at St. Mark's Hospital for nearly a century, has now been superseded.

In 1919 Ernest Miles described his standard method of haemorrhoidectomy: a V-shaped flap of skin at the anal margin was raised at the base of each primary pile, the base of the V being at the muco-cutaneous junction, and a stout silk ligature was tied round the internal pile and the tissue thus dissected up. The anatomical difference between this operation and Salmon's operation—in which, it may be recalled, the scissor cut is made at the muco-cutaneous junction—remained unexplained until Milligan and Morgan's (1934) classical paper on the "Surgical Anatomy of the Anal Canal," which shows clearly that when this wide incision is made the longitudinal muscle is included in the ligature. This has now formed the most important feature of their later paper (Milligan, Morgan, Jones, and Officer, 1937), and a precise and ideal operative technique is now available. I speak with much enthusiasm regarding this operation, which enables the three primary piles to be removed completely; the ligatures are tied round the pedicles of the piles and are fixed by the inclusion of the longitudinal muscle, so that they cannot slip upwards and expose raw surfaces in the anal canal. The best ligature material is a matter of opinion: I prefer No. 3 chromic catgut on a round-bodied needle, tied by transfixion, with the knot on the lumen. The related portions of the external venous plexus are removed, together with the overlying skin, and post-operative tags are noticeably absent after this operation. Other benefits conferred by this operation are quicker healing, greatly reduced and almost absent risk of post-operative stricture, and total abolition of secondary haemorrhage, due, I presume, to the better fixation of the ligatures.

RESULTS OF OPERATION

When the operation is correctly performed for prolapsing haemorrhoids in a patient of middle age or over a permanent cure can be confidently promised in all cases. If the operation has to be done for young subjects under 30 the outlook is not so consistently good; I agree with Miles that some reserve must be exercised in promising cure in these cases, seeing that the primary piles may not all be fully developed at the time of operation. Apart from this, recurrences after operation are only rarely seen, and are due to faulty technique—that is, inadequate exposure of the piles and ligation of their lower extremities only, or omission to secure all three primary piles.

Conclusion

I should like to take this opportunity of stressing the safety of a haemorrhoid operation when done under modern conditions and the certainty of cure of a distressing and disabling complaint. The common notion among the public that haemorrhoidectomy is a very painful operation is one that should be strenuously opposed. The modern operation under local anaesthesia, with a carefully considered and well-tried after-treatment, is far from being a serious ordeal: the patient is able to walk to a bath on the third post-operative day, and the anal wounds are usually almost healed in two weeks after operation.

Summary

Essential points in the preliminary examination of a case of haemorrhoids are detailed: how to recognize the difference between internal and external haemorrhoids, the three degrees of internal haemorrhoids, and other associated anal conditions.

The treatment of external piles is described.

The three main lines of treatment for internal piles in routine use at St. Mark's are given: palliative, injection, and operative.

The safety of a haemorrhoid operation done under modern conditions, and the certainty of cure, are stressed.

ELECTRICALLY INDUCED CONVULSIONS IN TREATMENT OF MENTAL DISORDERS *

BY

Wm. H. SHEPLEY, M.B., Ch.B., D.P.M.
Senior Assistant Medical Officer, Warlingham Park Hospital

AND

J. S. McGREGOR, M.B., Ch.B.
Assistant Medical Officer, Warlingham Park Hospital

(WITH SPECIAL PLATE)

It has long been observed that any severe shock, traumatic, pathological, or psychological, may occasionally lead to dramatic improvement in certain cases of mental disorder. Within the field of psychiatry the term "shock therapy" may be taken to mean the purposive induction of a sudden and disturbing physical or mental impact with specific remedial intent, to alleviate a disordered state of mind. To-day the term is used with narrower connotation, and denotes the induction of a state of coma by the administration of insulin (Sakel) or the production of epileptiform convulsions by such drugs as cardiazol, triazol, or picrotoxin. Dr. Lazlo von Meduna, in 1934 at Budapest, was the first to practise convulsion therapy, by using a solution of camphor in oil administered intramuscularly. This was soon superseded by the intravenous injection of an aqueous solution of cardiazol, giving more certain and controlled action (von Meduna, 1934). Meduna adopted the latter method of treatment because it had been observed that when epilepsy supervened in some cases of schizophrenia the schizophrenic symptoms cleared up (Muller, 1930). This has since been recorded by other workers (Shepley, 1938). Von Meduna (1937) suggested hypothetically that a biological antagonism exists between schizophrenia and epilepsy, and although the validity of this hypothesis is still disputed it is agreed by most workers that, despite certain disadvantages, the treatment is justified by results.

A new method of inducing convulsions by means of electric current has recently been introduced to this country, and definite advantages are claimed for it. It originated at Rome, being evolved by the Italian workers Cerletti and Bini in an effort to overcome the disadvantages of the drug method. The introduction of the electric method may appear to require some justification, since it necessitates the use of considerable voltage. The disadvantages of the drug methods are well known, and it is only necessary to summarize them here. In our experience the principal drawback is the extreme fear and apprehension engendered in some patients, a fear which is so great as to induce Neustatter and Freeman (1939) to use general anaesthesia in an effort to overcome it. This fear is also a great disadvantage where it is necessary to repeat the injection in order to obtain the major fit. Again, extreme and distressing psychomotor excitement often lasting some hours is met with; also such sequels as vomiting, confusion, and irritability are common in spite of careful preparation of the patient. Transient loss of memory and even gross intellectual impairment have also been reported (Dynes, 1939). Dislocations of the jaw and fractures of spine and femora have occasionally been noted by some observers (Stalker, 1938; McGuinness, 1939), while cardiac complications such as arrhythmias, auricular fibrillation, and heart-block have been recorded (Dick and McAdam, 1938). Difficulties are also encountered from the thrombosis of veins, as well as from their inaccessibility in obese subjects and those whose veins are of poor calibre. To some extent these difficulties can be avoided by the use of triazol, but this carries certain new disadvantages.

Nor is the induction of convulsions by the drug methods devoid of mortality, though this is certainly of low incidence. The report of the Board of Control for the year 1938 gives the number of deaths from cardiazol as ten: no analysis of these figures, however, is given. Without any suggestion of comparison, but merely as an indication that electrically induced methods are reasonably safe, it can be stated that a considerable number of such convulsions have been induced without fatality in patients treated at the Rome clinic. In evolving the new technique Cerletti applied the experience gained in previous research upon the problems of epilepsy undertaken at Genoa. He had produced epileptic fits in animals, chiefly dogs, by means of the normal electric current (125 volts A.C.). This was applied for a fraction of a second, the electrodes being placed in the mouth and the rectum. The technique and the physio-pathological results were published by his pupil Chiauzzi (1934). Together with his assistant Bini, Cerletti continued his researches in Rome. It was Bini who constructed the simple but practical instrument used to regulate the voltage and the duration of the passage of the current. This when perfected was patented in Italy by Bini, and was described by him as an "apparatus for electric applications." In the clinic at Rome where Cerletti carried out his observations the histological examination of the cerebral cortices of dogs was made after the application of much higher voltages than necessary to induce a fit and following the induction of multiple fits. These examina-

---

* Received for publication December 1, 1939

tions showed an absence of such neuro-pathological changes as had been found following insulin coma and in a lesser degree following cardiazol convulsions (Accornero, 1937), which included the presence of haemorrhages, disappearance of Nissl's granules, and other cell changes of a more chronic nature, such as alterations of the cytoplasm, glial alterations, and dilatation of vessels with changes of endothelium. These changes were observed throughout the cortex in two groups of dogs, the first having been killed by insulin administration and the second by other means following thirty insulin comas.

Technical Aspects, including Description of Apparatus

The apparatus is essentially a modification of the Bini patent designed and built for us by a British firm, the "Solus" Electrical Co. Ltd. (Plate, Fig. 1). It consists of two independent electrical circuits. The first is a low-voltage D.C. circuit suitable for direct measurement of the patient's head resistance. The second is capable of applying to the electrodes an A.C. voltage which can be varied by means of a tapped auto-transformer between 50 and 150 volts. It is able to deliver 2,000 mA, and the time of the shock is automatically limited by means of an electrical time switch adjustable between 0.1 and 0.5 second. The apparatus is housed in a light portable switch-table.

The Electrodes.—These consist of four silver-plated straps mounted on a rubber cushion and fixed to a chrome metal frame. The whole is mounted on an adjustable clamp connected to the apparatus by a two-core lead (Fig. 2).

Application of the Electrodes.—The electrodes are covered with a piece of thin linen soaked in 20 per cent. salt solution. Over the head at the junction of the temporal and parietal bones contact paste (the formula for which is here given) is smeared and the electrodes are firmly applied to the patient's head. Care must be taken that they are in close apposition, or the measuring of the head resistance will be unreliable.

Formula for Contact Paste

Solution No. 1.—Dissolve 50 grammes of gum tragacanth and 60 grammes of glycerin in 1 litre of tap water by heating on a water bath for two hours, stirring continuously.

Solution No. 2.—A saturated solution of common salt in water, 1 litre.

Solution No. 3.—100 grammes of distilled water (hot) and 20 grammes of potassium bitartrate (hot).

Add solution No. 3 to No. 2 and mix with No. 1; then add 3 grammes of pure carbolic acid. Cool and add 500 grammes of powdered pumice-stone, and mix. Should the mixture be too fluid more tragacanth may be added. The advantage of this paste is that it is non-greasy.

Measuring Head Resistance.—The electrodes being connected up, the change-over switch is placed in the position of "Measurement" and the apparatus switched on to the mains. Before measurement the measuring circuit has to be compensated or made independent of incoming mains voltage. This is accomplished by means of a knob marked "Calibration," together with a milliamperemeter, and by inserting a known resistance in the circuit. On switching over from this resistance to the electrodes a potentiometer can be adjusted so as to make the milliamperemeter read on the red line. The patient's resistance can be read directly in ohms on the potentiometer. The apparatus permits of direct measurements of resistances between 0 and 2,000 ohms, and measurements up to 4,000 ohms by adjusting to a green line on the milliamperemeter and multiplying the results by 2.

Shock.—After switching over from "Measurement" to "Shock" the voltage to be applied can be adjusted and pre-read on the voltmeter. The choice of the voltage is based on the previous resistance measurement and on experience. The required shock time is then adjusted on the time switch and the shock will now be applied by means of a press button, which is held down slightly longer than the adjusted time. The electrical time switch terminates the flow of the current after the adjusted time. As a safety measure the time switch is so designed that a breakdown would merely prevent operation. However, as a further safety measure, releasing of the button will instantly break the current, independently of the time switch.

Measurement of Shock Current.—The measurement of the current passing through the head during the shock time is obtained by a ballistic method which permits of direct reading of the milliampere-seconds which have passed through the patient's head during the shock. This reading, together with the setting of the time switch, allows easy calculation of the current in milliamperes, and is therefore useful for obtaining comparative values. This apparatus shows three advantages over the Italian, as follows: (1) the electrical time switch; (2) the ballistic method of measuring the milliampere-seconds; (3) the arrangement for compensation of fluctuation in the mains.

Voltage Determination.—This is largely a matter of experience, and the figures given by the Italian workers appear of little help to us, for in our experience their upper and lower limits of 80 to 115 volts are too low. The lowest voltage with which we obtained a major fit was 90, giving 600 mA through the head. Measurement of the head resistance affords some indication of the voltage to be applied, but it bears little relation to the actual resistance on the "shock" circuit. The voltage used by us varies between 90 and 145, with a time setting of 0.1 to 0.2 of a second.

Results of Passage of Current

These may be described as the major fit and the abortive fit, but in both the immediate effect is loss of consciousness.

The Major Fit.—This is a typical epileptic fit. Consciousness is lost immediately the shock button is pressed, and the fit occurs at once or after an interval varying up to one minute. There may be a cry, but so far we have not observed a cough such as is commonly noted after an injection of cardiazol. The mouth opens and a gag can be inserted. The body is seized in intense generalized tonic contraction, which lasts on an average ten seconds. In this stage the face becomes flushed and there may be dilatation of the vessels of the skin of the upper part of the chest. This is followed by the clonic stage, during which the face may become cyanosed and there may be frothing at the mouth. In one case only have we observed complete arrest of respiration, which was readily overcome by pressure on the chest. In this stage there may be voidance of urine and evacuation of faeces. The pupils during the fit are widely dilated and fixed and the conjunctivae may be injected. At the end of the fit the deep and superficial reflexes are usually absent, but within a minute or two the tendon jerks are found to be very brisk or even exaggerated and knee and ankle clonus have been elicited in some cases. The systolic blood pressure often shows a fall of 10 mm. Hg immediately after the fit, and the pulse is found to be slower. These effects have passed off in about five minutes. The average duration of the fit is fifty seconds, and the patient is restored to consciousness and able to talk somewhat drowsily within a few minutes. Until consciousness has returned some patients are slightly restless, but we have not observed any psychomotor excitement such as is so commonly met with after cardiazol.

The Abortive Fit.—Here again consciousness is suddenly lost for a few seconds. In most cases there is an initial generalized myotonic flexion of the body which is often strong enough to cause the patient to assume a sitting posture for a moment. The face becomes flushed, the pulse rate is accelerated, and the blood pressure shows an increase of about 10 mm. Hg. Respiration may be shallow and the face assumes a dusky hue. The pupils may be dilated and fixed, but most often they react briskly. Although this is what is most commonly seen during an abortive attack the effect may be so slight as to cause only loss of consciousness and flushing of the face. The electrodes may be reapplied within two minutes and another attempt made to produce the major result. No objection is raised to this by the patient, and there appears to be no contraindication.

In both of these types of attack there is a retrograde amnesia for a period of about two minutes before the passage of the current. Fifty major fits have been induced without untoward occurrence. The only complaint made by some patients is of slight headache.

Summary and Conclusions

A method of inducing epileptiform convulsions by electricity has been described. The chief advantage of this method over other convulsion therapies is that it ensures instantaneous loss of consciousness, so that there is no fear or apprehension. While in a preliminary report such as this it is not possible to make definite statements regarding therapeutic results, we have every reason to believe that these will compare favourably with those obtained by other methods, and indeed may be better, as the patients do not live in fear and dread of the next treatment day. Another advantage is the absence of recovery symptoms such as psychomotor excitement and vomiting.

We have also applied this method to patients in insulin coma with entire absence of ill effects.

We are indebted to Dr. T. P. Rees, medical superintendent of the Warlingham Park Hospital, for permission to publish this report and for his active interest in the work; also to the "Solus" Electrical Co. Ltd. for their technical advice and co-operation, to Drs. Kalinowsky and Kurt Fried for certain contributions.

TREATMENT OF OTORRHOEA BY ARGYROL DISPLACEMENT

BY

W. OGILVY REID, M.A., B.Sc., M.B., F.R.C.S.Ed.
Deputy Medical Superintendent, Downs Hospital (L.C.C.), Sutton, Surrey

A very large percentage of the cases of chronic otorrhoea which come to this hospital require operation on the mastoid to cure. Conservative treatment is, however, extensively used where operation does not appear to be called for and also in "borderline cases" in which there is just a chance that operation can be avoided. In addition, following mastoid operation, some further treatment to the middle ear is often required to achieve a dry ear. Of the various conservative measures adopted I have been most favourably impressed by argyrol displacement. As a local application argyrol is well recognized by those who treat the discharging ear, but it would appear that the use of it by the displacement method is not so frequently resorted to. This article is written to advocate its wider use.

It is a truism that none of the ear drops in general use can be expected to benefit the condition if they do not get the length of the diseased middle-ear mucosa at least. For this reason thorough toilet of the ear to remove any obstructing discharge or debris is regarded as essential before the instillation of the drops. Even so, the medicament inserted cannot in most cases be expected to reach the furthest recesses of the tympanum and epitympanum, where mucosal disease may lurk. It is in an attempt to achieve this desirable object that resort is made to the displacement method of Proetz. The principle of the latter is that air is evacuated from the middle-ear cleft as completely as possible and the appropriate fluid is then allowed to fill up the vacuum so created. The process is a gradual intermittent one, and the complete "displacement" of the air and replacement by drops is achieved by repeated partial evacuations until something approaching the ideal is achieved—that is, the complete filling of the middle ear and its recesses by the medicament, in this case 10 per cent. argyrol solution. It will be recalled that the same principle is applied in order to fill the middle ear with zinc sulphate solution before the electric current is passed in the treatment of otorrhoea by ionization.

Choice of Cases

Cases definitely requiring operation are, of course, excluded. In cases doubtfully placed in this category the method is worth a trial in the first instance. Otherwise, any case of chronic otorrhoea may receive the treatment. Of those, the cases with a fairly thick muco-purulent or frankly purulent discharge do best, and for the cases at the other end of the scale, as it were, with a purely mucoid discharge, ionization would appear to be preferable and achieves the better result.

Technique of Argyrol Displacement

The ear is cleaned thoroughly. Then, the patient lying with the affected ear uppermost, the latter is filled with 10 per cent. argyrol to the lower level of the tragus. The Siegle speculum is then fitted into the meatus with the bulb compressed. When satisfied that the connexion between speculum and meatus is airtight the bulb is allowed gradually to expand. This manœuvre is repeated three times.

In many cases it will be found that the essential airtight connexion between Siegle and meatus cannot be achieved, and in those resort is made to the alternative method of tragal pressure. A piece of wool on top of the finger is held in front of the tragus and the latter then pressed forwards over the meatus so as to occlude it completely. A little further pressure is now exerted so as to force this temporary "cork" slightly into the meatal opening, after which it is released gradually, when a definite sensation of suction is experienced. This is repeated three times or so. The level of the argyrol in the meatus will now be observed to have lowered appreciably, indicating that the fluid has passed successfully into the middle ear by displacing the air in the latter. The outer ear is finally packed with cotton-wool to absorb surplus argyrol and the patient allowed to stand up. The treatment is repeated daily.

Discouragement should not result from the fact that the discharge may be more in quantity and worse in quality in the early stages of treatment. On the contrary, this is actually an indication that the case in which it occurs is likely to respond well eventually. When one remembers that argyrol acts essentially by promoting a local leucocytosis and so indirectly bringing about control of the infection the sequence of events is more readily understood. In a favourable case these are as follows. About the sixth day of treatment the discharge becomes very much greater and may be more purulent in character. This may continue for as long as a fortnight before the next phase becomes manifest. The discharge now becomes progressively more mucoid, and gradually diminishes in amount until the ear is only moist. The argyrol is then omitted and the ear simply cleaned out daily, dried with spirit, and a little boric powder insufflated.

Results of Treatment

The following is an analysis of the results achieved in a series of 116 cases:

Cases cured	72 (62.07 %)
Cases not improved	37
Cases not completing treatment for various reasons	7
Cases readmitted for treatment	2

Without an adequate control series it is of course unscientific to claim any particular virtue for a method, but one feels it must be agreed that a 62.07 per cent. cure rate justifies the use of argyrol displacement, especially as it is a simple procedure which can quite well be carried out at clinics treating large numbers of cases. As the number of attendances is a factor of importance in the organization of such clinics, it should be emphasized that although the treatment must be repeated daily and no breach of continuity be allowed to occur the total period of treatment need not be a long one. In this series the average number of treatments necessary to achieve a dry ear was only twelve, although quite wide variations were noted, the least number required being three and the greatest thirty-six. Of the thirty-seven failures recorded a few were cured by ionization; but the majority came to operation, and can therefore hardly be regarded as a reflection on the method here described as a non-operative treatment.

The eradication of nasopharyngeal infection is essential in any attack, operative or non-operative, on the discharging ear, and that measure was of course not omitted in the cases in this series. Nevertheless the value of this method as a means of permanent cure of otorrhoea is not established here. But such criticisms may be levelled with equal weight against any other conservative procedure—the arrest of discharge for a reasonable length of time being accepted as the criterion of success.

Conclusion

It might be well to conclude this article by emphasizing the fact that the treatment here advocated can be quite satisfactorily carried out by a nurse trained in the technique, and at the same time I take the opportunity of acknowledging the efficient work of the staff who treated the cases in the above series under my supervision. Thanks are also due to Dr. C. Price, medical superintendent of the hospital, for his helpful interest in the work.

Genoscopolamine.—Genoscopolamine is an aminoxide of the alkaloid scopolamine in the form of the hydrobromide, and was first produced by Polonovski in 1925. According to the authors it is a useful substitute for scopolamine, atropine, or stramonium in the treatment of Parkinsonism. In the twenty-two cases treated it had a beneficial effect, especially upon rigidity, tremor, muscular weakness, salivation, and upon the oculogyric crises. Its toxicity is low, and it is especially effective when used in conjunction with small doses of atropine. —Genoscopolamine: Its Use in Parkinsonism.' J. H. Scharf and S. T. Manong.—*J. nerv. ment. Dis.*, May, 1939, **89**, 682.

ACUTE TORSION OF THE GALL-BLADDER

BY

A. H. BARBER, M.A., M.B., M.R.C.P., F.R.C.S.

Late Lecturer in Anatomy in the University of Birmingham

Torsion or axial rotation of the gall-bladder cannot occur in a normally situated organ. In the vast majority of cases the gall-bladder lies in a shallow fossa on the under surface of the liver, and only its fundus and posterior surface are covered by peritoneum. In its development the gall-bladder is intimately associated with the liver. The liver is formed as a diverticulum from the ventral surface of the foregut. This diverticulum grows forwards into the septum transversum and gives off solid buds which form the right and left lobes of the liver. The original diverticulum from the foregut forms the bile duct, and from this the cystic duct and gall-bladder are developed as an outgrowth or evagination. This outgrowth is normally of such a length that only its distal end (the fundus) comes to lie below the level of the anterior border of the liver. In very exceptional cases, however, it is so elongated that the whole of the ultimate gall-bladder lies below the anterior border of the liver, and the fossa for the gall-bladder is occupied by the lengthened cystic duct. In these circumstances the gall-bladder is completely invested with peritoneum and hangs freely in the abdomen, and unless this very rare anatomical abnormality is present true torsion cannot occur.

In certain cases the peritoneal relations are such that the gall-bladder is attached to the liver by a double fold of peritoneum which forms a mesentery. No doubt this will allow of considerable movement of the gall-bladder, but no complete axial rotation can take place. With regard to torsion, the peritoneal arrangements are of little significance compared with the all-important relation of the gall-bladder and cystic duct to the liver. While abnormalities of the bile ducts have been carefully studied, very few statistics appear to have been published on anomalies of the gall-bladder. Brewer (1899) states that in 100 dissections of the gall-bladder and biliary ducts he found five cases in which the gall-bladder was attached to the liver by only a double fold of peritoneum, but no record is given of any case where the gall-bladder was attached to the liver merely by the pedicle of the cystic duct and vessels. The latter condition must be extremely rare, and torsion in these circumstances becomes such a simple matter that one would infer that it must almost inevitably occur. The mechanism producing it would appear to be the movements of the gastro-intestinal tract. Such a theory appears to offer an explanation of the following case of acute torsion.

Case Report

The patient, a warehouseman aged 46, was admitted to Boundary Park Hospital, Oldham, on Monday, January 23, 1939. On the previous day, just before his dinner at 2 p.m., he was seized with a very severe abdominal pain which was in the right upper abdomen; it "doubled him up" and he felt "as though he had been kicked in the stomach." He had had his breakfast at about 8.30 a.m., and until the onset of the sudden severe pain he had felt perfectly well. He was in fact looking forward to his Sunday dinner, and said he felt he could have eaten two; but through the onset of the pain he was unable to eat anything. The pain continued all day, and at 11 p.m. he vomited. During the night he could not sleep and in the morning vomiting became persistent.

At about 11 a.m. he was seen by his doctor, who sent him to hospital. I saw him immediately after his admission.

He was a well-developed man of spare build; he suffered from chronic bronchitis, but otherwise had had no previous illnesses of any significance. His abdomen was scaphoid and very rigid, with considerable tenderness in the right hypochondrium and epigastrium. No mass was palpable; his temperature was 99°, pulse 112, and respirations 24. A diagnosis of perforated peptic ulcer was made and immediate operation decided upon.

The abdomen was opened through a right upper paramedian incision, and on going through the peritoneum a deep blue-black tensely distended structure literally popped through the wound. It was about the size and shape of an orange, and was seen to be an abnormally situated gall-bladder which had twisted through 360 degrees in a clockwise direction. Its blood supply was cut off and it was becoming gangrenous. The whole of the gall-bladder was completely covered with peritoneum and was suspended from the anterior border of the liver by the cystic duct and vessels. The cystic duct, which was much longer than usual, continued its course superficially embedded in the liver in what is normally the fossa for the gall-bladder. There was a considerable amount of blood-stained fluid in the upper abdomen. The gall-bladder was removed by placing a ligature around the cystic duct and vessels at the level of the anterior edge of the liver. It was an extremely simple operation; no easier cholecystectomy could ever be performed. A small drain was placed in the upper abdomen through a separate stab incision. On examination afterwards the gall-bladder was found to be full of blood-stained bile; there were no stones, and the wall was not thickened except by oedema. Until the torsion had occurred the gall-bladder had apparently been physiologically normal. The patient made a good recovery; his bronchitis troubled him somewhat, but he was discharged on February 28.

Commentary

Several points about this case call for comment. With regard to the diagnosis one had no hesitation in believing it to be a perforation. The persistent vomiting was against this diagnosis, but the extreme rigidity and tenderness appeared to leave no room for doubt. It seemed probable that a small leak had occurred on the previous day and had later recurred on a larger scale. But apart from the precise diagnosis, the clinical picture could not be interpreted as anything but an "acute abdomen" requiring immediate surgical intervention. The fatal mistake of regarding it as a severe case of cholecystitis and biliary colic appears impossible.

The sequence of events in the history seems to provide an explanation of the mechanism of the torsion. It occurred immediately before the patient's Sunday dinner, when waves of peristalsis in the fasting stomach would be at their maximum. These waves passing down the stomach from left to right would tend to rotate the full gall-bladder in a clockwise direction; and once a protective spasm of the recti had been called into play this muscular contraction would tend to keep up the torsion rather than to undo it. Lastly, the treatment of the condition is extremely simple and effective.

Most of the cases hitherto recorded have been in elderly women, and according to Short and Paul there have been only six cases recorded in males. The first account of the condition was published by Wendel in America in 1898. In describing his case Wendel commented on the anomalous length of the cystic duct, which permitted the extreme mobility and migration of the gall-bladder; and in performing cholecystectomy he divided the cystic duct at the anterior border of the liver. In more recent years cases have been reported in this country by Lett (1909), Frankau (1922), and Irwin (1921), while Short and Paul in 1934 added three others and gave a comprehensive account of the subject together with a summary of all previous cases.

Clinical Memoranda

Treatment of Foetal Hydrocephalus

(WITH SPECIAL PLATE)

Foetal hydrocephalus may be a source of considerable difficulty during delivery. The usual methods of treatment are through the vagina—for example, puncture of the skull or tapping the spinal canal: these may be difficult to perform, and since the patient is in labour and the lower uterine segment is already considerably stretched and attenuated, vaginal manipulation may be the factor causing rupture of the uterus. It has been suggested by Walsh that these disadvantages may be overcome by transparietal aspiration of the foetal skull. The following is an account of a case treated by this method.

A primigravida aged 23 was admitted to hospital on February 24, 1939. The head was not fixed, and *x*-ray examination showed foetal hydrocephalus (Plate, Fig. 1). On the same date 14 ounces of cerebrospinal fluid were withdrawn from the skull. Fig. 2 shows the skull after aspiration. Labour began on February 25, and spontaneous delivery took place on the 27th, after thirty-eight hours in labour. The child weighed 5 lb. 8 oz. The patient made a good recovery and was discharged on March 13.

The technique of aspiration is simple. The skin of the abdomen being prepared and the bladder emptied by catheter, the skin is anaesthetized by injection of 1 per cent. novutox in the midline just above the symphysis pubis. The foetal head is fixed with one hand on the abdomen, and a long intramuscular needle attached to a 10-c.cm. syringe is inserted through the anaesthetized area of skin into the skull. Aspiration is repeated till no more cerebrospinal fluid can be withdrawn.

The possible disadvantages of the method are injury to the bladder or puncture of a loop of bowel, which, rarely, may lie in front of the uterus. The advantages are the ease of performance, the absence of shock, and the lessened risks of sepsis and perforation of the uterus.

Assistant Medical Superintendent, Stepping
Hill Hospital, near Stockport.

Fracture-Dislocation of Cervical Spine

(WITH SPECIAL PLATE)

The following unusual case is probably worth being placed on record.

CASE REPORT

In July, 1938, a very miserable Egyptian peasant woman, about 30 years of age, came to this hospital with a two-months history of having fallen from a height of nine or ten feet, with resulting injury to the neck. A diagnosis of fracture-dislocation of the cervical spine was made. No paralysis of limbs or trunk was found, reflexes were normal, and respiration appeared normal also. A lateral radiograph (Plate, Fig. 1) showed a surprising state of affairs: there was a forward dislocation between the atlas and axis to a degree that would seem incompatible with continued existence. The woman was not very intelligent, but careful questioning made it clear that although she was stunned by the fall she never suffered from any noticeable paralysis at any time.

Treatment was begun with gradual traction, which was applied by means of head-harness and a pulley and weights, with the patient lying flat on her back, with no pillow, the head of the bed being raised on blocks so as to obtain counter-traction from the body weight. After two days a small pillow was placed under the shoulders and lower cervical vertebrae to increase the extension of the neck. After eight days the dislocation seemed almost reduced, but no further progress was apparent, and the patient was getting distinctly restive. Accordingly she was anaesthetized carefully and traction was exerted, while the neck was cautiously manipulated and a plaster helmet and collar was applied, extending from vertex to upper thorax, leaving only the face uncovered. The result of this manipulation is shown in Fig. 2 (the bones had to be outlined in this and the next figure as the thickness of the plaster made the films rather indistinct). The reduction was not quite perfect, but was considered to be as good as was possible.

The woman's husband would not leave her in hospital indefinitely, and before long we were obliged to let her go out, after extracting a promise that she would attend the out-patient department at least once a month. She did not, however, visit the hospital again till October, 1938, when the plaster was found to be firm but filthy. She complained of headache, and the ears were ulcerated and oedematous; this latter was due to the plaster having been nibbled away to allow her to hear better. The plaster was removed, and the patient was kept flat on her back till her skin and ears had recovered. She refused to have another "helmet" applied, and so use was made of the following device, which Dr. Kamel Hussein of Cairo looked up for me in a French surgical journal:

A plaster collar was applied from the upper thorax to just below the occiput, leaving also a little freedom for the lower jaw. A metal loop was incorporated in the plaster at its upper end posteriorly; extension of the upper cervical spine was maintained by means of a band going round the forehead and tied firmly to the loop behind. The patient slept on her back at night with a pillow under her shoulders, and the band was loosened to give her a rest from pressure on the forehead.

The patient was unwilling to stay in hospital for more than three weeks, by which time she was educated in the use of the appliance and seemed less discontented than before. The radiograph taken at that stage showed a slight slipping of the reduction, but her refusal to undergo further manipulation forced our hands, and she was allowed to go out in plaster. In this radiograph (Plate, Fig. 3) there appears to be a bony mass extending from the body of the axis to the basi-occiput. The patient did not appear again till January, 1939, when the plaster was found to be in a satisfactory condition. She was requested to come again after a month, but, despite letters and offers of free treatment and travelling expenses, she has refused to come near us, her excuse being that she was quite well and could see no reason for making a long journey. It is a pity that another, and probably very interesting, x-ray film is not available.

A member of our Egyptian staff was travelling near her village in May, 1939, and visited her at my request. He reported that she had removed her plaster and seemed to be quite well. In July, 1939, Dr. Griffiths of this hospital happened to be at her village, and so examined her. He reported that her appearance was normal, that she held up her head well and could nod quite effectively, but that lateral movements, though present, were limited. The neck seemed firm; a bony protuberance could be felt below the occiput, and she had an increased anterior curve of her lower cervical spine (probably compensatory). In fact, a radiograph, if available, would probably closely resemble Fig. 3. Whether or not she is living "on the brink of a precipice" I would not like to say. Anyhow, the end-result would appear to be functionally satisfactory.

CONCLUSION

I am aware that the result in this case is not perfect, but conditions made it very difficult to do any better. Such a fracture-dislocation is not unique, but the extreme degree of displacement, the complete absence of paralysis, and the time elapsing between the injury and proper treatment make the case a distinctly unusual one.

I am indebted to the radiologist for his help and to the principal medical officer, Dr. N. J. Griffiths, for his permission to publish this case.

C.M.S. Hospital, Old Cairo,
Egypt.

Union in a Pathological Fracture due to Metastases from Gastric Carcinoma

(WITH SPECIAL PLATE)

Union in fractured bone which is the site of secondary carcinoma is unusual except in the case of prostatic carcinoma. The following rather incomplete case record seems rare enough to justify publication.

CASE REPORT

The patient was a married woman aged 71. I was first asked to attend her at her home in June, 1938. Her complaint was that she felt weak, had no appetite, and had nausea. She had no vomiting, was anaemic, and had lost weight. Examination revealed a small fixed tumour at the pyloric part of the stomach. There was no enlargement of the liver and there were no palpable glands anywhere. The other abnormality found was auricular fibrillation. I advised my patient to go into hospital for complete investigation, but this she absolutely refused to do. She was a fine old lady, but shy and dour—of the old Scottish school. Having told the patient's relations what I thought of her condition, I did what I could to make her as comfortable as possible, using simple therapeutic measures for the cardiac and gastric disorders.

In November, 1938, she complained of neuralgic pain in her right arm. This did not have any definite nerve distribution, and responded to analgesic drugs. The cardiac condition improved and the gastric condition remained much the same. On December 13, while up and about in the house, she was lifting an empty enamel washing basin with both hands when she was seized with acute pain in her right arm and dropped the basin. The pain was sickening; the power of the arm was lost and unnatural mobility was present. I saw her shortly afterwards and found that she had a fracture of the middle of the right humerus with overlapping of fragments. Having put on temporary splints, I insisted on removing her to hospital. At Kilmarnock Infirmary under morphine and local anaesthesia I put the arm up in a U-shaped plaster splint reinforced around the middle and with the plaster carried up over the tip of the shoulder. The arm was then radiographed. and the plates showed a pathological fracture of the middle of the humerus (Plate, Fig. 1). The radiologist's report was "pathological fracture of humerus due to metastases from a possible carcinoma."

The patient returned home in three days' time with a fore-arm sling. She was comfortable and free from pain in the arm. Thereafter her general condition slowly deteriorated. In January, 1939, a new complaint was neuralgic pain in the right lower jaw. There was no clinical evidence of bone change. In February the only change in her condition was a slight haemoptysis, and some dullness was found at the right lung base. This settled and did not recur; it might have been caused by a small pulmonary infarction, since the cardiac condition was more unsettled.

On April 5, at the Infirmary, I removed the plaster from the arm and managed to get radiographs of it (Fig. 2) and of the lower jaw. The fracture of the arm was firmly united, but I put a light plaster collar round the limb for safety. The jaw showed metastases. The light plaster was removed at home on June 5, and both the patient and I were delighted with the free and confident arm movements. Firm bony union could be felt. By this time there was enlargement of the pyloric tumour, enlargement of liver, ascites, and marked emaciation. The patient was troubled with epigastric pain and could swallow only small quantities of fluid. She required morphine for the pain. She died one week after removal of the light plaster, having had an obstructive type of vomiting with haematemesis and signs of advanced carcinoma of the stomach. She died on June 12, one year after I had first seen her.

COMMENTARY

The clinical picture without the aid of gastric analysis, radiographs, etc., was that of carcinoma of the stomach.

The fracture of the right humerus was pathological and apparently due to metastases from a carcinoma.

The fracture was completely united after four months—confirmed clinically and by radiographs.

IAN B.-K. MACGREGOR, M.B., Ch.B.,
Assistant Surgeon, Kilmarnock Infirmary.

Torsion of an Ectopic Gestation

(WITH SPECIAL PLATE)

The case of ectopic gestation described below presents two unusual features and seems to be of sufficient interest to justify its publication. The majority of ectopic gestations do not cause severe symptoms until some complication has occurred, and a laparotomy is generally performed only when rupture of the tube or abortion has brought on intraperitoneal haemorrhage. In the present instance the symptoms that resulted in the patient's admission to hospital were found at operation to be due to torsion of the tube, which was impacted in the pouch of Douglas. Secondly, pregnancy, whether tubal or uterine, at the age of 52 years is an unexpected condition and one unlikely to be considered in differential diagnosis.

CASE REPORT

A married woman aged 52 was admitted to Redhill County Hospital in April, 1939, with a history of abdominal pain which had started three days previously. The pain was described as "gnawing," and was at first generalized. Later it became more severe on the right side than elsewhere. The onset of the attack was accompanied by vomiting. About one month previously she had been admitted to another hospital on account of a similar attack. She was the mother of six children, the youngest of whom was 13 years old. Questioned after the operation she stated that she had always menstruated regularly and that she had continued to do so without any intermission, except during her pregnancies, until two months before the onset of her present illness, when she had missed a period. One month later she again menstruated "normally."

On examination she was of average build and looked somewhat young for her age. Her temperature was 97.2°, pulse 84, respirations 20. Her tongue was clean. There was marked abdominal rigidity on the right side with localized tenderness over McBurney's point. On vaginal examination she was found to have a cystocele. The uterus was normal in size. There was a fullness palpable in the right fornix and there was tenderness in the same situation. The rectum was full of hard faeces. A diagnosis was made of acute appendicitis with a probable pelvic abscess.

Operation.—I opened the patient's abdomen through a right subumbilical paramedian incision. No free fluid or pus was seen. The appendix appeared normal. A search was then made in the pelvis and revealed a mass tightly impacted in the pouch of Douglas. Some recent adhesions were separated and the mass delivered. It was then found to consist of the right Fallopian tube, which was tightly twisted on itself several times at its isthmus. The tube was distended to the size of a large hen's egg and was of a dark plum colour. Salpingectomy was performed easily and the abdomen was closed without drainage. The patient made an uninterrupted recovery and left hospital in good health.

The appearance of the haematocele at once suggested an ectopic pregnancy, though the age of the patient made this seem rather unlikely. The tube was accordingly sent for section. This shows a quantity of blood clot in the midst of which are a number of typical placental villi (see Plate).

I am indebted to Mr. J. N. Deacon, medical superintendent of Redhill County Hospital, for permission to publish this case.

Surgeon, Redhill County Hospital,
Edgware.

Colles's Fracture and Backward Dislocation of the Elbow

The article by Mr. R. Salisbury Woods in the *Journal* of October 14, 1939 (p. 767), prompts me to write of a somewhat similar interesting case.

CASE REPORT

On April 18, 1939, a man aged 38 was admitted to the Oldham Royal Infirmary with a history of having fallen about sixteen feet from a ladder on to his right hand. Examination revealed a posterior dislocation of the elbow-joint. His wrist was swollen and there was pronounced radial deviation of the hand and wrist. *X*-ray examination showed marked postero-lateral dislocation of the right elbow, the radius and ulna being displaced laterally to the extent of the width of the lateral condyle of the humerus. Radiographs of the wrist-joint revealed a fracture through the "waist" of the carpal scaphoid bone, with considerable separation of the fragments. The ulnar styloid process was detached. The semilunar bone was dislocated towards the flexor surface.

Under a general anaesthetic the dislocated elbow was reduced. Hand traction was made at the wrist for about two minutes and a scaphoid non-padded plaster-of-Paris cast put on. A lead and opium dressing was applied to the elbow, and the arm was rested in a sling, with the elbow-joint extended to just beyond a right-angle because of the gross effusion. Further *x*-ray examination showed reduction of the posterior dislocation of the elbow and good position of the scaphoid fragments, but the dislocated semilunar bone was still unreduced. On the following day the plaster cast was removed. A local anaesthetic was given, novutox 2 per cent. being injected into the wrist, and manual traction was applied to the wrist with counter-traction to the forearm for a full ten minutes. Later radiographs showed that the displaced semilunar bone was reduced. A scaphoid plaster cast was reapplied. Immediate active use of the fingers was begun, and active movements of the elbow-joint were started on the fourth day.

On May 30 there was practically full extension of the elbow, with flexion limited to 60 degrees. On June 21 full flexion and extension were present. Subsequent *x*-ray films showed that the scaphoid bone was uniting, and on September 6 further radiographs disclosed good union of this bone, with slight limitation of movement at the wrist-joint. The patient was discharged from hospital on September 13—five months after the accident—with full function of the elbow- and wrist-joints.

I wish to thank Mr. H. Poston, honorary orthopaedic surgeon, for his supervision of the treatment and for permission to publish this case.

MICHAEL LENTIN, M.B.,
Senior House-surgeon, Oldham
Royal Infirmary.

Reviews

A TEXTBOOK OF PATHOLOGY

Pathology. An Introduction to Medicine and Surgery. By J. Henry Dible, M.B., F.R.C.P., and Thomas B. Davie, B.A.(Cape), M.D., M.R.C.P. (Pp. 932; 374 illustrations, including 8 plates in colour. 36s.) London: J. and A. Churchill Ltd. 1939.

There are few full-length textbooks of pathology by British authors, and the appearance of a new one is therefore in any case an important event. If its merits as the student's principal guide in this subject make a wide appeal it is something which does not happen more than two or three times in a generation, and the new work by Dible and Davie certainly will appeal. The purpose of studying pathology has never been better expressed than in their preface, and the authors' aim of enabling the student to envisage the processes underlying the clinical manifestations of disease has been admirably followed out. A novel and commendable feature is the interpolation between the sections on general and regional pathology of another entitled "Special Infections," in which infective disease is classified aetiologically. Chapters on diphtheria and anthrax, as contrasted types of bacterial infection, are followed by ten others, among the subjects of which tuberculosis, virus diseases, and infections by the pyogenic cocci are obvious choices in view of their characteristic nature and the variety of tissues which they may involve. Others have not so clear a claim to description here, and the section might well have included a chapter on the special features of infection by protozoa. Both here and elsewhere in the book the characters of the micro-organisms concerned are fully described, as are the mechanisms by which the body resists infection: indeed, for most purposes, except that of technique, this work will, incidentally, almost serve as a textbook of bacteriology.

Just as there is much to commend, there is not a little to criticize. Among matters of fact are a diagram of the renal arterial system (Fig. 27) which is anatomically incorrect, and the devastating suggestion that chronic phthisis predisposes to squamous-celled cancer of the lung. The whole subject of lung cancer is dealt with in only nineteen lines. There is much that is highly unorthodox, if not positively untrue, in the chapters on arterial disease: atheroma is not usually believed to occasion cardiac hypertrophy, as is deliberately asserted on page 566, nor, as stated on the following page, is it "the common cause of senile gangrene of the extremities"; this is a consequence to be ascribed more exclusively to Mönckeberg's sclerosis, which is described later. The doctrine that atheroma can result from raised blood pressure is also highly disputable, and its repetition by an examinee might well be detrimental to him. In describing tumours of bone the authors appear to accept the term "osteogenic" as correctly describing growths in which bone is formed, whereas it should be restricted to those of osteoblastic origin. In contrast to the usual clearness of the teaching is the highly abstruse argument which opens the chapter on diseases of the reticulo-endothelial system; the authors' natural desire to define their own opinion on a debatable subject has here made that subject too difficult for the ordinary reader. The book is easily readable, but picturesque language is rather forced in some places, and misspelt words are unduly frequent: "pacchymeningitis" occurs repeatedly, as does "empyrical," which has evidently exchanged a letter with "saprophite."

To set against these faults there are many chapters of outstanding merit, among which those on diseases of the alimentary tract, on tuberculosis, and on the causation of tumours are particularly successful. The historical data introduced into the text often add greatly to its interest. Illustration is lavish; a few drawings are over-emphatic of essential features (for example, Fig. 215), but the photographs used reach a very high standard of excellence. The book is assured of a wide popularity.

FRACTURES AND RELATED INJURIES

Fractures and Other Bone and Joint Injuries. By R. Watson-Jones, B.Sc., M.Ch.Orth., F.R.C.S. (Pp. 724; 1,040 photographs, x-rays, and diagrams, many in colour. 50s. net, postage 1s.) Edinburgh: E. and S. Livingstone. 1940.

This magnificent volume covers the whole field of fractures and related injuries. It is based upon a series of over 47,000 cases, and as these have been followed up at frequent intervals for long periods the methods and results described may be accepted with confidence. Moreover, every statement which is made is backed by superb radiographs and illustrated by outline drawings which leave no possible doubt of the author's meaning.

The volume opens with a general description of the principles of fracture treatment, including chapters on the mechanism of repair, the causes and treatment of delayed union, of joint stiffness, and of other complications. Perhaps the most interesting and original chapter in this section is that on avascular bone necrosis, which will, we venture to think, reveal to many surgeons the cause of ultimate failure in what had at first appeared to be entirely successful operations. There follow chapters on radiographic diagnosis, on the general principles of reduction and immobilization, and on the treatment of open and infected fractures. A short but interesting section follows on pathological and birth fractures in various regions of the body.

Fractures of the spine are described with the care demanded by their frequency and by the great changes which have taken place in recent years in their treatment, while the description of cord injuries, though brief, is adequate for the present purpose. It is, however, to injuries of the limbs that one naturally turns with the greatest interest, and here the vast experience of the author is revealed on every page. Every possible injury involving the bones or joints is described in the utmost detail and its treatment is discussed with a clearness of outlook which is quite remarkable. The author has avoided the error of describing innumerable methods and has confined himself to those which he has found useful and which are standardized in regular practice.

Where every detail has been studied with such care it is difficult to choose any subject for special reference, but the chapter on injuries of the hip stands out as a masterpiece. When it is remembered that at least fifty different methods have been described for the insertion of a Smith-Petersen pin one is grateful to the author for limiting his description to a simple and accurate technique which should satisfy the most exacting surgeon. Moreover, the difficulties that may arise and the traps into which the surgeon may fall are fully discussed, and no room can be left for doubt that the methods described are sound.

Mr. Watson-Jones has succeeded in producing a volume worthy of the Liverpool School and of his great predecessors there. In soundness of judgment and sanity of outlook it could not be surpassed. The absorbing interest of the book is increased by the beauty of the illustrations, and it is assured of a very warm reception. It could not have appeared at a more opportune moment.

MANIPULATIVE THERAPY

Treatment by Manipulation. By H. Jackson Burrows, M.D., F.R.C.S., and W. D. Coltart, M.B., F.R.C.S. (Pp. 36; 30 figures. 5s. net.) London: Published by the *Practitioner;* in conjunction with Eyre and Spottiswoode. 1939.

Manipulative surgery—the authors criticize the term as tautological—has produced a spate of literature in recent years. The surgical profession can certainly no longer be accused of having neglected its study, although the number of unqualified practitioners who indulge in it is still large. The public still believe that these unqualified manipulators have some special methods or some personal touch which are more important than the knowledge of surgery and pathology, and it is not unusual for a patient to greet an orthopaedic surgeon with the statement, "I don't know whether I was right in coming to you; perhaps I should have gone to an osteopath (or a bone-setter or chiropractor)."

This little book deals simply and solely with the routine methods of manipulation used by the authors. It is based upon a series of over 800 manipulations carried out at St. Bartholomew's Hospital, so that, although others will be sure to criticize and claim that they have other and better methods, at least we have here a substantial experience. Indeed, methods should be individual; a grip or a method of applying force need not necessarily be stereotyped; a method which comes naturally to one may be awkward to another. But the descriptions and the illustrations give an excellent basic guide. The short section on general considerations is an admirable example of brevity and lucidity in which every word and phrase counts. Special points may be mentioned—for example, the advisability of re-examination immediately before anaesthesia so that the surgeon reminds himself of the range of movement and of the painful movement, the presence of a small organic basis in hysterical cases, and the necessity for mobilizing and strengthening exercises after manipulation, in contradistinction to massage and electrical treatment carried out by the masseur. Finally the dangers of and failures in manipulation are summed up in less than two pages. This book does not pretend to do a great deal, but what it includes it does well.

TUBERCULOSIS AND PUBLIC HEALTH

Tuberculosis and National Health. By H. Hyslop Thomson, M.D., D.P.H. (Pp. 244. 10s. 6d. net.) London: Methuen and Co. 1939.

Dr. Thomson states in his preface that during the last twenty years there has emerged a considerable volume of literature on tuberculosis; he has endeavoured to clarify his own views on the subject in the light of present-day knowledge, and trusts that the study may be of some service to those who, in clinical practice or investigation, are closely associated with the disease, and to others who take an interest in the national aspect of the problem. Dr. Thomson is a well-known county medical officer of health who some years back had first-hand experience of the management of tuberculosis. His study is based on a bibliography of 248 references, of which 220 are to English, twenty to American, and one to French periodicals and books; the remaining seven references to Continental work have been studied in abstracts appearing in English journals.

The sections on the incidence and significance of tuberculosis and its relations to nutrition, housing, and the milk supply are up to date, and contain much information with which every tuberculosis worker should be familiar. On the other hand, the discussions on pathological and clinical aspects of the disease contain not only clear and sound deductions but also statements that are vague, misleading, or even inaccurate. We may instance the definitions of "types of tuberculosis" and of allergy, the paragraph on chronic miliary tuberculosis, the list of "stigmata the presence of which should suggest the possibility of a primary tuberculous infection," and this sentence: "In the adult, more especially the young adult, the primary pulmonary focus is generally known as Assmann's focus." Few will agree that a reasonable estimate of the percentage of positive tuberculin reactors among adults in this country as a whole is probably 50 for urban districts and 20 for rural districts, "judging from figures available"—no such figures for the general population are in fact available in this country. And a claim the importance of which cannot be exaggerated—that there is increasing evidence that tubercle bacilli introduced via the gastrointestinal tract produce a pulmonary primary infection in man—should not have been brought forward without stating the evidence; any evidence to this effect has, in the reviewer's belief, long been discredited.

On the other hand, praise must be given to the author's discussion of "open" and "closed" phthisis, his insistence on team work in the management of extrapulmonary tuberculosis, and such a statement as "when one is closely and continuously concerned with the clinical aspects of tuberculosis it is liable to be regarded as a morbid entity requiring special attention in relation to diagnosis and treatment, while the importance of viewing it as an index of the health standard and social conditions of the community is less likely to receive the attention it merits."

To summarize, therefore, the book gives an uncritical review of a narrow cross-section of recent work on tuberculosis, and an uninspiring account of its treatment and prevention. But it contains an excellent survey of the relations of the disease to public health in general, and therefore fulfils adequately the function, as regards this country, implied in the title of the book.

ANALYTICAL PSYCHOTHERAPY

Technique of Analytical Psychotherapy. By Wilhelm Stekel. (Pp. 408. 21s. net.) Translated by Eden and Cedar Paul. London: John Lane. 1939.

That psycho-analysis has proved its usefulness as a method of research into the mechanisms of the mind a large number, if not the majority, of the medical profession will nowadays agree, but its position as a method of practical therapy is less secure. The daily hour's treatment for two to five years can only be for the few, and all but the strictly orthodox school have sought for methods of shortening this course. One of the first of these apostates from full discipline was Dr. Stekel, who in this volume summarizes his method and experience of it. He is not guiltless of hurling abuse and ridicule at those who disagree with him, but that has been observed in other branches of the medical art. This book, as its title indicates, is a description of the course of an analysis by the author's active method, which consists in the intervention of the analyst at certain points when his "intuition" shows him that he may usefully cut short the analysand's interminable associations and restore him to the straight path which leads to recovery. This intuitive intervention is of course a source of ridicule to the orthodox non-interventionists, and it is easy to see that it may be a method of considerable danger in inexperienced hands; but the reader is likely to be impressed, and to believe that this method, used by a physician of the ability and experience of Stekel, is a real advance.

The author lays great stress on the unconscious fight waged by the patient to preserve his illness, and all who are experienced in psychotherapy will recognize the truth of this observation. Stekel admits that the patient often wins, and indeed only succumbs as a result of his love (transference) for the physician. An interesting chapter is that entitled "Diseases of the Conscience," in which it is pointed out that the blow to the patient's conscience involved in the gratification of instinctive urges may be in some cases a worse trauma than the repression of these urges.

This book, which is excellently translated, so that it is really pleasant to read, should be studied by all psychotherapists—not that they will all be wise in following the intuitive method, but because they will profit by the intelligent and restrained treatment of the subject.

Notes on Books

The work on heat stroke by Dr. L. Dérobert, which will appeal mainly to the physiologist and to a lesser degree to the pathologist and clinician, represents an experimental study undertaken by him at the Institute for the Study and Prevention of Occupational Diseases in Paris with the object of determining the pathogenesis of the disorders included under the name of heat stroke. Among the subjects treated in the book are thermogenesis in the muscles, brain, viscera, skin, skeleton, blood, and lymph, the general action of heat on the cell and the organism, the regulation of heat at rest and in activity, thermolysis as the result of chemical and physical mechanisms, the former consisting in a diminution in the excretion of CO_2 and the latter in evaporation of water by the skin and lungs. The disorders in the regulation of temperature are considered under the headings of artificial hyperthermia of cerebral, peripheral, or mixed origin, fever, heat stroke and the accessory syndromes of heat stroke, sunstroke, experimental heat stroke in dogs and rabbits, the naked-eye and microscopical lesion found in this condition, and the biological changes in heat stroke. An extensive international bibliography, in which Anglo-Saxon literature is well represented, is appended. *Les Troubles de la Thermorégulation (Coup de Chaleur)* is published by Masson et Cie, Paris, price 60 francs.

As the third edition of Dr. A. Piney's *Recent Advances in Haematology* appeared in 1931, and as the subject has in the interval undergone many changes, the fourth edition (Messrs. J. and A. Churchill; 15s.) is, as the author points out, practically a new book. It contains rather fewer pages, whereas the number of illustrations, including the coloured plates, has been doubled, those of the bone marrow deserving special attention. The author's conviction is that "the future of haematology would seem to lie in the hands of the laboratory workers, but there is still ground unbroken by the old-fashioned but trusty tools of the clinician."

The recently published *Proceedings of the Seventh Session of the International Office of Military Medicine and Pharmacy*, held at Bucarest in June, 1937, contains twelve articles contributed by medical officers of eight different nations (France, Turkey, Sweden, Rumania, Switzerland, the United States, Czecho-Slovakia, and Yugoslavia). The French text of each article is followed by a summary in English. The subjects discussed are recent improvements in French barracks, treatment of wounds, organization of the medical services in France and Sweden, the creation of hospital zones in war, the utilization of civil hospitals and V.A.D. by the Swiss A.M.S., the danger of typhus, the interrelationship of medicine, surgery, and dietetics in civil and military practice, psychology in the army, the dosage of drugs, anti-tuberculosis organization in the Yugoslav army, and appliances for the transport of the wounded in the French navy. The volume is published by the Office International de Documentation de Médecine Militaire, Liége, Belgium.

Thirty-two years ago a young French paediatrician wrote a summary of his special subject promising a future skill which has been amply fulfilled. Now, after a gap of thirteen years, during which numerous treatises and contributions to the medical press have freely appeared, Professor P. Nobécourt has found time to prepare a sixth edition of his *Précis de Médecine des Enfants* (Paris, Masson; 150 fr.). This volume, with over 600 illustrations, covers the field in an admirable manner. The author's well-known success as a lecturer has given him a facility for selection which is essential in a summary, and his graphic style gets over the common fault of many a synopsis, for the book is eminently readable. Since the fifth edition, which appeared in 1926, there have been many advances in paediatrics which are ably reflected in this new and completely revised version. Deficiency diseases, disorders of the blood, and virus disorders of the nervous system account for most of the new chapters, but, in addition, careful search shows that advances and discoveries in many other directions have been incorporated in existing sections. Those who have attended Professor Nobécourt's attractive clinical demonstrations will be grateful for this epitome of his views, and it is regretted that while praise can be freely given for every other aspect of this book it must be criticized in conclusion for the all too common fault among French medical publications—the absence of an index. For a book of over 1,300 pages this is an unpardonable blemish.

An Outline of Medical Psychology, by Dr. E. Fretson Skinner, is published by H. K. Lewis at 6s. The author sets out in this small volume to reduce the subject to its simplest terms for the benefit of the medical student. The first part is intended to introduce the student to the idea of psychology via his biological and physiological studies in very simple terms—perhaps unnecessarily simple, for most medical students could digest something a little more complex and therefore ultimately more helpful and illuminating. This initial physiological approach is suddenly abandoned never to be taken up again, for the second part is a very elementary and uninspired narrative of the Freudian doctrines of psychopathology. The third part is clinical, ending with general directions of no great clarity for treatment and the case histories of a few patients whose treatment is by no means fully carried out. This book is not likely to be very helpful to the student, but that may not be entirely the fault of the author, for the successful training of the psychotherapist will only be attained by his own often bitter experience with his patients, though this may, as the author says, be greatly helped by a personal analysis.

In the book entitled *Medical Treatment in General Practice*, which is based on the experience of ten years' teaching, Dr. D. R. Dhar, who holds several medical appointments in Calcutta, has provided a useful and up-to-date work of reference which will doubtless find a large circle of readers among practitioners and students in India. Special care has been taken to include Indian preparations in description of the diets which, according to Colonel R. N. Chopra in his foreword, are not mentioned in European or American textbooks. The value of the book has been increased by the treatment being preceded by a short account of the diagnosis and symptomatology of each disease. We have found an unusually large number of misprints in addition to those noted in the errata, especially in the names of authors and journals quoted in the footnotes, and in the prescriptions, the elements of which in many instances show a regrettable mixture of English and Latin. These, however, are comparatively trivial faults which should not detract from the general usefulness of the work. The book is published by D.M. Library, Calcutta, price 22s. 6d.

The Psychological Aspect of Delinquency (Baillière, Tindall and Cox; 2s. 6d.) is a series of six lectures given to the Bath and Bristol Mental Health Society under the chairmanship of Dr. ELIZABETH CASSON, who contributes a foreword. The only lecture worthy of note is that by Dr. J. R. Rees, which is directed to magistrates. He stresses the importance of diagnosis in all cases as a preliminary to treatment, though this treatment may take the form of punishment in or out of prison. The anti-social rebel may theoretically require psychotherapy, but may fail to benefit by it owing to his non-cooperation. The bizarre crime and that out of keeping with the character of the individual is almost always psychoneurotic in character and amenable to treatment. Dr. Rees urges the magistrate to hate the delinquent's anti-social act but not the delinquent himself.

Preparations and Appliances

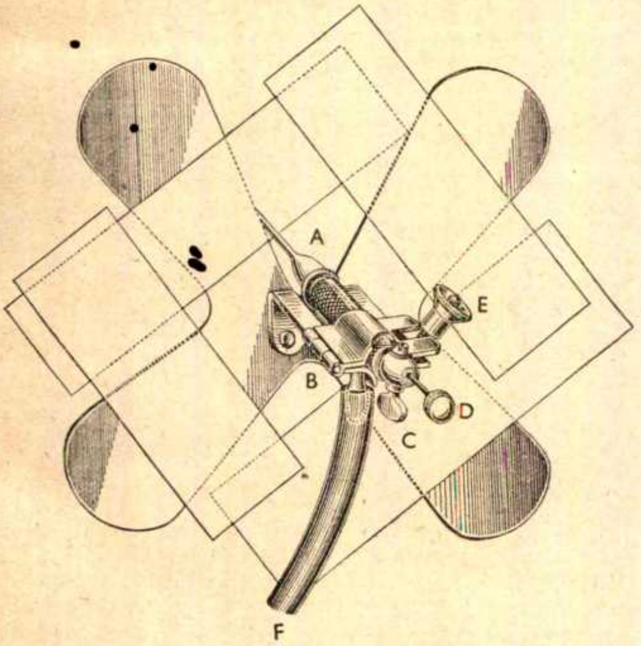
NEEDLE AND HOLDER FOR ARTIFICIAL PNEUMOTHORAX

Dr. DAVID A. HERD (Killingbeck Sanatorium, Leeds) writes:

In 1936 I devised a pneumothorax needle holder primarily for use in cases of spontaneous pneumothorax; it was also useful in cases of empyema. The benefits of that device were limited owing to the type of needles then employed, and to obviate their defects I have designed a different type of artificial pneumothorax needle and holder.

The holder consists of four pliable aluminium flanges which can be shaped and strapped to the chest wall with adhesive plaster. A grooved portion projects at right angles from the centre of these flanges and is provided with a hinged flap, B, and locking nut, E.

The needle differs from other types in having a long cylindrical barrel and lateral opening placed at right angles to the shaft, so that when placed in the groove its length can be adjusted in accordance with the thickness of the chest wall. Needles (A) of standard pattern can be fitted to this type of barrel. This needle can be used as an ordinary artificial pneumothorax needle or in conjunction with my holder. Tap C enables stylet D to be inserted and thus clear a blocked needle without disturbing the needle or patient.

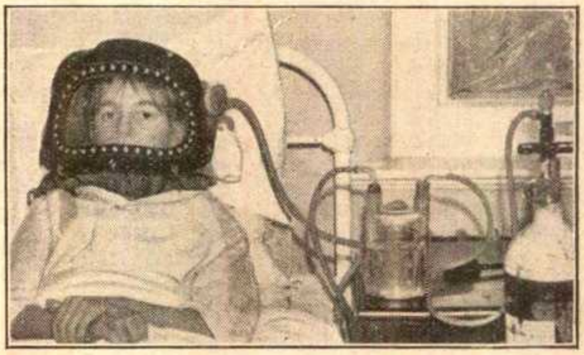


These instruments have been successfully used at the above sanatorium, and were made for me by Messrs. Charles F. Thackray, Ltd., Park Street, Leeds.

A SIMPLE OXYGEN TENT

Dr. W. HARTSTON, medical superintendent, Brumby Isolation Hospital, Scunthorpe, writes:

A simple and effective oxygen tent can be obtained at slight cost and with negligible trouble by conversion from a Government gas protective helmet. The tail piece and wire legs at the back of this helmet come away after removing the two retaining screws. The bellows and wide tubing above it are removed at the shoulder by unscrewing the metal band which fixes them to the port of air entry. Over this port is now stretched a square of rubber containing a metal nozzle—the nozzle of a car or bicycle inner tube with its surrounding rubber does admirably—and held in place by screwing on the metal band previously removed. The skirt of the bag is tucked round the patient inside his shirt or pyjamas. The apparatus is now ready for use, and can be connected to a Wolff's bottle or a flowmeter and ice chamber and the oxygen cylinder in the ordinary way. The improvised oxygen tent can be reconverted to its original purpose as a gas helmet in the same two minutes that it takes to prepare the more frequently required oxygen tent. The photograph is by A. H. Sanders, Scunthorpe.



VITAMIN E IN CAPSULES

Phytoferol capsules are a preparation of vitamin E (British Drug Houses Ltd.). Each capsule contains a quantity of a concentrate of vitamin E that is biologically equivalent to 3 mg. of *dl*-α-tocopherol. This latter substance was synthesized last year and forms a convenient standard for concentrates which contain the natural vitamin.

Messrs. B.D.H. have prepared a booklet in which they summarize the experimental and clinical evidence regarding the action of vitamin E. During the last few years several papers have recorded striking successes in the prevention of abortion by administration of vitamin E, and there is evidence that this may also check incipient toxaemia of pregnancy. Finally, the action of the vitamin on male impotence and undescended testicles is being investigated by American authors.

VITAMIN K THERAPY

Kapilon (Glaxo Laboratories Ltd.) is a preparation of a synthetic substance (2-methyl-1:4-naphthoquinone) which has an action similar to that of vitamin K. The latter is the chicken anti-haemorrhagic factor, the separate identity of which was only established a few years ago. Last year it was found that a simple naphthoquinone derivative produced the action of the vitamin, and the natural form is now believed to be a naphthoquinone derivative. The vitamin is fat-soluble, an important source being hog's liver fat. It is concerned with blood coagulation, and its chief measurable action is to reduce the bleeding time in cases of prothrombin deficiency. The use of this vitamin in obstructive jaundice was suggested in 1935. A paper by Macfie, Bacharach, and Chance (1939) describing its actions has recently appeared in this *Journal*.[1] The authors found that the intramuscular injection of the synthetic product was of striking value in the prevention and treatment of haemorrhage in jaundice.

Nova et Vetera

Dr. WILLIAM BEAUMONT

Life and Letters of Dr. William Beaumont originally appeared in 1912 on the occasion of the centenary of Beaumont's entry into the practice of medicine, for on June 9, 1812, he was granted a licence to practise physic and surgery by the Third Medical Society of the State of Vermont, as by law established. Sir William Osler twenty-seven years ago welcomed this full account of the pioneer-physiologist of the United States. This introduction has wisely been reproduced in the new edition,[1] and is now accompanied by a present-day appreciation of Beaumont's experimental work from Professor Andrew Conway Ivy, and goes on to record that at the meeting of the International Congress of Physiologists in Boston in 1929 each guest was presented with a medallion bearing the likeness of Beaumont and a facsimile of the original edition of his book. Then "William Beaumont, the frontier physician and physiologist, on this occasion, was figuratively canonized as the patron saint of American physiology." Another addition to the book in its new form is a double-page coloured plate showing Beaumont in military costume collecting gastric juice from the gastric fistula of Alexis St. Martin. This is reproduced from the painting in oil by Dean Cornwall, A.N.A., 1928, in the possession of Messrs. John Wyeth and Brother of Philadelphia. The text of the *Life and Letters* remains as in the original, and, as Professor Ivy remarks, "One truly does not know gastric physiology and pathology as one should until Beaumont has been read critically and *in toto*."

PIONEER ABDOMINAL SURGEONS

Annual orations and introductory addresses usually come under the heading of ephemeral literature, for they have served their purpose when once they have been delivered. The Bolingbroke Lecture given by Mr. Zachary Cope before the South-West London Medical Society in May, 1938, is an exception to the rule. It now appears in an extended form under the title *Pioneers in Acute Abdominal Surgery*.[2] The acute conditions are volvulus, intussusception, strangulation by a band, peritonitis associated with perforation of the stomach or bowel, and obstruction of the large intestine caused by stricture. The operative treatment of these conditions lies within the memory of those still living, though a few were undertaken in pre-anaesthetic days. The pioneers were driven to operate in sheer desperation when every other means of relief had failed. It is difficult to decide whether in the beginning the courage of the surgeon or the heroism of the patient is the more to be admired, but Mr. Cope shows how much both the surgeon and the patient have to be thankful for owing to modern advances. He tells, for instance, of the French wine merchant in 1776 who, with a stricture of the large intestine, was advised, laxatives having failed, to swallow two pounds of quicksilver in the hope that the weight of the metal might overcome the obstruction. A month later Pillore of Rouen made the first recorded artificial anus and the patient survived for twenty-eight days. The mercury was found at the necropsy lying unchanged in the last convolution of the jejunum. But this was nothing to the treatment which a patient might have to undergo before an operation was thought to be imperative. There was a stout-hearted lady of 64 in the year 1820 to whom—

> "All the medical resources of art were exhausted in fruitless attempts to procure evacuations. Salts, senna, aloes, colocynth, jalap, scammony, gamboge, elaterium, calomel were given in their largest doses and variously combined: castor oil was also administered in doses of three ounces; and as vomiting was by no means frequent these medicines were commonly retained. Injections of every sort and by different means were also administered. It was attempted to pass a flexible catheter beyond the obstruction through which clysters might be thrown into the bowel above the seat of it. She was once bled without any relief to her symptoms, and when all other means had failed some large doses of laudanum were given on the supposed possibility of the existence of spasm. Finally the surgeon made an opening into the colon in the left iliac region, and after a stormy convalescence the patient recovered. The surgeon when reporting the case adds complacently the operation has afforded her a moral as well as a physical advantage. She is now at no loss for an interest, and is provided with something to think of for the rest of her life."

This extract shows that Mr. Cope has provided a readable as well as a useful little book. He has gone to original sources for his information and has been at great pains to find portraits of the pioneers, from J. L. Petit in the eighteenth and F. T. Paul of Liverpool in the twentieth century. The portraits are well reproduced by the publishers. The sources of information are indicated and it is thus easy to trace the beginning of any of the operations mentioned. There is an index of names and another of subjects.

THE NATIONAL HEART HOSPITAL

A Multifarious Founder

The early history of the National Hospital for Diseases of the Heart, which was founded in 1857, the year of the Indian Mutiny, shared the disturbed atmosphere of its birth. As Captain Robert Whitney says in his pamphlet "The Place of Hearts" (obtainable from the hospital, Westmoreland Street, W.1, price 2s.), the pious founders of long-established hospitals are not likely to be embarrassed by records of their past, but the story of the adventurer, Dr. Eldridge Spratt, who combined in his own person the offices of founder, medical staff, treasurer, chairman, and secretary, was far otherwise. This Gilbertian arrangement worked with perfect harmony and admirable speed so long as decisions alone were needed for ordering equipment, drugs, and food; but it appeared in another light when demands for payment reaching Dr. Eldridge Spratt, the physician, were passed on to Mr. Eldridge Spratt, the secretary, for settlement. A committee was set up by the founder and the times became stormy, resignations were frequent, and on occasions the founder only was present at the meetings; he had many schemes for raising money, and acted on the principle that charity begins at home. On the night of January 18, 1875, he broke burglariously into the hospital and carried off instruments, furniture, pictures, books, and a large quantity of lead in a removal van, and some of the spoil was never recovered. For the first three years the hospital "staff" did not overwork himself, for the average daily attendance of patients was a little more than one; but in 1871 the medical staff was doubled by the appointment of Dr. David Leslie as physician.

The hospital began at 67, Margaret Street, Marylebone, then moved to Newman Street, and in 1874 came to more or less rest at 32, Soho Square for forty years till January, 1914, when the present hospital was opened on the site of St. James's, Westmoreland Street, the church to which large congregations were drawn by the Rev. H. R. Haweis, an original and somewhat unconventional preacher, who rivalled the Rev. Page Roberts of Vere Street in attracting the medical inhabitants around Cavendish Square. Haweis had in 1868 been appointed chaplain to the hospital, but resigned in a month "as a result of various rumours connected with the hospital and also appertaining to Dr. Spratt's private character." Since 1914 the hospital has attained such a high position that it can afford to smile at the frailties of its founder.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY DECEMBER 30 1939

RESULTS OF TREATMENT OF GASTRIC CANCER

It is accepted that about one-third of malignant tumours are situated in the stomach, and that surgical excision is at present the only known means of cure for cancer in this site. Any study of end-results in the treatment of gastric cancer thus resolves itself into an analysis of surgical methods and results. Since the experience of any individual surgeon or even a group of surgeons in one hospital is both limited on account of numbers and dependent on the skill and technical ability of the surgeon, his assistants, and the radiologist who contributes to the diagnosis, a wider field is necessary for statistical purposes. Livingston and Pack, two New York surgeons, have brought together for review the great body of data published in the last sixty years, comprising nearly one thousand publications, and have submitted them to critical study and analysis. Their results covering reports of 14,000 gastrectomies for cancer are now available.[1] Billroth in 1881 successfully removed an advanced colloid carcinoma from the stomach by a procedure to be classed as a subtotal gastrectomy, but in the first five partial gastrectomies for cancer one patient alone survived, and that only for four and a half months. Billroth later expressed dismay at the high general mortality and gave it as his opinion that not more than one in two hundred cases showed conditions suitable for an attempt at resection, though later he raised his estimate as to operability to one in fifty or sixty. Since that time it is possible to trace a gradual evolution of improvement in results, and recent articles in this country and elsewhere on the subject of gastric cancer cures set entirely new standards of attainment. Reports have been published of 20 per cent. ten-year cures among all patients leaving the hospital after gastrectomy for cancer. About one-third of immediate survivors of gastric resection for cancer are alive at the end of three years, one-fourth are living at five years, and one-fifth live beyond ten years from the date of discharge from hospital. Since steady and progressive advances have been made during the six decades since the first gastrectomy for cancer, it is reasonable to believe that the limits of attainment in the surgical management of resectable gastric cancer have not yet been reached; certainly recent progress has exceeded that of any previous period of surgical activity. The experience of one of our own surgeons (whose results are included in Livingston and Pack's series) may be cited. Sir James Walton[2] found over a thirty-five-year period that the operability rate has increased from 28 per cent. at the time of the last war to 44 per cent. in the years 1928–35. Radical operation was possible in 224 of his 572 cases seen—over one-third of the total number.[3]

In gauging the end-results much confusion has arisen from failure to distinguish between resectable gastric cancer and surgically incurable gastric cancer. From two-thirds to three-fourths of gastric cancers are unresectable when first seen, while at no time in surgical history and at no point in the world have the definitive cures of gastric cancer ever exceeded 5 per cent. of the total number of patients with the disease. At present, therefore, 95 per cent. or more of all afflicted die of the disease within less than two years. We have thus to envisage a disease within a disease, the total number of patients having cancer of the stomach as distinguished from the resectable fraction of this total. This resectable gastric cancer as a separate entity is still one of the most common forms of cancer and is highly amenable to surgical therapy, which offers a distinctly favourable outlook for definitive cure. Livingston and Pack point out that it is wrong to allow the outlook for the disease as a whole to dominate the picture. To state that a patient with a resectable gastric cancer has but a 1 to 5 per cent. chance for a long-term survival when in reality this is a 20 to 50 per cent. chance of cure is a serious error.

Further analysis shows that the attained cures are represented by the total cases, less those found to be inoperable, less those that are unresectable, less those that do not survive resection, less again the natural rate of decline among immediate resection survivors. A large part of the loss of numbers in survivors after discharge from hospital after resection is due to deaths from natural causes, which are high for the age group associated with gastric cancer. The number and size of each of the "loss factors" preclude both now and for the future the attainment of large percentages of long-term cures among all patients seen. But for resectable gastric cancer the situation is relatively simpler; cures are resections performed, less the resection mortality, less again the natural rate of post-resection decline in survivors. The resectable patient has thus but two hazards: the resection risk and the post-resection death rate from recurrence or natural death. The former hazard is under surgical control, while the latter rests largely in the hands of Nature and can be but little affected. The training of surgeons and surgical teams to work under optimal conditions is necessary and attainable. But in order to obtain a small number of long-term cures operations in large number are a necessity. Further, the operability rate proves of greater significance than the rate of resection mortality. This is seen from the fact that a 50 per cent. loss from inoperability means a loss of half the patients from all possibility of cure, while a 50 per cent. loss from resection mortality will mean but numerically few patients of the total number with the disease.

---

[1] *End-results in the Treatment of Gastric Cancer: An Analytical Study and Statistical Survey of 60 Years of Surgical Treatment.* By Edward M. Livingston, M.D., and George T. Pack, M.D., F.A.C.S. London and New York: Paul B. Hoeber. (3 dollars.)

[2] Walton, James, *Medical Society's Transactions*, 1936, 59. 182.

[3] Idem, *British Medical Journal*, December 9, 1939, p. 1127.

The problem for the community, then, is the finding of resectable gastric cancers. They are numerically common, for necropsies reveal that even at the time of death from gastric cancer approximately one-fourth of these tumours are still confined to the stomach or to the stomach and immediately adjacent lymph nodes; and as Sir James Walton has found, resection is possible in more than one patient in every three. All patients with the disease, except those unequivocably proved to be unresectable, should be surgically observed and a large percentage surgically explored. Resectability or unresectability is often ascertained with complete certainty only through surgical exploration. But the role of the medical practitioner in bringing the patients early to investigation of equivocal symptoms in those of cancer age may equal in importance the role of the skilled surgeon. Unless after full investigation growth can be definitely excluded an operation should be considered.

INDIAN HEMP AGAIN

Professor Robert P. Walton of the University of Mississippi has produced a timely and elaborate monograph on "America's new drug problem."[1] The hemp plant, *Cannabis sativa*, utilized from time immemorial for the manufacture of fibre and rope, from which for a thousand years in the Orient a narcotic has been extracted and largely used, has within the last two decades provided an anxious problem in the Occident. It was omitted from the *British Pharmacopoeia* of 1932. Professor Walton discusses the history of Indian hemp, its use and abuse, the pharmacology and therapeutics of the drug derived from it, the growth and extension of the "hashish vice," and more especially the modern development in Western countries of the habit of smoking "marihuana" cigarettes. The acute and chronic effects on mind and body of the ingestion of the drug are given and its pharmaceutical and chemical qualities studied. The work receives commendation in a foreword by Professor Geiling of the University of Chicago for its value to the psychiatrist, the criminologist, and the sociologist as an authoritative account of a drug "which already has a long and dishonourable history and now is again engaging attention as the result of an increasing addiction to its use in modern civilized countries."

The use of cannabis as a narcotic under the names of bhang, ganja, charas, or ma can be traced back in parts of Asia to A.D. 950, though doubtful references have been traced in Homer, the Old Testament, and Pliny. Its euphoric properties—mental exaltation, and consequent oblivion to miserable surroundings—led to its widespread acceptance, either by smoking or oral ingestion of the crude flowering tops or their contained resin. The ascription of the word "assassin" to addicts of hashish by DeSacy is disputed by other philologists. Writers like Dumas (in his *Count of Monte Cristo*) and Baudelaire (from his own experience) invested hashish addiction with literary glamour. Gautier, from his adventures in the Quartier Latin with his colleagues, graphically described the hallucinations of time and space, the beatitude and hilarity which hashish intoxication provided "as a synthetic escape from bourgeois environment." It seems that the social evils resulting from the "hashish vice" attracted little attention before the nineteenth century. It is related that Napoleon's generals, following the Egyptian expedition, made abortive efforts to eradicate the evil. It was not until 1840 that the use of cannabis therapeutically was recognized in Europe, and until 1910 that its non-medical use began to spread elsewhere than in the Orient. In Mexico, where the hemp grows wild, it is related that the drug was eaten, drunk, and smoked at the close of last century. It is, however, since 1910 that the smoking of hashish in the form of marihuana cigarettes has attracted attention in the State of New Orleans. The habit spread like wildfire. Thousands of kilogrammes of the "weed" were imported annually. An international group of dealers acted as a distributing centre and reaped large fortunes. The trade extended northwards, followed by a "crime wave." State after State succumbed to the traffic. Cabarets and night clubs and the underworld became ready purchasers of the drug and peddlers invaded the schools selling marihuana cigarettes to children. From 1927 until the present year legislative measures have been adopted in State after State with a view to suppressing the evil by confiscating "the weed" and punishing traffic in it by fine and imprisonment. In New York in 1934 there were 300 convictions for violation of the Marihuana Law, and 170 tons of the cannabis plant were seized in 1935. In Harlem there are said to be hundreds of dens where marihuana is smoked. Since 1931 the traffic has invaded Canada; cigarettes reached Montreal from New York and shipments of hemp were arriving from the West Indies and West Africa. Ottawa and Toronto claimed their addicts and the use of marihuana is said to be very popular on the Pacific coast.

[1] *Marihuana: America's New Drug Problem. A Sociologic Question with its Basic Explanation Dependent on Biologic and Medical Principles.* By Robert P. Walton. J. B. Lippincott. (12s. 6d.)

It was largely on representations from Egypt and South Africa that Indian hemp and its galenical preparations were brought under national and international control. Although hints were made that these should be included in the Hague Opium Convention of 1912, it was not until the Geneva Convention of 1925 that this was given effect. In Egypt, Russell Pasha has waged vigilant warfare against hashish; of 500 kilos seized in 1937, more than 400 were imported from abroad through Port Said, Alexandria, or Suez, and Russell has warned against any relaxation of control. Professor Walton's monograph is an opportune addition to the information needed for the international campaign against narcotic addiction, more especially in its most modern and insidious form of marihuana.

Colonel R. N. Chopra, M.D., and Captain G. S. Chopra, M.B., have recently contributed to the *Indian Medical Research Memoirs*[2] an exhaustive research on the present position of hemp-drug addiction in India. The history of the cultivation of hemp and the distribution and control of its production are related. The social and religious associations of its use and its employment for euphoric and aphrodisiac purposes are discussed. As the result of an analytical study of 1,238 addicts to hemp the authors conclude that while small occasional uses of the drug may do little harm continued and excessive indulgence leads to general debility, premature decay, mental derangement, and is, in some cases, conducive to crime.

AXILLARY THROMBOSIS

No doubt in large measure because of the work of Leriche and his co-workers at Strasbourg, French medical literature suffers from no lack of contributions on vascular surgery. E. Roelsen[3] of Copenhagen has recorded in the *Lyon Chirurgical* seven cases of so-called primary subclavian or axillary venous thrombosis from the university clinics of Copenhagen, and discusses the cause, clinical features, and treatment. Sir James Paget[4] in 1875 appears to have been one of the first to describe the condition, but he regarded it as of gouty origin. Von Schrotter[5] was the first to describe the post-traumatic variety. The majority of cases appear to be of this nature, and, as one might expect, the right subclavian or axillary vein in young or middle-aged men is most often involved. Cases are met with, however, in which no preceding muscular strain could be held responsible, and which, therefore, in contrast with the post-traumatic ones, might be described as spontaneous. One such case was recorded by J. C. Ross[6] in 1933 of a man aged 27 who awoke one morning to find the condition fully developed. There is usually a history of muscle strain, such as might be caused by using a screwdriver with the arm in an awkward position; swelling of the arm occurs; the superficial veins are distended; and the axillary vein may be palpable as a tender cord. There are no pyrexia, no constitutional effects, and no demonstrable changes in the blood. The Wassermann reaction is negative. Roelsen advisedly uses the expression "so-called thrombosis" of the subclavian and axillary veins, because in twelve of the reported cases the vein was found to be thrombosed but in nine others it was free from clot, while fascial investing filaments were found adherent to the surface of the vein. A number of cases have been operated on, though most are found to clear up if the arm is put at rest in abduction for a week or longer. Roelsen illustrates his paper with some infra-red photographs which show well the relatively greater superficial venous network on the side of the lesion. Numerous theories of causation have been suggested. Roelsen favours Cottalorda's view that there is primarily venous spasm following some form of stimulus applied to the perivenous sympathetic nerve net, and when thrombosis is present this is secondary to the venous spasm. It is suggested that if resolution does not soon follow the placing of the part at rest the vein should be exposed, freed from its adherent fascial coverings, and stripped of its nerve net (perivenous sympathectomy); and that if this is not effective a segment of the vein should be excised. It is perhaps rather early to assess the value of these operations. Good results have been claimed for them, but probably most British surgeons would not resort to them until after a prolonged trial of conservative measures, and, indeed, the condition usually responds so well to rest and abduction that any more active treatment should only very rarely be necessary.

HYPOTHALAMIC LESIONS IN PEPTIC ULCER

The work of Dodds and co-workers,[7] showing that injection of extracts of posterior pituitary may lead to acute ulceration of stomach and duodenum, has recently been continued by Nedzel,[8] who reports the results of injecting sixty-two dogs with 20 pressor units of pitressin per 5 kg. of body weight twice a week over a period up to six months. Twenty-three of these animals had lesions of the stomach and duodenum ranging from a small injury to a large ulcer. These lesions were most easily produced in March, April, and May, and Nedzel suggests that this may bear some relation to the frequent clinical complaint by ulcer patients that cold or changeable weather precipitates the onset or return of symptoms. Nedzel's findings lend weight to the present tendency to modify Virchow's vascular theory of ulceration by invoking functional spasm of mucosal vessels and auto-digestion. In a review of the acute gastric disturbances and lesions following hypothalamic stimulation, the subject of a Hunterian Lecture by Heslop in 1938,[9] Vonderahe[10] describes pathological changes of a haemorrhagic nature in the diencephalon and medulla in fourteen patients who died from acute complications of peptic ulcer. The haemorrhages were in the anterior hypothalamus at the level of the hypothalamic sulcus, involving the grey matter of that area and of the superior paraventricular nuclei; lower down similar changes were seen in the dorsal motor nucleus of the medulla. Adjacent areas with the same blood supply were unaffected. In a control series of thirty-five brains no such haemorrhages were found in thirteen, whereas in the others haemorrhages were particularly marked in persons dead from irritative lesions of the abdominal viscera and in some cases of diabetes mellitus. In these control investigations, however, the pattern of distribution of the haemorrhages differed from that found in peptic ulcer. Vonderahe suggests that strong afferent stimulation from visceral areas may lead in the end to irreversible organic changes in the nervous system, and suggests that "many of the sequelae following recovery from a severe attack of peptic ulcer—the irritable pulse rate, the increased sweating, the signs of 'sympathetic imbalance'—all point to injury in the parasympathetic centres of the dorsal motor nucleus of the vagus nerve, while quick fatigability, irritability, emotional changes, and alterations in regulation of metabolism, sleep, and temperature indicate injury to the thalamus and hypothalamus. To say that such manifestations are merely neurotic is frequently untrue, and injustice may be done by not recognizing an organic handicap." While agreeing that his findings may represent a contribution to our uncertain understanding of the pain of ulcer, clinicians will probably join issue with him in his conclusion, quoted above, on the ground that the "sympathetic imbalance" of ulcer patients, for the most part, long antedates the ulcer, and is related to the pre-existing "diatheses" described by Hurst and to the psychological characteristics noted by Davies and Wilson and others. The acute abdominal complications of peptic ulcer are also perhaps more notable for the subsequent —unfortunately often temporary—improvement of the patient rather than the reverse. Vonderahe's interesting findings may perhaps be related by future investigation to Sir Henry Head's[11] observation of areas of "referred" hyperaesthesia of the skull in patients with severe visceral disease.

EXPERIMENTAL ULCERATIVE COLITIS

Drury and Florey were the first to graft portions of the colon of animals into the skin so that the mucous membrane was exteriorized, and they have published observations on the vascular reactions. The mucous membrane of these grafts is easily susceptible to surface irritation. Normally there is a mucous covering, and, with careful dressing to protect this, the mucous membrane of grafts which have been on the surface of the skin for many months may present microscopical appearances identical with those of the healthy bowel wall. Prolonged exposure of the grafts to the ordinary friction of everyday life gave rise to inflammatory changes, which, however, were healed readily with careful attention. After a dressing is placed on the surface some mucus is formed, and this apparently protects the mucous membrane from further irritation. Irritation is not the sole stimulus to secretion of mucus, since isolated loops of colon produce more mucus when cathartics are given, which affect the remainder of the colon. Lium,[1] in some observations on the processes of inflammation and healing in colonic grafts, noted that chronic surface irritation caused by leaving the grafts without dressings for forty-eight hours led to muscular spasm and an initial copious outpouring of mucus, which was followed by a more watery secretion when the goblet cells were exhausted of mucus. Muscular contractions induced in the graft —by rubbing, by applying acetylcholine after intravenous injection of prostigmin, or by intravenous injection of Shiga dysentery toxin, the action of which is to produce violent spasm of the bowel muscle—resulted in oedema, petechial haemorrhages, and superficial ulceration of the mucous membrane of the graft. These changes were not due to local alteration of the circulation through the graft—that is, to ischaemia alone—unless accompanied by muscular contraction. The author suggests that spasm may be a prime factor in the causation of ulcerative colitis. Ulceration is found to occur in the colon proximal to an obstructive lesion; below the obstruction the mucous membrane is normal. Ulcerative colitis may be conceived as a specific reaction to a number of influences which can initiate spasm of the colonic musculature. These include possible over-activity of the parasympathetic nervous system, infections such as dysentery, and vitamin deficiency. Once the colon becomes spastic it is potentially an organ that can produce severe damage to its own surface structures, for the exhaustion of mucus-secretion together with nutritional deficiency may delay the healing processes. The author's experimental findings would conform with those arrived at clinically by von Bergmann—namely, that in the evolution of ulcerative colitis a sequence can be traced from spastic colon and mucomembranous colitis before ulceration occurs. Though suggestive, these observations of Lium need confirmation.

DENTAL FLUOROSIS

For some years attention has been directed to a dental disease, characterized by a mottling of the enamel of the teeth, which has been traced to the presence of an appreciable quantity of fluorine in the drinking water. This has been seen particularly in certain regions in the neighbourhood of the Rocky Mountains, U.S.A., but it has also been observed in Africa, Australia, Argentine, Canada, Italy, and, nearer home, at Maldon in Essex. The effect of minute quantities of fluorine (one part per million) in domestic water has already been commented upon in these columns,[2] and observations have been published recently[3] on the existence of dental fluorosis in England, Australia (Queensland), and the United States. The first sign of the disease is the formation of a brownish substance, usually on the labial side of the front teeth, taking the place of a deficient deposit of enamel. The result is that the teeth appear irregularly pitted with shallow cavities more or less filled with food debris. Not all the teeth are affected, and the condition is often confined to those at first attacked. In the Rocky Mountains region, where the subject has been closely investigated, only those children were found to be affected who were born in the district where fluorides were present in the water supply or who lived in that district during the period of enamel formation. No further cases occurred after a change over to a fluoride-free water supply. Ainsworth[4] observed dental fluorosis in a certain number of school children (aged 5 to 15 years) at Maldon, noting that their dentures were, generally speaking, good and less carious than was usual among council school children. It was found histologically that the pitting was due to loss of enamel and not to deficient formation, and that in areas where fluorosis was endemic the potable water contained approximately 5 parts per million of fluorides as against a tenth of that quantity in other areas. Bowes and Murray[5] have also published a report on the "mottled teeth" at Maldon, in which they discuss the quantitative composition of fluoritic teeth in the human subject and in experimental animals. They suggest that the pasty whiteness of such teeth is the result of deficiency of iron in their composition. Dean[3] states that among school children living in districts in the United States where fluorosis is endemic there is less dental caries than in districts where domestic water supplies are relatively free from fluoride; he suggests that dental caries may, to some extent, be controlled by the nature of the potable water supply. Fluorosis identical in all respects with that seen elsewhere has been observed by F. W. Clements[3] in a number of districts in the interior of Queensland (Australia). The regions concerned are those where the main water supply is derived from deep bores (3,000 feet) and contains from 1.6 to 3 parts per million of fluoride. In other areas the water supply is from surface wells or the river, and in these the children are free from the disease.

THE SITE OF ANTIBODY FORMATION

The much-debated question of where antibodies are formed is only part of the larger problem of the source of serum proteins generally. To attribute this function to the liver, an organ already, it would seem, overburdened with multifarious supposed activities, is easy but unconvincing, and now known to be incorrect to the extent that other tissues are certainly involved as well. All of these tissues, the liver included, contain reticulo-endothelial cells, and it is a reasonable hypothesis that these cells form the globulins of which antibodies consist, if not others as well. This idea was indeed current before certain evidence now available existed to support it, since it was well known that these cells phagocytosed bacteria and other antigens, and the specific antibody to which these gave rise could only be supposed to be formed at the site of their destruction. To have brought this process under direct visual observation, confirming its reality and to some extent following its intimate mechanism, is the claim now made by Florence Sabin.[1] This achievement was made possible by the use of a "marked antigen"—that is, an antigenic substance the particles of which are recognizable microscopically in the tissues. The substance used was the alum precipitate from an azo-dye—egg-albumen compound synthesized previously by Heidelberger and Kendall for the quantitative study of antigen–antibody reaction by means of colorimetry. Suspensions of this compound were injected into rabbits by various routes, and it could then be identified easily in the cytoplasm of phagocytic cells of the reticulo-endothelial system, the situation of these cells naturally depending on the route of the injection. Two essential facts emerge from the numerous details of a study of the subsequent behaviour of these cells. One is that the disappearance of the dye-protein from them after apparent digestion in a vacuole coincides with the appearance of antibody in the circulating blood. The second is that at this stage there is a profuse detachment of fragments from the surface of these cells. This shedding of "surface films" is a function of the normal macrophage, and its observation was what led Ranvier to give to these cells the name "clasmatocyte." Sabin concludes that this is the mechanism by which these cells liberate globulins, and adduces a further argument from embryological data which supports the same conclusion. The normal process of globulin formation by reticulo-endothelial cells is thus accelerated and qualitatively altered by the phagocytosis of an antigen. Sabin goes so far in final conclusion from these observations as to define an antigen as "a substance which can specifically modify the synthesis of the cytoplasm of the cells of the reticulo-endothelial system." This is a far-reaching and most important conclusion, which one would hesitate to accept in full from any less experienced observer, since, although the serological data concerned are exact enough, the rate of disappearance of particles from cells in living tissue is scarcely amenable to quantitative statement, and it is on the correlation of these two kinds of observation that the conclusion depends. It nevertheless bears the stamp of truth and accords well with all other knowledge of the subject. That an important constituent of the blood is formed by the disintegration of shed particles of cell cytoplasm rather than by expulsion from cells in an already dispersed form is a novel idea, and it naturally raises the questions whether other serum proteins are formed in the same way, and whether a similar mechanism takes part in other syntheses in the body.

The Minister of Health and the Secretary of State for Scotland, have jointly appointed Dr. Edward Ellice Henderson, a medical officer of the Ministry of Health, to undertake the duties of Inspector of Anatomy in England, Scotland, and Wales.

SURGICAL PROCEDURES IN GENERAL PRACTICE

This is one of a series of articles contributed by invitation

FRACTURES ROUND THE ANKLE-JOINT

BY

ERIC I. LLOYD, M.B., B.Ch., F.R.C.S.

Fractures round the ankle-joint are among the commonest of lower limb injuries, and their treatment is a matter of such overwhelming importance that every doctor should know as much as possible about it, so that he can either decide to treat these cases—with a full knowledge of his responsibility—or get such specialized assistance as circumstances permit. These fractures used to be treated in bed on a splint for six weeks with the minimum of reduction and the maximum of rest. Everyone now knows that a "walking plaster" is the proper thing, but the urgent necessity for obtaining and keeping exact reduction is less generally realized. There are still occasions when a patient's future is irreparably blighted by a good plaster worn for six or eight weeks on a very ill-reduced fracture. It is unfortunate that a patient in plaster can often bear weight with comfort on a fracture which is not in good position.

Classification

Pott's fracture was a term originally applied to fracture-dislocations of the ankle in which the foot was displaced outwards upon the leg. The advent of *x* rays has permitted more exact diagnosis and encouraged division of ankle-joint fractures into groups which were not recognized by Pott (1714–89). Ashurst's classification (1922) divides ankle-joint fractures, according to their method of production, into external rotation (61 per cent.), abduction (21 per cent.), and adduction (13 per cent.) fractures, the remaining 5 per cent., which include compression fractures, being atypical forms. Fig. 1 shows this diagrammatically, and it may be noticed that first-degree fractures involve structures on one side of the joint only, whereas both sides are involved in those of the second degree. It also shows that when both bones are broken the line of fracture of the first break to occur is oblique in torsion fractures and transverse in abduction and adduction fractures.

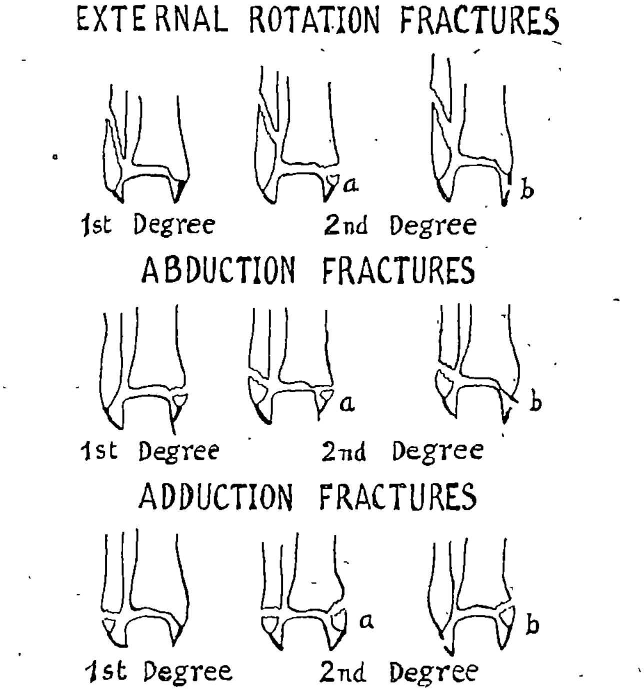

FIG. 1.—Ashurst's classification of ankle-joint fractures (after W. G. Campbell).

Minor Fractures

Campbell (1938) has recently demonstrated that first-degree ("minor") fractures can be safely treated with a local anaesthetic and that immediate weight-bearing without plaster can then be allowed. It must be remembered, however, that some first- and second-degree fractures look identical on the radiograph, though there is risk of displacement in the second group and not in the first. Obviously it would be dangerous to treat second-degree fractures without plaster, and it is important to distinguish them at once by pushing the foot laterally or medially towards whichever bone is seen on the radiograph to be fractured. This is painful only when the astragalus presses against the broken bone, which does not occur if the ligament on the opposite side of the joint is intact. There is no necessity to test the ligament when the radiograph shows that both bones are broken, because the fracture is then obviously not first-degree. The test consists in a purely lateral movement of the foot on the leg, and is vitiated if a rotatory movement is accidentally added (Roberts, 1938). The important distinction between minor and major fractures depends, therefore, first on a radiological and secondly on a clinical examination, in that order.

Treatment (Campbell, 1938).—One side of the foot only is damaged in minor fractures, and the resulting haematoma is entered by a Record needle after anaesthetizing the skin. Ten to twenty c.cm. of 2 per cent. procaine or novocain is injected; this should relieve the pain completely and allow weight-bearing within a few minutes. The patient walks without splint or plaster and attends daily for the next two or three days, but the injection is repeated only if pain recurs. Radiographs may be taken after the first two days and subsequently at intervals of a week until consolidation is seen to have occurred, when no further treatment is necessary. In the fracture clinic of the Royal Northern Hospital it has been found possible to ignore many of these fractures and to dispense even with a local anaesthetic.

Major Fractures

Both sides of the joint are damaged in this group (that is, either both bones or a bone and a ligament) and displacement has already occurred or is liable to do so. Bone injury is seen on the radiograph and a torn ligament is diagnosed by the clinical test (Roberts) described above, which is, of course, only necessary when the injury is bony on one side of the joint and ligamentous on the other. A further deformity (not shown in Fig. 1) sometimes occurs in rotation fractures when the force continues to act until the astragalus breaks off a wedge-shaped piece from the back of the tibia, and the foot may then be displaced backwards as well as outwards. A similar fragment occasionally breaks off from the front of the tibia, but this is generally due to a hyperextension mechanism, which is unusual. The fracture is called third-degree

(Ashurst) if the whole lower end of the tibia is fractured in addition to the primary deformities.

Anaesthesia.—Local anaesthesia may be used, but it is not always satisfactory even in recent cases. The skin is painted with iodine and anaesthetized and a Record needle passed into the haematoma and into the ankle-joint. Ten to twenty c.cm. of 2 per cent. procaine or novocain is injected, and the same procedure is repeated on the opposite side of the limb. A general anaesthetic is, however, usually preferable, and gas and oxygen after preliminary morphine 1/6 grain, or omnopon 1/3 to 2/3 grain with scopolamine 1/150 grain, given hypodermically, is satisfactory.

Treatment of Major Fractures

If there is damage on both sides of the joint but no displacement the limb is put in plaster without either anaesthetic or manipulation. Displacement, however, is more common, and necessitates both anaesthesia and manipulation, preferably under radiological control.

OPERATION

The patient is in the dorsal position with the affected limb hanging over the end of the table and the knee bent at a right angle to relax the tendo Achillis. The surgeon sits on a low stool at the end of the table with the patient's foot on his knee and the most recent radiographs in full view. A felt strip a quarter of an inch thick and three and a half inches wide is stitched round the upper third of the leg (Fig. 2) and, the proper length for two plaster slabs is then measured with a gauze bandage or tape. The first slab will run like an elongated stirrup down each side of the leg and across the heel, and the second will pass from the middle of the felt strip round the back of the heel to the tips of the toes.

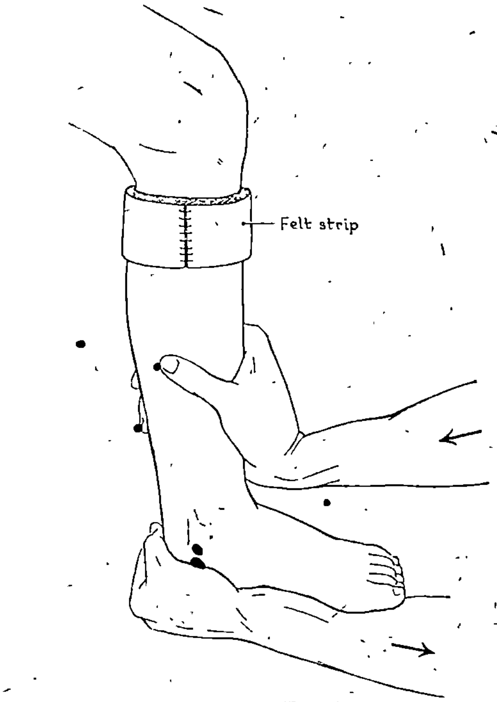

FIG. 2.

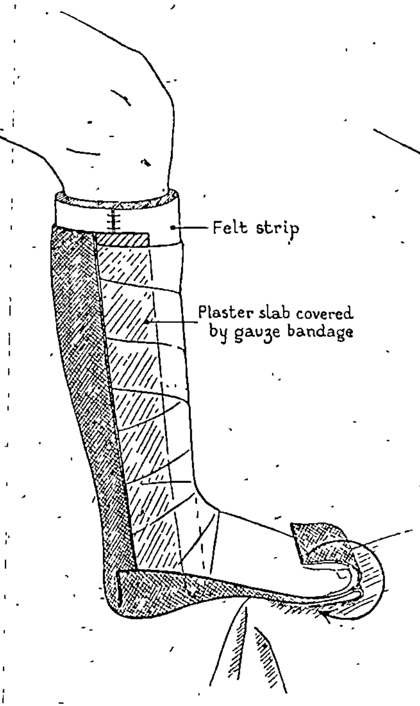

FIG. 3.

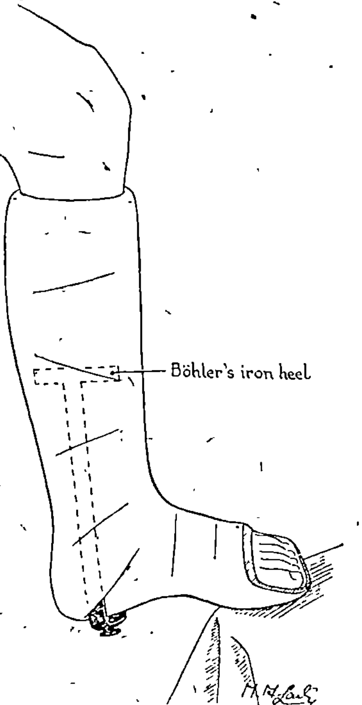

FIG. 4.

The fracture-dislocation is now reduced by taking the back of the heel in one hand and pulling the whole foot forward, while the other hand acts as a fulcrum and pushes against the front of the leg just above the ankle (Fig. 2). The lateral displacement is corrected by steady pressure inwards or outwards (depending on the type of fracture shown on the radiograph) while maintaining the forward position of the foot. Firm steady pressure is required, and there need be no fear of producing over-correction unless the internal malleolus is broken at exactly the joint level. The ankle is held in the corrected position and reduction confirmed by screening in two planes with a shock-proof portable x-ray set, but the foot-piece of the operating table must be removed before the antero-posterior view becomes possible.

When reduction is perfect in both planes the two plaster slabs are prepared by an assistant as follows. A six-inch plaster bandage six yards long is put in water and rolled backwards and forwards upon itself to make the lateral (stirrup) slab the required length. Only one bandage is used, and the slab is folded longitudinally upon itself and fixed to the inner and outer sides of the limb next the skin with a six-inch gauze bandage six yards long. The posterior slab is made in the same way from one plaster bandage, but its width is not halved by folding, and it is held in place by a plaster bandage (6 inches by 6 yards). Both slabs are put on very wet with three ends resting on the felt strip and the fourth hooked round the dorsal surface of the toes (Fig. 3). The margins of the posterior slab are cut by a knife for a distance of half an inch at the point where it passes round the heel, and both slabs are moulded smoothly on the limb by the surgeon, who has shifted his grip to include the plaster, but continues to hold the fracture fully reduced. The foot is held at a right angle and midway between varus and valgus, while the fingers and thumb press closely behind and below the two malleoli. The common practice of putting the foot in varus (inverted) is a mistake, and though the heel may be pressed into slight varus the forefoot should be, if anything, in valgus.

The fractured limb is now screened or radiographed in both planes, and anything short of perfect reduction necessitates removing the plaster and repeating the procedure. The plaster reaches the tips of the toes below and supports their plantar surface, but is cut away dorsally so that each toe is visible and movable (Fig. 4).

AFTER-TREATMENT

The patient is returned to bed with his plastered limb on a soft pillow and the knee slightly flexed under a cradle, which supports the bedclothes. A rubber heel is applied to the plaster next day with an elastoplast bandage; and the patient is encouraged to bear weight on the injured limb with the help of crutches or sticks, which he discards in a day or two. Böhler's iron heel is very good, but it has to be applied with a plaster bandage and interferes considerably with subsequent radiographs. On the other hand, a rubber heel necessitates the wearing of a felt or leather boot in any but the driest weather, as it soaks up moisture and then has to be changed. Rubber sponges can be bought for sixpence, and these cut in half transversely make excellent heels.

Walking is encouraged from the first, and the distance covered should be increased daily from a hundred yards to several miles. It is usually best to split the distance into three short walks rather than to take one long one, and to elevate the limb on a couch or stool during part of the intervals. Some swelling of the foot is common, and is perhaps useful in diminishing the risk of redisplacement. Circulatory troubles are rare in these fractures, but cyanosis or pallor of the toes must be treated by elevation of the limb or splitting the plaster. Pain is generally present for the first day or two and is disregarded if circulation and sensation remain normal, but the plaster must be split or removed and subsequently reapplied if pain persists or recurs. Bivalving the plaster is not advisable.

Usually a patient is able to walk unaided in a few days and can even resume his occupation during the period of fixation, which should last for a minimum of six weeks and be continued for ten or twelve weeks in severe fractures or in old patients. Radiographs are taken at fortnightly intervals until the plaster is removed. It is then replaced by a four-inch elastoplast bandage, which extends from the base of the toes to the tibial tuberosity and which is worn for three weeks. All bandaging may be then discontinued unless oedema persists, when another elastoplast bandage should be worn for three weeks. Movements of the ankle are encouraged as soon as the plaster-of-Paris has been removed, but no other treatment is necessary, and no good purpose is served by wedging the shoe or by the use of an outside short iron. The patient's desire for massage must be diverted to simple rehabilitation exercises (rowing and bicycling) which he has to perform himself.

Excellent results may be expected from this treatment, and most of the patients should ultimately regain painless movement of approximately normal range. The average period of disability after Pott's fracture in adults was reported to be forty-seven weeks when treatment was not given by an organized fracture clinic and eleven weeks when it was (B.M.A. Report, 1935). These figures probably do considerably less than justice to the first group, but there is now no doubt that segregation of fractures cuts the disability period to a minimum and almost abolishes what was previously a high rate of permanent incapacity after Pott's fracture. Good results are, however, less frequent when treatment has been delayed, when fixation has been insufficiently prolonged, or when the patient is old. Anything short of perfect reduction will of course militate against a good result, however careful the subsequent treatment.

Difficult Recent Fractures

Open operation is nowadays hardly ever necessary, though it is occasionally justifiable when a fractured internal malleolus can be seen on the radiograph to have rotated through 90 degrees. In such cases Böhler (1935) advises that the surgeon should be content to expose the fragment and replace it in position without any metallic fixation, though he doubts the necessity for doing even this in all cases. There are, however, some fractures which cannot be reduced by the above methods but which can be successfully treated by skeletal traction. This may be applied in one of two ways:

(*a*) *Gradual*, by inserting a Steinmann's nail through the os calcis and applying traction of from 10 to 30 lb. by means of a Böhler stirrup with the limb on a Braun splint. This method may take several days to accomplish its purpose, after which the weight should be gradually diminished and the limb left on the splint for a week or ten days and plaster then applied round the nail, which is removed in a few days if the radiograph still shows good position of the fragments.

(*b*) *Immediate*.—A Steinmann's nail is inserted through the os calcis and the limb extended on a Böhler screw-traction apparatus. Reduction is assisted by the hands, and the malleoli are compressed with an os calcis redresseur or Thomas wrench if necessary. The fracture is screened while the limb is still on the screw-traction apparatus and before applying plaster-of-Paris. The nail is removed when the position is seen to be satisfactory, and walking begins on a rubber heel as already described.

Old or Neglected Fractures

These offer considerable difficulty, and it is often hard to know whether to attempt reconstruction of a fracture or to arthrodese the ankle-joint at once. It is sometimes worth attempting correction up to about six months after the original accident in young patients, though this may entail an open osteotomy of the fibula. The osteotomy is performed in the line of the old fracture; the wound is sutured and the limb placed on a screw-traction apparatus with a Steinmann's nail through the os calcis as already described. Traction is applied and a redresseur (Böhler) compresses the malleoli. Position is checked by the *x*-ray screen and plaster is applied with the limb still on the traction apparatus. Subsequent procedure is the same as that described above.

Long-standing deformities which cause much pain are best treated by arthrodesis of the ankle. The joint surfaces have then been too much damaged by traumatic osteo-arthritis for a good result to be expected from reconstituting the fracture, and "there is no doubt that a well-arthrodesed ankle is infinitely superior to one in which a moderate result has been obtained by means of a reconstruction operation" (Ollerenshaw, 1929).

Chronic Rheumatism.—The signs and symptoms of various forms of arthritis of the hip-joint and sciatica are discussed. Important points in treatment are said to be: (1) the prevention of haemorrhages after gold therapy by control of the platelet count, which should not be allowed to fall below 150.000 per c.cm.; (2) the administration of iodides; (3) the use of vitamin B_1; and (4) intradermal injections of histamine in cases of sciatica. The indications for surgical treatment are also considered.—Chronic Rheumatism in 1938. F. Françon.—*Rev. Médecine*, May, 1939, **56**, 272.

THE CANCER CAMPAIGN

Research to Continue during the War

The annual general meeting of the British Empire Cancer Campaign was held on December 14 at the Campaign's offices in Grosvenor Crescent. Lord Hailsham presided, and read a letter from the Duke of Gloucester, President of the Campaign, addressed from the general headquarters of the B.E.F. His Royal Highness said that he entirely approved of the Grand Council's decision to contribute towards the national effort by placing its appeal organization and equipment at the disposal of one of the national war charities (St. Dunstan's) instead of itself conducting appeals; but at the same time it was encouraging to learn that important cancer research would continue to be carried out under the auspices of the Campaign.

"I understand" (wrote the Duke) "that those who are skilled in such research and whose services are not required at this juncture for national scientific purposes will continue to apply their efforts to the solution of the problem. The cessation of any medical research, and more especially cancer research, except in circumstances where the personnel was not available, would be deplorable. . . . In England and Wales alone the population is depleted yearly by the loss of very many thousands of lives through this dire disease, and I am told that in the continent of Europe the deaths from cancer amount to at least half a million annually. It is therefore all the more incumbent on us to use every effort to bring cancer under early and complete control."

Lord Hailsham said that at the meeting of the Executive Committee, sitting with the powers of Grand Council, which was to follow immediately on the annual meeting, recommendations would be brought forward from the Grants Committee that an expenditure of £35,000 be made on behalf of about twelve cancer research centres and a number of independent research workers; this was only £6,000 less than the grants made last year. Part of this research would be financed out of capital put on one side for such an emergency and the balance made up from legacies. He went on to refer to the contributions which the Allies—Great Britain, France, and Poland (the native country of Marie Curie)—had made to the cancer problem.

Professor G. Grey Turner, in moving that the honorary officers and members of Grand Council and its standing committees be continued in office, mentioned that he had recently returned from a visit to North and South America, where, he said, the work of the Campaign and of cancer research generally was watched with the keenest interest and with the hope that it would not be eclipsed even in the present time of national preoccupation.

Lord Horder, in moving the adoption of the annual report, said that it would be obvious from this document, which was larger than any previous issue, in how many directions research was being pursued. The Duke of Gloucester's timely remark that the cessation of research, if personnel could by any means be found, would be deplorable gave a very desirable lead. When war broke out there was an almost universal move to close down voluntary effort, however urgent it might be; but second thoughts, as was so often the case, had brought wisdom. Cancer research, after all, could be carried out to some extent by those who were, from age or other disability, precluded from making a more immediate contribution to the service of the country.

Sir Alfred Webb-Johnson, in seconding, hoped that it would be made widely known that research was continuing to be helped by the Campaign. Thanks to the careful husbanding of the finances, it was possible to carry on to some extent even without fresh appeals.

Sixteenth Annual Report

The annual report of the Campaign, edited by Mr. J. P. Lockhart-Mummery, is a weighty document embodying separate reports from not far short of fifty laboratories, research departments, oversea branches, and individual research workers. This heterogeneous collection of information of unequal value has been reduced to an ordered narrative by the editor in his twenty-page summary in which he reviews the work which is proceeding, especially in the biological and physical fields. One slight point of criticism was voiced by Professor Grey Turner at the annual meeting—namely, that little or nothing was said concerning the surgical aspects of the problem. The editor writes of the new spirit of hopefulness which now animates cancer research. "Students seem to feel that a point has been reached at which ignorance may be transmuted, almost any day, into clear understanding."

He discusses the work now proceeding in many laboratories on cancer-producing agents such as some of the tars, which suggests that they exert their effects in conjunction with other agents. "Such assumptions as the doctrine that 'irritation' of itself is a cause of cancer have been discounted in favour of precise knowledge about the agents which do in fact cause the disease. The way has thus been opened to intensive study of particular as opposed to general problems. New facts, too, have emerged—for example, that a relationship exists between the quality of inhibiting growth and the quality of causing cancer. It is being asked, in consequence of this observation, if cancer may not represent an adaptation of the cell to circumstances in which normal activity has become difficult."

The experimental work on the biological effect of neutrons is yielding interesting information. The effects are similar to those produced by *x* rays and gamma rays, but there are some quantitative differences. As to the high-voltage *x*-ray plant in the cancer research department of St. Bartholomew's, this is now working satisfactorily at one million volts. The first treatment at this voltage was given towards the end of February. Not only is steady operation at 1,000 kV completely assured, but a kilovoltage of 1,200 is within the bounds of possibility. Over fifty patients have now been treated at 700 kV. "It is already certain" (says the department) "that an inoperable carcinoma of the rectum can be made to disappear; this satisfactory result has occurred in four out of eight cases treated."

Distribution of Cancer in England and Wales

The report contains the third and concluding instalment of a study by Dr. Percy Stocks of the distribution of cancer of various organs in the population of England and Wales. The standardized mortality ratios for separate counties and towns have been worked out, and in this instalment nine maps are given showing the distribution of mortality during the decade 1921–30 amongst females from cancer of various sites.

The general distribution of highest mortality is in North Wales, a small area south of the Wash, and the East Riding. For almost all the sites examined the urban rates are in excess of the rural, even after a correction has been made for the fact that many cancer patients resident in country districts die in town hospitals. In North Wales the high cancer mortality rate is entirely accounted for by an enormous excess of stomach cancer affecting both sexes. Some areas of the North of England with an adverse social environment, of which Durham County is an example, also show a large excess of gastric cancer, but here it is usually accompanied by a parallel excess of uterine and skin cancer and a pronounced deficiency of ovarian, breast, rectal, prostatic, and bladder cancer which is not seen in North Wales. Gastric cancer has a low incidence in the south-eastern counties, in Norfolk, and in most of the agricultural areas of the South and Midlands.

Dr. Stocks compares the cancer problem to a jig-saw puzzle in which many kinds of specialists are at work, with the danger that increasing specialization may result only in forming unconnected islands of the complete picture. It is the medical statistician's job to search for bridges between the islands.

VALUE OF CANNED FOODS

Canned foods were a war-time invention, 130 years ago, for the feeding of the troops during the Napoleonic campaign, so that the subject of Sir William Savage's Chadwick Lecture on December 12, the health aspects of canned foods, had a topical interest. He reminded his audience of the magnitude of the canned food industry to-day. Over 350 different canned commodities are on the market. Of the canned food eaten in this country between 85 and 90 per cent. is imported, so that such an industry requires two kinds of supervision—one in the country where the canning is done, and the other in the country where the food is consumed. Canning requires a high degree of knowledge and scientific attention to detail, and Sir William Savage said that he had studied canning conditions in the United States and Canada and had been impressed by the careful control which was exercised and the excellence of the food used. As for the examination of the product after arrival in this country, it was, if anything, over-thorough, but, of course, the reputation of canned food must vie with that of Caesar's wife.

Possible Risks to Health

Possible health risks were discussed by Sir William Savage under three heads: nutritional changes during manufacture, danger of chemical additions from the container, and bacterial infections or poisoning. Quantitatively the process of canning caused no detrimental changes; indeed, the advantage was with the canned food because everything in the tin was edible. Qualitatively there were possible changes in vitamin content. There was no loss in respect of vitamins A and D, and so far as vitamins B_1 and B_2 were concerned, while there was some loss, it was not greater than resulted when similar foods were cooked. It was with cooked food, not with raw, that canned products should be compared. Vitamin C also underwent some loss, but by modern canning methods much of this vitamin was retained, and here again the loss was comparable to that which occurred on cooking. In America canned tomatoes were even used as a source of vitamin C for infants. As for chemical contamination, in former days there was a possibility of this from solder, but solder was now very little used, and there was no evidence that either tin or lead was a health hazard with canned foods. For thirty years, Sir William Savage said, he had been looking for cases of tin poisoning arising in this manner, and had only discovered one doubtful instance. Lead poisoning was more important, being cumulative in its effect, and minute doses taken over a long time would be deleterious, but here again with modern canning there was practically no danger. Bacterial infections presented a more complicated problem. Three types of food poisoning must be considered—namely, botulism, infection with living bacteria of the food-poisoning type, and the "toxin" type of outbreak caused by the toxic products of bacteria. From 1915 to 1930 there were many outbreaks of botulism, incriminating some American canned products, but scientific investigation had led to efficient methods of prevention and the risk was now almost eliminated from commercial canned products, though it still attached to home canned. Food poisoning with living bacteria occurred with canned foods, but was comparatively rare, and the incidence was much less than with foods not canned. Outbreaks of the "toxin" type were at one time fairly frequent with canned foods, but the number had been materially diminished, especially so far as meat was concerned; canned marine products were still sometimes implicated.

A Beneficial Invention

Altogether Sir William Savage's verdict was that although canned foods did cause a certain amount of food poisoning they were safer than ordinary foods. The dangerous foods, he said, were those which were manipulated—for example, partially heated and then put out to cool, such as meat pies and made-up rissoles. He thought that a good deal of unnecessary prejudice was caused with regard to canned products because, on a case of food poisoning, the first question of the doctor was apt to be, "What canned foods have you been eating?" Scientific investigation did not justify that innuendo, and altogether the canning process, which might prove exceptionally useful during the war, was a most reliable and beneficial invention.

EXPERIMENTS ON ANIMALS IN 1938

The Home Office White Paper[1] setting out the licences granted in 1938 under the Cruelty to Animals Act, 1876, shows how carefully the authorities keep watch on the use of animals in scientific research. When an animal is used under licence alone it must be kept under anaesthesia during the whole of the experiment, and if pain is likely to continue after the effect of the anaesthetic has worn off, or if the animal has been seriously injured, it must be killed before it comes round. Various certificates are issued to allow the holder to modify the conditions of the licence. During 1938 licences were issued to 2,152 persons, and 566 of these performed no experiment. The total number of experiments performed was 958,761. Anaesthetics were given for all serious operations. Antiseptic conditions must be observed so that the wounds shall as far as possible heal without pain. If suppuration takes place the animal must be killed, but it is generally necessary for the success of these experiments that the wounds shall heal cleanly. After the wounds have healed the animals are not necessarily or even generally in pain, for important organs may be removed without causing pain after the operation. When a part of the nervous system is excised the resulting degenerative changes are painless. No cutting operation more severe than a superficial venesection was performed under Certificate A—that is, without an anaesthetic. The 908,846 experiments performed without anaesthetics mostly concerned inoculations and feeding; some were oral administrations, inhalations, external applications, and the abstraction of body fluids. Certificate A is chiefly given to allow the animal to be kept without an anaesthetic during the time required for the development of the results of a drug or injection. In many of these experiments the results are negative and no pain at all is caused. Licences were granted to forty-eight cancer investigators, who performed over 35,000 experiments, mostly without anaesthetic. The bulk of these were inoculations in mice or exposure of animals to radiations. The large majority of all the experiments were performed for municipal or Government authorities.

During the year the inspectors made over a thousand visits to registered places, mostly without notice. They found the animals suitably housed and well cared for and the licensees generally attentive to their duty. No better indication of the care taken to protect animals could be given than the report of the trivial irregularities observed by inspectors. A licensee allowed to inject fluid into nerve trunks inadvertently divided two nerves; another, entitled to give inoculations to animals at one place, gave some at another; two more licensees performed ligation of blood vessels in rabbits, an operation not covered by their certificate. These offenders were all admonished or warned.

Encephalography in Neuroses.—Wigert describes encephalographic findings, usually of a type indicating cerebral atrophy, in a number of apparently psychoneurotic patients, and ascribes an aetiological significance to them. He concludes that, in certain cases which we call "psychoneurotic," the essential condition is a character anomaly which is organically conditioned and which cannot be influenced by psychotherapy or other methods hitherto employed.—Encephalographic Findings in So-called Psychoneuroses (Ger.): V. Wigert.—*Acta psychiat. Kbh.,* 1938, **13**, Fasc. 4, 401.

Reports of Societies

CONVALESCENT SERUM IN ACUTE RHEUMATIC FEVER

At a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on December 12, Sir **WILLIAM WILLCOX** presiding, Dr. C. A. **GREEN** communicated some preliminary observations on the use of convalescent serum in the treatment of acute rheumatic fever.

The work which Dr. Green brought forward related to a number of young male adults in a physical training establishment who had shown rheumatic manifestations. In the majority of cases a nasopharyngeal infection antedated the insidious onset of pain in one or more joints which necessitated medical attention, when the patient was found to be febrile. On the whole the joint lesions in these cases had not been very striking and rapidly improved, leaving no permanent injury. The initial pyrexia rarely lasted longer than one week, but exceptional cases continued febrile for months. The symptoms were gradually relieved by salicylates. Cardiac complications were found in certain of the cases, but fortunately a number of the patients showed no tendency to develop cardiac lesions, and as these were otherwise healthy young adults it was decided to use a serum taken from them during their convalescence after acute rheumatic fever. The serum was taken from four to eight weeks after the temperature had subsided, in the absence of any other indication of persistent infection.

The serum, which was filtered and preserved, was used for the treatment of cases of acute rheumatism presenting the classical fleeting joint pains with a marked tendency to cardiac involvement. The initial effect of serum therapy had been in most cases satisfactory in that the temperature and pulse rate rapidly returned to normal limits and the symptoms were relieved. He gave the case histories and temperature charts of fifteen patients, some of whom had been treated by serum alone, while in others this treatment had been supplemented by further measures. Of ten cases in which no salicylates or other preparations were used during the illness seven reacted favourably to convalescent serum. The injections were mostly from 10 to 50 c.cm. of serum, generally given intramuscularly, on three successive days. Out of seven cases in which the treatment was successful, six were primary attacks and one was a recurrence. Given in the early stages the serum did appear to reduce the period of pyrexia. Of the fifteen cases nine were considered to have benefited. The volume of serum available was not large enough to permit really adequate dosage in every case. Two of the patients showed a partial collapse, but both of them rapidly responded to appropriate treatment. In a few instances the serum had no effect on the course of the disease. The final estimation of the value of this mode of treatment must be deferred until all possible cardiac lesions had been assessed.

In attempting to demonstrate the mechanism by which such serum might act it was noted that the intradermal injection into the human skin of joint fluid from an active case of acute rheumatism produced an erythematous swelling. Serial specimens of serum taken during convalescence from the patient from whom the joint fluid had been obtained were mixed and incubated *in vitro* with the joint fluid. It was found that serum taken in the later stages of convalescence prevented the appearance of the erythematous reaction on intradermal injection of the mixture, whereas serum in the early stages of the illness had no such effect. The nature of this reaction was unknown, but it was possibly an example of toxin-antitoxin neutralization.

Sir **WILLIAM WILLCOX** said that rheumatic fever or acute rheumatism was one of the most fascinating subjects in medicine. Those of them who worked in hospitals thirty or forty years ago would remember how much more common and virulent acute rheumatism was in those days. The search for the cause of acute rheumatism had so far been in vain. Every two or three years someone discovered a fresh "cause," but all that was known was that the haemolytic streptococcus was very closely associated with the condition. It had not been demonstrated as yet whether another factor was also at work. There had been great hopes that Swift in America had discovered the associated causal factor in rheumatic fever, but at the recent conference in the United States in September last he very frankly stated that he had found that the cause of rheumatic fever was still elusive. The unpleasant symptoms—namely, fever and pain—could be controlled by salicylates, but no remedy was known which would control the development of cardiac lesions unless it was prolonged rest and the utmost care to avoid infection. He thought that Dr. Green's paper offered some hope that the cardiac complications of rheumatic fever might be prevented or minimized by the use of convalescent serum. It was interesting that in two cases anaphylaxis should have occurred, much as in the case of foreign serum, though the onset was not so rapid and the symptoms, although alarming, were not fatal.

Polycyclical Rheumatism

Dr. W. H. **BRADLEY** said that if a series of untreated cases of rheumatic fever were watched they would be found to fall quite naturally into two groups—a monocyclical group, which resolved quite rapidly, within perhaps a week of the onset of the disease, and continued to make progress to recovery, and a polycyclical group, which persisted for weeks and months. It was therefore very difficult without taking a large series of controls to come to any conclusion whatever about the value of serum therapy. In the polycyclical group rises and falls of temperature were quite common, and at the period of the rises the appearance of new manifestations of rheumatism was to be expected. Some work was done on human serum a few years ago by Coburn, who had noticed that as the patient recovered the anti-streptolizing titres rose to high levels, and therefore he selected human serum in which there was a high anti-streptolizing titre and used it as a therapeutic agent. But he was discouraged by the rather severe collapse-like reactions which he occasionally encountered, and therefore he did not persist. The liability of rheumatic patients to collapse, not suddenly, as was usual with anaphylaxis, but rather later, after the injection of human serum, was a phenomenon which Coburn had noticed. One little point which could be controlled in the further studies that he hoped Dr. Green would be able to make was the determination of the albumin-globulin ratio of all the serum he preserved. Certain tables which Dr. Green had shown regarding the neutralizing of a hypothetical toxic substance in joint fluid also furnished a reminder of the polycyclical nature of the disease and of the precipitin reaction which Coburn had recently described. Coburn had stated that serum taken from a rheumatic subject during the last few days before he started his rheumatic attack contained a substance which was precipitated by serum from the patient during the cycle, and that a similar precipitation reaction occurred between the serum taken from the patient during the cycle and during the interval between cycles.

Dr. H. J. **PARISH** asked what happened in the use of serum of normal non-rheumatic subjects. Were reactions obtained with normal serum?

Dr. **GREEN** replied that he agreed entirely that clinical rheumatic fever showed these monocyclical and polycyclical varieties or degrees. What he had brought forward was only a preliminary investigation and was subject to many qualifications in the light of later research. The effect of normal serum in these cases had not been tried out.

Prophylactic Vaccination against Pertussis

At the same meeting Dr. I. H. **MACLEAN** read a short paper on "Prophylactic Vaccination against Whooping-cough."

Vaccination against whooping-cough in this country was started by Freeman, and the early results were encouraging, but pertussis vaccine somehow came into disrepute. It was only vaccines from very smooth strains of *B. pertussis* that were antigenic. There was only one way of controlling whooping-cough and that was by the cough-plate method of diagnosis. At least half the cases which came to his hospital as such were not pertussis at all, as established by the cough-plate method, though there was a spasmodic cough. The cough-plate had drawn attention to what might be a new disease—namely, para-pertussis. At the Annual Meeting of the British Medical Association in Aberdeen this year Sir John Ledingham had suggested that pertussis vaccine might be combined with alum-precipitated diphtheria toxoid in prophylaxis against both diphtheria and pertussis. Some experiments had been carried out at St. Mary's which had shown that vaccine precipitated by alum remained a good antigen, but it had not yet been possible to work out the best dose and the best conditions.

Dr. Maclean gave particulars of the courses of immunization which had been followed at St. Mary's:

	Clinic Cases	Exposures		Clinic Cases	Exposures
1936	64	5	1938	119	8
1937	153	22	1939	140	10

To this series had to be added forty-six cases from other sources with forty-six exposures, and in the whole series there had not been one known failure. This was subject to the qualification that owing to dispersal following the war the clinic had been closed and it had not been possible to keep track of cases. The statistics did not refer to cases vaccinated during the contact period. Immunization during the incubation period was not often successful. At most 25 per cent. of the cases did not develop whooping-cough in that they did not have severe cough and vomiting, but nearly all of them would give a positive cough-plate. Possibly in another 30 to 50 per cent. the disease could be modified, but in the remainder there was no success at all. There was a stage when immunization during the contact period might do no good, and sometimes he had a suspicion that it might do a little harm. His cases included only those which had been immunized at least one month before being exposed to the disease.

His practice was to give three or four doses of 4,000 million of the vaccine at weekly or bi-weekly intervals, and then a stimulating dose of 4,000 million one month later, using the secondary response to push immunity up to its maximum. The total dose was thus from 16,000 to 20,000 million. He suggested that adequate prophylaxis could be obtained by smaller doses than the very large ones sometimes recommended.

Professor **ALEXANDER FLEMING** said that the prophylaxis of whooping-cough by vaccination was a therapeutic measure of first-class importance, comparable with typhoid vaccine, and far more valuable indeed for the reason that in this country whooping-cough was a widespread disease, whereas typhoid was not.

Dr. **YOUNG** asked whether para-pertussis was a separate disease and whether the vaccine of pertussis could protect against it.

In reply to this and other questions Dr. **MACLEAN** said that from some work he had done he was led to believe that an attack of para-pertussis would not protect against pertussis. A few strains of para-pertussis were now put in pertussis vaccine, but it was not yet decided how important it was nor what percentage of the vaccine should be made from para-pertussis. At the moment the provisional figure was 10 per cent. The immunity conferred was supposed to be lifelong, but now and then there were reports of recurrent attacks. As to the best age for vaccination, it was well to choose a time when the child was completely healthy, free from even a slight infection, and the best age was towards the end of the first year. Severe reactions were sometimes encountered, especially when dealing with under-nourished children and children who might be suffering from bronchitis or some minor ailment.

DISCIPLINE AND LEADERSHIP

The various "men of destiny" who, without any of the traditional prestige of the old emperors and kings, have imposed upon Europe a despotism greater than theirs make a rich theme for the psychologist, of which Dr. H. **CRICHTON-MILLER** took advantage in his address to the Medical Society of Individual Psychology on December 14.

Dr. Crichton-Miller, whose subject was "Discipline and Leadership," said that the first business of a dictator was to foster and exploit the suggestibility of his people. To ensure undiscriminating acceptance of dictatorship instinctual passions had to be maintained at a dynamic level and rational discrimination discouraged. Thus the national life in many countries was becoming increasingly antagonistic to the individual point of view, and as the standard of self-discipline fell that of coercive social discipline was raised. In democratic countries leadership was usually based on prestige or tradition, such as that of the hereditary monarch. Again, the history of the British Empire was full of such examples of leadership as that of Brooke of Sarawak, whose prestige was largely based on his English origin. Then there was the leadership accorded to physical superiority; men had always been ready to recognize the leadership value of physical qualities of a high standard. Another aspect of leadership was suggested by the recent installation of the Dalai Lama of Tibet, where the whole tradition and ceremony revealed the necessity for prestige deriving from magical sources for the primitive mind. Age was another source of prestige, though this was the subject of contradictory opinions, and Downing Street and the Oxford Union might not think alike. The French nation was interesting as a study in the psychology of leadership; the French were realists, less influenced by magic or romance than other peoples, and chose or displaced one leader after another as he pleased or failed to please the electorate—the opposite mechanism of prestige from that attaching to heredity or caste. There were also leaders, of whom Gandhi was a conspicuous example, who attained and kept their positions on purely psychological grounds. As for the mob leader, he was likely to gain control simply by the loudness of his voice and the dramatic quality of his manner. The mob would follow anyone who satisfied an uncritical demand for a leader who appeared to know what to do in an emergency.

From all this Dr. Crichton-Miller concluded that there was no real identity between the qualities which brought about the acceptance of a leader and those which made for good leadership. The best leaders would be chosen only by a group which was capable of rational discrimination, while any group which was stirred by overwhelming emotion, especially if it comprised a proportion of persons of low intelligence, would accept a leader at his own valuation. Dr. Crichton-Miller developed this point later in reply to a discussion when he said that he had come to feel that the ability to recognize a good leader was something intuitive and not really a development of our educational system. As things stood the political charlatan had a better chance of gaining leadership in many so-called educated groups than among simple folk who were more intuitive. As for the functions of a leader, the first was vision, without which the people perished—a protective vision for the fear-ridden group, an aggressive vision for the resentful, an emancipating vision for the downtrodden. He should be able to persuade the intelligent and open-minded of the wisdom of his ideals, but this was not enough for the unintelligent or those under powerful emotion. As an ideal leader he mentioned Abraham Lincoln, who used the strength of the North to give the slaves their freedom. No doubt in simple communities, such as the Eskimos or South Sea islanders, leadership was rarely called for; only as competition sharpened had social discipline to be called in to maintain justice. Later came the phase, in which we were at present, of education and rational control, with social justice based not only upon instinctual satisfactions but upon self-discipline. Beyond this was Utopia, in which self-discipline alone was enough to maintain social justice in spite of instinctual and narcissistic frustrations.

Local News

ENGLAND AND WALES

The King's Fund

At the meeting of the Council of King Edward's Hospital Fund for London held on December 19 H.R.H. the Duke of Kent read a message from His Majesty the King, who said:

"New methods for the prevention and cure of disease entail ever-increasing expenditure. Co-ordination and co-operation must constantly be sought, and in this connexion I am sure that the Council will feel that no greater tribute could well be paid to the work which the King's Fund has tried to do than the recent splendid gift of Lord Nuffield to form a nucleus of a fund for hospitals outside the London area." The Duke of Kent in his presidential speech said that the King's Fund would this year distribute £304,000. Of this sum £43,500 had been paid in special emergency grants and an extraordinary grant of £15,000 had been made to the Westminster Hospital and a further one of £15,000 towards the building of a new hospital on the amalgamation of the Central London and Golden Square Throat, Nose and Ear Hospitals. In view of the special circumstances this year, a further distribution would be made when the hospital accounts for 1939 become available. In talking of the needs of the hospitals the Duke said: "The Government is responsible only for the cost of the beds reserved for casualties. But for the civil work, which has never stopped and is now increasing, the hospitals are dependent on voluntary contributions, and the need is all the more urgent because so many of their supporters are themselves hard hit by the war." Sir Harold Wernher, in presenting the report of the Emergency Bed Service, said that since it opened in June, 1938, 10,000 cases had been admitted to hospital through this agency. Though the Service had been closed on the outbreak of war as the staff had been seconded to the Ministry of Health for work in connexion with the casualty scheme, it had been possible to reopen it by the middle of September, and it was now in full operation and handling a steady flow of cases.

A Maternity Home for Officers' Wives

Not the least among the very deserving projects to which we are asked to give our help at this time is that of a maternity home for the wives of officers. Many officers' wives in war time are unable to meet the ordinary fees of a maternity home, and they have usually no claim upon the military maternity homes. A real need thus exists, but thanks to the generosity of Mrs. Edward Baron, who has lent Fulmer Chase, near Slough, rent and rates free for the duration of the war, the first steps have been taken to supply this need. Fulmer Chase, which stands in 230 acres of country, is being adapted to accommodate twenty-eight beds, an isolation ward with a further two beds, a labour ward, lunch and dining room, and staff quarters. There will be two resident medical officers having special experience in obstetrics, and a consultant staff, drawn from the London hospital staffs in that sector, will visit the home when required. The fee for the majority of beds will be 15 guineas for three weeks, and this will be inclusive of all medical and surgical attendances, nursing, and maintenance. There will also be provision for grants in aid of special cases. It is hoped to open Fulmer Chase for the reception of patients about January 15. Promises of sums sufficient to endow two beds for the duration have been received, but funds are urgently needed if the work of the home is to be a success. The council responsible for carrying out this project includes Sir Comyns Berkeley, Dame Louise McIlroy, Professor W. Fletcher Shaw, and Dr. Frances Huxley, and donations should be sent to Sir Comyns Berkeley, who is the honorary treasurer. Further information and forms of application for admission, etc., can be obtained from the honorary secretary, Miss L. M. Brooks, Maternity Hospital for the Wives of Officers, 60, Portland Place, W.1.

Retirements from L.C.C. Service

Dr. J. A. H. Brincker, principal medical officer in the public health department of the London County Council, is retiring at the end of the year under the age limit. The Emergency Committee of the Council, after describing Dr. Brincker's work in a full-time capacity since 1911, and in a part-time capacity for several years before that, says that his knowledge has proved invaluable and "by his retirement the Council will lose the services of one of those rare experts whom it will be difficult to replace." Dr. W. K. Knobel, a senior medical officer, is also retiring under the age limit after eighteen years in the Council's service. To him the successful development of the tuberculosis scheme in its early days was in no small measure due, and the Committee says that by his retirement the Council lose the services of an able and experienced officer.

Memorial to Dr. Mabel Campbell

By her manifold interests and her vivid, generous, and courageous personality Dr. Mabel Campbell won a unique place in the life of the North of England. She was deeply and universally beloved. There is a general desire among her many colleagues, patients, and friends to perpetuate her memory in a manner expressive of her spirit. A committee representative of her various activities has been formed to institute a memorial fund, which will be applied to some beneficent purpose in keeping with Dr. Campbell's life of service. The chairman of the committee is Professor R. B. Green, Dean of Medicine, the Medical School, King's College, Newcastle-on-Tyne, and the secretaries are Mrs. George Hall and Miss Veronica Nisbet. Anyone who wishes to contribute should send a donation to the treasurer, Dr. Freda Herbert, the Medical School, King's College, Newcastle-on-Tyne.

FRANCE

[FROM OUR CORRESPONDENT]

Settlement of Doctors' Disputes by a "Conseil de Famille"

The French doctors' *Conseil de Famille* is an informal gathering of medical men before whom disputes between doctors can be brought with a view to a fair and peaceful settlement. The washing of dirty linen in public and the cost of formal litigation are avoided, and the chances of a satisfactory settlement are enhanced by the *esprit de corps* which reigns at these friendly and conciliatory tribunals. To give a fair example of the type of case brought before the *Conseil de Famille* reference may be made to a dispute ventilated anonymously in *Concours Médical* for August 27. A village was served by two doctors and a chemist, whose partiality for one of the doctors would seem to have been offensively demonstrative. One evening a patient with a fracture of the clavicle was given a prescription by the doctor in attendance. When the prescription was taken to the chemist's house the maid said that her master was not at home; she added in the presence of four witnesses that if the prescription had been written by the other doctor the chemist might have been at home. Dr. Paul Boudin, legal adviser to *Concours Médical*, is of opinion that a chemist is as much within his rights in refusing to serve a potential customer as any other tradesman, with this reservation, that the practice of pharmacy being in a certain sense a monopoly the pharmacist must have some reason for his refusal more valid than a personal animosity. Were such a case to be brought before a court of law the odds are that the maid would deny that she uttered the words reported by the witnesses, and the only result to be prophesied with certainty would be a further lowering of the prestige of the medical profession. Hence Dr. Boudin's advice to the offended doctor to appeal to the local medical society, which would consult with the local pharmaceutical society in order that a *conseil de famille* composed of members of both societies could arbitrate.

Diphtheria Inoculation

At a recent meeting of the French Academy of Medicine a resolution was adopted in favour of enforcing the new law concerning compulsory inoculation against diphtheria. The need for this reform has become pressing on account of mass migrations from France's eastern frontier and Paris to other parts of the country. According to this law the prefect of a commune threatened by an outbreak of diphtheria shall be entitled to prescribe compulsory anti-diphtheria inoculation for all children from the ages of 1 to 14 years. Only an injection *de rappel* of anatoxin would be necessary for those children certified by a doctor as having already been inoculated with anatoxin against diphtheria.

War Items

French medical students who have attained a certain level in the medical curriculum and who have been called to the colours before passing their clinical examinations are to be exempted from them on fulfilling certain conditions. The dossier of every medical student will, however, be scrutinized before such exemption is given.

It is announced that a group of Belgian surgeons are organizing an ambulance service with beds for 100 to 150 surgical cases. This service, fitted out on modern lines, will be called "Ambulance Antoine Depage" in memory of the Belgian surgeon who played so important a part in the last war.

Correspondence

Treatment of War Fractures by the Closed Method

Sir,—In several of your recent issues Dr. Trueta and his supporters, who advocate closed plasters for compound fractures, and his opponents, who fear the risk of encouraging anaerobic infection, have all omitted to mention a very simple modification of technique which enables one to have the best of both worlds.

The method referred to is the use of a plaster slab round two-thirds of the circumference of the limb, attached by a circular bandage of wet book-muslin which completes the remaining third of the tube. If the occurrence of rising temperature, excessive smell, or local discomfort makes the surgeon anxious to inspect the wound, all he has to do is to cut across part of the muslin bandage, anchoring the loose ends with adhesive strapping. If he finds no indication for removing the whole plaster, integrity can be restored by the addition of a new wet bandage. The book-muslin, from which most hospitals manufacture their plaster bandages, contains some starch, and when applied wet it absorbs some of the plaster over which it passes, so that it has none of the tendency to slide which is so troublesome with dry bandages on plaster; also, it is discouraging to the patient's fingers, unless he is quite determined to interfere, but such patients will manage to disintegrate the stoutest plaster.

The method was introduced to me during the last war by Dr. Danforth of Providence, U.S.A., but has long been popular with French surgeons and is used with modifications by Dr. Böhler in Vienna. I have used it ever since, particularly for cases of Dunn's tarsal arthrodesis, which are really compound fractures of special difficulty and in some congenital cases are subject to tiresome blisters, which heal much more quickly when dried by exposure to air.

When it is desirable to expose the wound to more rapid evaporation than can occur through the plaster, I find the best method of protection from dust, etc., is to cover the opening in the plaster loosely with a little box cut from "windowlite" and bound into shape with adhesive strapping. This substance allows ultra-violet light to penetrate to the wound; it is easily cut with ordinary scissors; it is less likely to tear the nurse's hand than wire netting; and it can be washed with antiseptics, so that it lasts for weeks, not needing any gauze or only a strip at the edges. Thus, though it is not cheap to buy, it works out much more economically than the old-fashioned repetition of gauze dressings.—I am, etc.,

Bath, Dec. 17. M. Forrester-Brown, M.D., M.S.

Sterilization and Storage of Dressings

Sir,—In a C.C.S. or base hospital an ample supply of small-sized dressing packages is of great advantage. It is inconvenient to have to search haphazard at a bedside for different materials within assorted bundles. Furthermore, the supply of sterile drums and of towels may be very restricted. For both sterilization and storage of small dressings cigarette canisters have proved very useful. The ration tins of the familiar brands are procurable in unlimited numbers, and may be used again and again.

The tin is converted into a miniature "drum" by piercing about a dozen fine holes in the lid (from without inwards) to provide entry for steam and subsequent vacuum drying. A tin can be packed with at least six large swabs, a few pledgets of wool, and on top a dressing towel twelve inches square. The loaded tins are packed in a large drum (it will take forty or more), and sterilization is carried out in the main appliance. As soon as is convenient each tin is removed from the main drum under aseptic conditions (the sister or medical officer should wear gloves and gown), and the lid and upper half-inch of each tin is dipped into paraffin wax which has been allowed to cool from 160° C. to 75° C. A completely effective and lasting sealing of the perforations and lid margins results.

In practice it has been found that these dressing preparations may be stored for long periods, and that the wax sealing is not injured by rough handling. In the wards and for minor operations their compactness has proved handy and economical. Sterility of the dressings is assured.—I am, etc.,

Bruce M. Dick,
Major R.A.M.C.; Surgical Specialist,

Stored Blood for Transfusion

Sir,—I am very glad that Dr. A. C. Kanaar (*Journal*, December 16, p. 1206) has so temperately discussed ways of deciding the value of stored blood.

If we suppose for the sake of argument that stored chilled blood has about the same value as an equal quantity of blood serum dyed with congo-red, and that it can improve the colour and pulse of a patient to the same degree, we can see at once what a disastrous thing it would be to allow our present organization for the supply of stored blood to supplant one for the supply of warm fresh blood after an air raid. A recent paper by O'Shaughnessy and others justifies one in presuming that stored blood may be better than dyed serum, since they have shown that a solution of haemoglobin can sustain life, though for a limited period. My small clinical experience of using stored blood has left me anxious and uneasy, and I confess I have reverted to the use of fresh blood when the patient is ill. I should receive the greatest help from such an experiment as the following, but I have no facilities for carrying it out.

> Establish what is a constantly fatal blood loss for a suitable given animal.
>
> Compare the effects of transfusion of serum, of chilled stored blood, and of fresh blood on groups of such animals previously bled to the fatal point.

If this experiment has already been done I should be grateful for the reference.

I am inclined to the opinion that we could establish an organization for the early supply of large quantities of fresh blood, which would be practically as good as the present chilled blood supply organization so far as British towns are concerned.—I am, etc.,

Birmingham, Dec. 19. Hugh Donovan.

Gas Injuries to the Eye

SIR,—With regard to the treatment of gas injuries to the eye, may I suggest the following routine treatment. The contaminated eye should be flushed with liquid paraffin, which should be instilled in a continuous or intermittent current, the overflow being absorbed with cotton-wool so as not to contaminate the adjoining skin. As mustard gas readily dissolves in liquid paraffin it will wash away all the poison from the conjunctival sac. A drop of cod-liver oil or, better still, cod-liver oil irradiated with ultra-violet rays, possessing an even higher bactericidal power (see *Lancet*, 1939, **2**, 1023), should be instilled every hour into the eye for twelve hours.

I am confident that this method would better justify "the hope of mitigating the damage to the eye" than flushing it with plain water (which dissolves mustard gas less than 1 in 100) as indicated in the official handbook.—I am, etc.,

Edinburgh, Dec. 15. M. LICHTENSTEIN.

Tuberculosis in the Last War

SIR,—In your leading article in the *Journal* of December 16 (p. 1191) upon public health in war time the view is expressed that "on balance it would almost seem that a state of war—apart from its hideous toll of young male life—may have a hygienic value for a community." Among statistics adduced in support of this astonishing statement are those for tuberculosis from 1913 to 1919. "Tuberculosis," it is asserted, "notably declined during the war. In 1913 the new cases of tuberculosis had numbered 117,000, but they never reached the six-figure level again, and in the first year after the war they were down to 77,000." Now, apart from the fact that 1913 was the first year in which notification of all forms of tuberculosis became compulsory in this country—with the consequence that the figure was swollen by arrears and therefore partly fictitious—notification figures are not generally accepted as providing an adequate estimate of trends of tuberculosis. As pointed out by Sir Arthur MacNalty, "The mortality figures are a much more trustworthy guide, and in almost all cases the incidence of the disease has had to be measured by its death rate."

Up to 1914 the death rate from tuberculosis in England and Wales for all ages taken together had been steadily declining, but during the war the decrease gave place to a material increase in mortality, the decrease being resumed after the termination of hostilities. Over the decade that included the war period the standardized death rates per 100,000 living were: 1911, 146; 1912, 136; 1913, 134; 1914, 135; 1915, 144; 1916, 142; 1917, 148; 1918, 154; 1919, 123; 1920, 112. The total deaths from tuberculosis during the years 1914–18 were 20,000 to 25,000 in excess of those expected on the assumption that the 1913 death rate had been continued throughout. The war-time rise particularly affected young women, whose mortality from pulmonary tuberculosis reached in 1918 a figure as high as it had been about 1890.

The increase in tuberculosis during the last war involved most of the belligerents and also some neutrals, such as Holland and Switzerland, and a considerable literature has arisen on the subject. The worst effects were in Germany and Austria (to which attention was drawn in an editorial of this *Journal*), where the food restrictions were the most extreme. It has been estimated that Germany lost an extra 280,000 civilian lives from tuberculosis as a result of the war and subsequent economic depression (1914–27); this works out as one person for every ten fatal military casualties. The increased mortality both in belligerent and in neutral countries was mainly among the civilian population, and was greater among women than among men. The worst year of all was 1918, and there was a great fall in most countries when peace was restored.

In the report of the Chief Medical Officer of the Ministry of Health for 1920 the causes to which the increase in tuberculosis mortality during the war were generally ascribed were stated to include underfeeding or lack of particular foodstuffs, greater industrial employment of women, and the general outbreak of influenza—to which possible causes must be added overcrowding due to shortage of fuel. What is the outlook for the present war? An American authority has suggested that "all in all, it is a foregone conclusion that the excellent record of diminishing death rates that has characterized the last few decades will suffer a serious setback in the warring countries during the current and impending struggle, even if we are spared so devastating a visitation as the influenza pandemic of 1918–19." Let us hope that this prognostication will not be fulfilled, and that the serious attention being devoted to the problem of tuberculosis in war time will avert the increases that in fact occurred during the years 1914–18.—I am, etc.,

London, N.W.1, Dec. 18. P. D'ARCY HART.

Administration of A.R.P. Casualty Services

SIR,—In your issue of November 18 (p. 1021) Dr. H. Mainwaring Holt raises many points of interest and instruction regarding the A.R.P. casualty service. Unification between voluntary and municipal hospitals and first-aid party stations is a necessary condition for the efficient working of the treatment scheme. Concerning training, we have found it desirable to establish, so far as possible, a uniform course for the personnel at the first-aid posts, consisting of lectures in first aid, in the medical treatment of gas casualties, and in the theory and practice of nursing. These lectures are given in a central depot, to which the nurses are brought, for one and a half to two hours each weekday. Exercises are also held at the posts in which the first-aid parties and the ambulance section take part, and casualties of various types are treated and decontaminated. Volunteers are notified when exercises are to be held, and are encouraged to take part in the work of dressing, undressing, decontamination, and in the supervising of patients in the rest rooms. The presence of the medical officer attached to the post at these exercises helps considerably in convincing the volunteers that they themselves have a part to play in the scheme.

It is a question as yet unsolved whether it is advisable to depend on volunteers for the majority of the work done at the posts. The response to this need must vary from place to place, depending on the social responsibility of the population, their educational level, and also on the congestion of the area. It would seem that a trained nurse is necessary, perhaps all the time, or, if this is not possible, for her to be within call in case of emergency. Continuous staffing, even on a small scale, would seem to be a necessity, and this could be implemented by further auxiliaries or volunteers when a raid occurred. It is inconceivable that a first-aid post could be closed for days or weeks and reopened at an hour's notice so as to be in a condition for duty. The mobile units in urban areas are intended to supplement posts already in being, and where they are called upon to occupy separate buildings these are in addition to the permanent first-aid posts at work.

It is undesirable for medical officers to accompany first-aid party personnel to decide the disposal of casualties on the streets; they are needed in the hospitals and the posts. The first-aid men on the streets may not be at such a disadvantage in deciding where to send casualties. They are provided with powerful battery lamps, and should be able to decide whether a patient may be assigned in the first place to the categories of "walking wounded" or "stretcher case." They are instructed that the former comprises cases of skin contaminations, abrasions, contusions, minor lacerations and haemorrhages, and fractures of the upper limb, and that "stretcher" cases (intended for hospital) comprise patients suffering from lung irritation, fractures of the lower limbs, spine, pelvis, ribs, and skull, and generally those who are not able to assist themselves.

The experience of the hospitals in the larger cities during the Spanish Civil War has tended to show that first-aid posts were not of great use and that patients were better brought direct to hospital. This is more satisfactory when the number of casualties at one time is not great. We cannot presume that aerial bombardment, if this is attempted on a large scale, would result in such relatively small numbers as occurred in Spain; they are likely to be much greater from the force of armament engaged. In such circumstances first-aid posts are likely to be of value in relieving hospitals of the minor casualties. In this respect a first-aid post adjacent to a hospital is of value.

In the matter of decontamination of the skin first-aid posts are likely to be of great use. Hospitals are hardly to be expected to tackle a problem which is essentially a hygienic one. Eye irrigation is another matter. The skill of first-aid personnel in irrigation of a number of patients and for the requisite time is still untested. Decontamination of severely injured patients cannot be attempted under the usual sprays and is perhaps better performed by the nurse at a sink, with running water and the necessary bleach cream, soap, and sponge. Such shocked patients will need to be handled with great care, but will require washing before their injuries can be attended to in order not only to safeguard themselves but to avoid contamination of the nursing staff.

Lastly, the first-aid post will perhaps perform yeoman service in resuscitation by providing rest, quiet, and liquid stimulant to the lesser-injured patients, and reassuring the highly excited and hysterical by offering encouragement and exhortation to their sense of duty, in a department designed for their help.—I am, etc.,

John Scully, M.B., Ch.B., D.P.H.,
Medical Officer in Charge of First-aid Posts,
for Medical Officer of Health.

Salford, Dec. 11.

Sedatives for Nervous Casualties

Sir,—The Emergency Medical Service memorandum issued by the Minister of Health dealing with the treatment of neuroses suggests morphine (gr. 1/4) by hypodermic injection, or preferably an intramuscular injection of sodium phenobarbitone (gr. 1½) combined with hyoscine hydrobromide (gr. 1/100), for restless or excited patients. Immediately following the above recommendation the memorandum (*British Medical Journal*, December 16, 1939, p. 1201) continues: "It may not be possible to retain these patients for long in aid posts and smaller medical establishments, but every effort should be made to return them to their homes if they improve sufficiently to do so with safety."

The passage quoted surely does not refer to patients who have had a potent sedative administered such as morphine or hyoscine, although the sequence creates that impression. It would scarcely be advisable or possible to send a patient home within twelve hours of receiving such treatment. It would necessitate the provision of accommodation for such cases at the aid post, or, alternatively, arrangements for sending them to hospital. A diagnosis would yet remain to be made, and a further period of hours would thus have to elapse before one could be reasonably certain that retardation, varying degrees of stupor, confusion, etc., were in fact psychiatric in origin and not toxic (due to after-effects of potent hypnotic drugs). Much delay and congestion would accordingly be occasioned by their use.

The barbituric acid group of preparations, on the other hand, have much to commend them for the immediate treatment and management of restless and excited cases. Evipan and pentothal sodium have been found most useful for this purpose. Readily administered, promptly effective, rapidly eliminated, therefore short-acting, there are virtually no contra-indications, and idiosyncrasy is rarely encountered. Most practitioners can recall cases in which morphine has failed to produce the effect desired, but very few indeed have had that experience with evipan. I have only encountered resistance to the drugs of the barbituric acid group in severe cases of alcoholism and drug addiction.

The rapid intravenous injection of 5 c.cm. of evipan will produce a period of unconsciousness varying from half an hour to several hours, which is followed by a period of post-hypnotic calm. The case can be investigated psychologically during this latter phase, a diagnosis facilitated, and treatment given—for example, interpretation and suggestion. A period of unconsciousness may not be considered necessary, in which event the slow administration of the injection will induce a hypnotic state during which good contact can be made with patients who earlier were psychologically inaccessible. The intravenous route allows maximum control. The response to the drug is immediate, and if an excited patient can be calmed with a small dose then obviously an advantage is gained. Patients who have received as much as 10 c.cm. of evipan have been able to drive motor cars within three hours with perfect control. Others may take somewhat longer to recover from the effects, but it is to be anticipated from my experience that the longest recovery period after evipan would be materially less than the normal recovery period following injections of morphine and hyoscine.

Dr. Maurice Wright in the *Journal* of September 9 (p. 578) writes: "I have myself worked at a fugue case for many months in a very intelligent man of the officer class, only to find out in the end that he was a true malingerer with no loss of memory at all." This suggests a further advantage in using the barbituric acid derivatives in the treatment of war neuroses, as cases of malingering can be readily detected in one short interview on account of the inability of a person to maintain a consciously concocted account of his symptoms or a studied and rehearsed imitation of a neurosis while in a hypnotic state.

The treatment of psychiatric casualties has been the subject of much discussion since hostilities began, and the management of cases which fail to respond to the simpler therapeutic measures constitutes a problem which may become acute at any time.—I am, etc.,

London, W.1, Dec. 18. Ellis Stungo.

Black-out and Ventilation

Sir,—Dr. E. J. Thomson's letter (*Journal*, December 2, p. 1116) raises a very important subject with regard to adequate ventilation of hospitals during present black-out conditions. Some hospital authorities have installed electric fans with the object of blowing fresh air through the building, but obviously this must be rather costly. A method which I have found to be both effective and relatively cheap is to have suitable-sized fibro-plastic vents made and fixed in key positions throughout the hospital. These vents are easily fixed in place of existing glass fanlights or fitted to the top of any window in such a manner that it is still possible to open or close top of window. Normally the window would be kept in the open position. The size of the vents would depend on size of window and the amount of ventilation required.

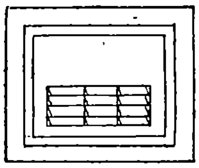

Fig. 1.
Inside.

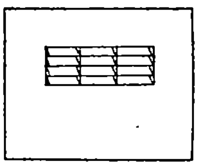

Fig. 2.
Outside.

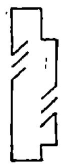

Fig. 3.
Vertical section.

The principle is simple and it is, of course, quite lightproof. Curtains are fixed below the inside vents, consequently air is free to pass into the room without any draught even in the roughest weather. The vents were designed and produced by the Sussex Plastering Co., Brighton.—I am, etc.,

Medical Superintendent, Eversfield
Chest Hospital.

St. Leonards-on-Sea, Dec. 7.

Medical Education in War Time

SIR,—Your Special Correspondent (*Journal,* December 9, p. 1155) is apparently unaware of the work being done at the West London Hospital Medical School. For the information of any of your readers who may share your contributor's ignorance I should be glad if you would allow me to state briefly the present position here.

We have forty-five students (thirty-four women and eleven men). All of these are working at the hospital with the exception of those attending the practical midwifery course at the West Middlesex County Hospital. While appreciating that certain advantages may accrue from a distribution of students in the sectors, as pointed out by your correspondent, I count this school fortunate in being thus able to preserve its corporate life—a not unimportant aspect of medical education. The number of beds is, of course, curtailed, but the reduction is partially compensated by a more rapid turnover of cases. All the out-patient departments, special and general, are in operation and clinical facilities are available at two adjacent L.C.C. hospitals. All the usual courses of lectures are being held.

At the time of writing we are still without our pathological department, which was closed under the Emergency Medical Service arrangements at the beginning of the war. I am hopeful, however, that this one defect in our teaching arrangements may be remedied by the New Year.—I am, etc.,

MAURICE E. SHAW,
Hammersmith, W.6, Dec. 11. Dean.

Relapses after Sulphonamide for Gonorrhoea

SIR,—I am interested in the article by Mr. A. J. Cokkinis and Dr. G. L. M. McElligott in your issue of December 2 (p. 1080).

One would think that if their somewhat depressing figures of the percentage of relapse after sulphonamide treatment approximate to the truth for the whole country the incidence of fresh cases would be steadily increasing since the introduction of the new treatment, as so many apparently cured gonococcus carriers at large among the community would be spreading the disease. That this unhappy result has not occurred must be due either to unusual self-control among the sufferers or to better experience in the number of relapses in other parts of the country. The proportion of relapses in this clinic has not been finally elucidated, as some improved methods of treatment have recently been introduced.

For the past three months an alkali (10 grains of sodium bicarbonate with each gramme of sulphapyridine) has been given throughout the treatment with a view to increasing the absorption of the drug, so that a smaller dose may be more effective. It has been found that 3 grammes daily for seven days clears up the great majority of cases and early relapses have been very infrequent. Of course the incidence of late relapses cannot as yet be estimated. Incidentally, the use of the bicarbonate appears also to have prevented gastric disturbance, which was fairly frequent before its introduction.—I am, etc.,

A. MURRAY STUART,
Medical Officer i/c,
Portsmouth, Dec. 19. V.D. Treatment Centre.

SIR,—I should like to congratulate Mr. A. J. Cokkinis and Dr. G. L. M. McElligott most sincerely on their paper in your issue of December 2, and also to state that I agree in every way with Dr. Neville Mascall's letter (December 16, p. 1204). One's experience of the increase in the defaulter rate since the institution of sulphonamide treatment would appear to be similar to that found by the early workers in the routine use of N.A.B. for syphilis—namely, that the disappearance of symptoms leads to a neglect of adequate treatment and observation and to a false sense of security. I concur also with Dr. Mascall's emphasis on the importance of the complement-fixation test for gonorrhoea in assessing "tests of cure." I should, however, add that in my opinion it is essential that the complement-fixation test be carried out in a laboratory where the technique of the test is in regular use, for by this means the personal factor in the reading of the test is reduced to a minimum. We have found at the London Lock Hospital that tests reported from laboratories where such work is rarely done are not dependable. The clinician must be prepared to re-examine a patient on whom the pathologist has reported a positive test, and will then be surprised to find how frequently he or she has overlooked a complication such as an early salpingitis. It is time that we clinicians realized that we may be saved from many mistakes by the habit of consulting with our colleagues the pathologists.

Although I have not yet collected sufficient data, I believe that Dr. Mascall's suspicion of the recent increase in "gonococcal carriers" will prove to be correct.—I am, etc.,

London, W.1, Dec. 18. GLADYS M. SANDES.

Personal Experience of Fractured Femur

SIR,—On August 26 of this year, while on leave in Newcastle-upon-Tyne, England, I fell a distance of about ten feet on to a stone kerb. My right great trochanter struck the edge and I felt the femur break. The pain was excruciating, but after a quarter of an hour I was able to get into the house, using two brooms as crutches. Later on in the day I was admitted into the Leazes Hospital under the care of the surgeon in charge of the orthopaedic department of the Royal Infirmary (Mr. Gordon Irwin), who, with that loyalty which medical men always show to their brothers in distress, came through from his week-end holiday in Cumberland specially to see me on Sunday, the 27th. *X*-ray examination on August 28 confirmed the diagnosis of fracture of the neck of the right femur, and on the 29th Mr. Irwin inserted a Smith-Petersen pin into the neck of the bone. Progress after operation was uninterrupted. I left hospital on September 3 (the day war broke out), was up on crutches on September 8 (eight days after operation), and sat up at table on September 9. One crutch was discarded on September 12 and the second on September 16, a stick being subsequently used to assist walking.

On September 21 I visited Edinburgh, driving a car part of the way there and back, and was examined by the consulting physician to the Colonial Office, Lieutenant-Colonel W. Glen Liston, and was passed as fit to return to duty to Nigeria after October 13. The remainder of my leave was spent in gardening (digging) to gain strength in my leg, and before leaving Newcastle for Liverpool on October 16 I walked a distance of five miles to test the leg out. *X*-ray examination showed the pin in excellent position, and Mr. Irwin passed me as fit. There was no shortening of the leg. As I had three days to wait in Liverpool before the ship sailed I visited the Royal Infirmary to see Mr. Watson Jones perform this operation. After seeing the *x*-ray films of my femur he described my result as perfect.

I resumed duty in Nigeria on November 8 and can walk well. I have no pain at all and my leg is now 95 per cent. normal—that is, just twelve weeks after operation.—I am, etc.,

Nigeria, Dec. 2. E. C. BRAITHWAITE.

Follicular Reticulosis

SIR,—The paper by Dr. Joan M. Ross in your issue of November 25, entitled "Classification of Non-infective Enlargement of Lymph Nodes," included a description of the condition known as follicular reticulosis. Noting that only about forty-five cases of the disease have been described I thought it would be of interest to your readers to know that we have such a case in the London Homoeopathic Hospital at present.

He is a man aged 47, employed by the L.C.C., who was admitted on November 29 as a possible case of Hodgkin's disease. He complained of swollen glands in the neck, armpits, and groins of about five years' duration. He also had swelling of the leg of four months' duration, with sciatic pain for two months. His previous history included trouble in the apex of the right lung when 18, which took the form of a general debility; an indefinite history of nervous indigestion; several attacks of influenza; a wrist abscess in 1923; and boils and carbuncles five years ago, after which the present trouble started. He had recently suffered from lassitude and increased nervousness. The family history revealed the possibility of tuberculosis on his mother's side, and of his three sisters one had an illness that might be tuberculous, while the other two were not robust.

On examination it was found that he had enlarged, solid, discrete, freely movable glands in the neck and axillae. The neck glands included one to the left of and just below the occipital protuberance. There were similarly enlarged glands in both groins and a mass of glands in the left iliac fossa at a higher level which were not so freely movable. These were somewhat tender and appeared to be embedded in the pelvic fascia. Abdominal examination revealed the liver to be palpable at the costal margin, while the spleen was grossly enlarged and appeared to occupy the entire epigastrium, extending down the left flank and to the umbilicus. Its edge could easily be felt on inspiration.

The patient's blood count showed a red cell count of 4,900,000; 98 per cent. haemoglobin; and 8,650 white cells, of which there were 67 per cent. polymorphs, 1 per cent. eosinophils, 1 per cent. basophils, 4 per cent. large mononuclears, and 28 per cent. lymphocytes. The blood sugar and blood sedimentation rate were within normal limits. Mantoux and Wassermann tests were negative. An *x*-ray film of the chest revealed no abnormality of the lung parenchyma and no enlargement of the hilar glands.

Biopsy of one of his left inguinal glands revealed a follicular reticulosis. The lymph nodes were seen to be hypertrophic, but there was no excessive fibrous tissue deposition. There was no evidence of Hodgkin's disease, lymphosarcoma, or tuberculous disease. Since admission the general condition of the patient has been quite good. He developed oedema of the left leg, presumably due to obstruction of the venous return by the enlarged glands, but this has now subsided. There is so far no evidence of effusion into the serous cavities. I should like to acknowledge my indebtedness to Dr. Joyce Peake and Dr. J. D. Kenyon for their permission to report this case.—I am, etc.,

London, W.C.1, Dec. 21. Ernest Hope Lamb.

Treatment of Varicose Ulcers

Sir,—I have been interested to read the various opinions about the treatment of varicose ulcers. I agree that practically all varicose ulcers can be cured by rest in bed, if the patients can afford time to stay there, but in my experience they never can—or at any rate never will. Some ambulant cases get rapidly well under elastoplast dressings; upon others it has no effect for the better at all.

I have recently, however, applied tannic acid jelly—I use tannex—the burn dressing, to these ulcers with promising results. I put a thin smear of jelly on the raw surface and allow it to dry on. This takes about an hour. Then I cover it with a light gauze dressing and an elastic webbing bandage. Patients say that the tannic acid jelly relieves them of any pain at once and is most comfortable. This only needs dressing twice a week, though the bandage is taken off at nights. Any accumulation of discharge can be gently expressed from beneath the scab daily, and healing seems to be very rapid.—I am, etc.,

Watlington, Oxford, Dec. 17. T. L. Crawhall.

The completion of the new Dental Department marks an important step in the Dental School of King's College Hospital, which, since its foundation, had had the use of one of the hospital wards. The removal of the department from this ward, contemplated some time ago, was hastened at the outbreak of war by the need to provide more beds for air raid casualties, should such an emergency arise. The new building will be primarily concerned with conservative treatment and the instruction of students. In declaring the department open Sir Frank Pearce, consulting dental surgeon to Guy's Hospital, said that although its Dental School was only opened in 1923, King's College Hospital already had a great dental tradition, begun by Sir John Tomes, whose lectures and writings had a profound effect on the practice of dentistry not only in this country but wherever dental surgery was practised: the tradition was continued by Samuel Cartwright, Ashley Gibbings, Arthur Underwood, and C. E. Wallis. The combination of medical and dental education under practically one roof, and in many cases by the same teachers, would be beneficial to future dental surgeons and was, in his opinion, no less important for future physicians and surgeons.

Obituary

PROFESSOR VON EISELSBERG

Professor Grey Turner writes from the British Postgraduate Medical School, London:

I should like to add a brief British tribute to the memory of that great surgeon Anton von Eiselsberg. I have the most vivid recollection of a visit to his clinic with the Surgical Club in April of 1912. I think what struck me more than anything else was the extraordinary contrast between conditions then and what I had seen during a previous stay in Vienna in 1899. At that time there were active surgical departments, but they were living on great traditions, and there seemed to be very little consideration for the individual patient. In the von Eiselsberg Clinic things were entirely different, for the great master was kindness itself to all those who came under his care, and had the greatest consideration for their every welfare. One instance especially remains in my memory. At that time Eiselsberg was recognized as a pioneer in the surgery of the pituitary, and he showed us some patients on whom he had operated for the removal of tumours by the nasal route. There was a most suitable case for operation in the clinic, and the patient was demonstrated to us, and we were extremely anxious to witness the operation. At the same time von Eiselsberg was most desirous to show us what he could, but as the patient was suffering from a slight cold he felt that the risk of infection would be greater than ought to be undertaken, and the operation had to be postponed until some time after our visit. I am sure that it was as great a disappointment to the professor as it was to his visitors, but he would not allow himself to be persuaded to do anything that might be detrimental to the welfare of the patient, and I shall always regard the incident as a fine example of surgical restraint. But to make amends von Eiselsberg demonstrated the steps of the operation on the cadaver. This was conducted in a sort of subterranean cellar, and I recall that we seemed to walk a very long way along devious corridors to a queer little out-of-the-way place where everything had to be done in artificial light. None the less, the conditions of the actual operation were closely followed, and he used all the special instruments which he had devised. Even on the cadaver it was a beautiful piece of workmanship.

But during our stay we saw a great deal of his operative work and many of the after-results, and were much impressed by his manifold activities over a wide field, for he was a great general surgeon. He appeared to be untiring, and with much else to see and to do in the happy care-free Vienna of those days we found it difficult to take advantage of all the opportunities with which he provided us. Clairmont, now of Zurich, was his first assistant, and I believe poor Ranzi was also on his staff, and it was delightful to notice the pride in their work shown by the professor and the opportunities he gave them for demonstrating their own methods. There was no sign of jealousy or officious superiority. But long after they left his service his assistants continued to look to him for inspiration and advice, and in turn he took an abiding interest in their welfare and activities. When I next saw him at work in 1929 he was nearly 70 and just about to retire from the chair. The war and after the war had profoundly affected him, and the buoyancy of former times was no more, but he was operating and regularly at work in the clinic, and with the same gentle solicitude for the welfare of his patients. It is only a couple of years ago since he published his autobiography under the title of *The Life Story of a Surgeon.*

Von Eiselsberg received many honours, and in 1913, at the time of the last International Medical Congress in London, he was admitted an honorary Fellow of the Royal College of Surgeons of England, and he was also an honorary Fellow of the Royal Society of Medicine and a Foreign Corresponding Member of the British Medical Association.

We regret to announce the death on December 16, at Lahore of Dr. James Cairns, C.I.E., O.B.E., chief medical and health officer to the North-Western Railway of India and honorary president of the Punjab Branch of the British Medical Association. He was the only son of the late Bailie James Cairns of Holyrood Crescent, Glasgow, and graduated M.A., M.B., Ch.B.Glas. in 1909. He obtained the D.P.H. of Cambridge in 1914 and the D.T.M. and H. of the English Conjoint Board in 1931. Dr. Cairns was acting M.O.H. for Bombay in 1919 and for some years held the post of principal medical and health officer to the G.I.P. Railway before his appointment to the North-Western Railway. He joined the Glasgow and West of Scotland Branch of the B.M.A. in 1923, was vice-president of the Punjab Branch in 1935–6, and president in 1936–7, and represented the Branch at the Belfast Annual Meeting in 1937.

Readers in Auckland (N.Z.) will learn with regret that Dr. Arthur W. T. F. Mickle died at Harrogate last month at the age of 85, after a trying illness cheerfully and patiently borne. The youngest son of the late Dr. David Mickle of Kirklington, Yorks, he belonged to the Lister era and qualified in Edinburgh with the L.R.C.S. and L.M. diplomas in 1877. He obtained the degrees M.B., C.M. of the University in Edinburgh in 1882 and proceeded M.D. in 1894. After holding house appointments at Edinburgh and Dundee he took several asylum appointments, and then for some years was in general practice in London. Finally he went to New Zealand and practised for many years in Auckland. "R. W. P." writes: Dr. Mickle loved that sunny island and its people, and must have been dearly loved in return. For family reasons he returned to England about eight years ago, when I first met him. He was so youthful in spirits and looks, so kindly, so simple in heart and tastes, and these qualities with his quiet good humour and his keen interest in medicine and travel and politics made up a singularly attractive personality and a fine old English gentleman.

The Services

DEATHS IN THE SERVICES

Deputy Surgeon General William Tait, R.N. (ret.), died at Alverstoke on December 13, aged 84. He was educated at the University of Edinburgh, where he graduated M.B., C.M. in 1878. He entered the Royal Navy soon after qualifying, attained the rank of deputy surgeon general on October 10, 1906, and retired on May 6, 1913. He served as surgeon on H.M.S. *Temeraire* during the Egyptian war of 1882, receiving the medal and the Khedive's bronze star. Later he served as medical officer of the gunboat *Lily* when she was wrecked on the coast of Labrador in 1889, and on H.M.S. *Cleopatra* in 1894, when she landed a party at Bluefields, Nicaragua, for the protection of the inhabitants during a rebellion. He was the author of *The Cruise of the Cleopatra* and of a *History of Haslar Hospital.*

Lieutenant-Colonel William Lincoln Baker, R.A.M.C. (ret.), died suddenly at Ferndown on December 9, aged 63. He was born on December 2, 1876, and was educated at St. Mary's Hospital, taking the M.R.C.S., L.R.C.P. in 1899. He entered the Royal Army Medical Corps as lieutenant on April 25, 1900, became lieutenant-colonel on December 26, 1917, and retired on April 20, 1920. He served in the South African War of 1899–1902, when he took part in operations in Cape Colony, Orange River Colony, and the Transvaal, and received the Queen's medal with three clasps and the King's medal with two clasps.

Lieutenant-Colonel Gerald Ainslie Kempthorne, D.S.O., R.A.M.C. (ret.), died suddenly, after an operation, on December 4 at St. Austell, aged 66. He was born on May 10, 1873, and was educated at the University of Cambridge, where he graduated B.A. in 1898, and at St. Thomas's Hospital, taking the M.R.C.S., L.R.C.P. in 1902, and later the D.P.H. of the London Colleges in 1913. After acting as house-surgeon at the Derbyshire Royal Infirmary he entered the Royal Army Medical Corps as lieutenant on August 31, 1903, became lieutenant-colonel on June 3, 1926, and retired on May 10, 1931. He served in the war of 1914–18, when he was twice mentioned in dispatches and received the D.S.O.

Universities and Colleges

UNIVERSITY OF OXFORD

C. Ounsted (Christ's Hospital) has been elected to a War Memorial Medical Scholarship of £100 at University College.

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

Final M.B.—*Part I (Surgery, Midwifery, and Gynaecology):* G. A. Ballance, E. D. Barlow, M. W. Bird, T. R. M. Bristow, P. P. Brown, B. D. Burns, J. C. K. Campbell, G. K. F. Cohen, J. G. Craddock, R. W. Danziger, R. V. Dent, W. R. B. Dickinson, J. A. Elliott, M. A. Fawkes, J. H. P. Gauvain, M. J. Greenberg, T. S. S. Gregory, M. H. K. Haggie, R. T. Hastings-James, K. M. Hay, R. C. Howard, J. H. Humphrey, R. R. Hunter, T. B. Hutton, J. D. H. Iles, R. C. Jack, J. H. Jacobs, D. W. M. James, E. E. Jones, J. Joyce, J. H. Keesey, T. A. Kemp, J. D. Kidd, H. P. König, J. A. N. Lock, B. C. H. Luker, G. T. B. MacKinnell-Childs, W. B. D. Maile, J. E. M. Melville, R. S. Monro, R. Morton, T. L. Oliver, A. Ponder, A. G. Porter, W. L. Price, J. M. Pullan, H. Rabinowitz, J. F. Roberts, D. Scott, J. F. Smith, N. Southwell, G. E. Spear, P. N. Stanbury, G. E. Stein, R. E. Symes-Thompson, J. R. Tasker, A. C. Thackray, C. C. Thomas, G. T. G. Thomas, P. D. Trevor Roper, H. D. S. Vellacott, F. A. Whitlock, H. H. Wolff, M. W. W. Wood. *Women:* J. J. H. Beattie, M. K. Cole, M. C. Simpson.

UNIVERSITY OF LONDON

At a meeting of the Senate, held on December 20, the William Julius Mickle Fellowship for 1940 was awarded to F. G. Young, D.Sc., Ph.D., and the degree of D.Sc. was conferred on T. C. Angus, a recognized teacher at the London School of Hygiene and Tropical Medicine.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examination indicated:

Final M.B., Ch.B.—Peggy Anderson, A. P. Bates, D. Bolchower, R. Cocker, Barbara H. Fiddian, P. Haslam, J. E. Horrocks, E. Lee, D. Livshin, A. Manch, A. S. Ogden, J. C. Ramsden, J. C. A. Renshaw, G. G. Robertson, W. P. Sweetnam, H. E. Thackray. *Part I:* Eva Abrahamson, I. C. Campbell, A. C. C. Davey, Elisabeth J. Davy, I. Dickson, W. Dickson, H. Diggles, J. W. Emerson, G. R. Ferguson, L. A. Gifford, B. L. Hoffmann, E. W. Jones, F. T. Jones, G. Lancaster, F. L. R. Makin, A. Manch, H. Walmsley, Mary J. Walmsley, C. S. Williams.

Third M.B., Ch.B.—*Pathology and Bacteriology:* E. P. Abson, R. G. Balf, J. Ball, J. K. Brown, D. M. Coates, B. O. Dowdell, Jeanne M. Edwards, E. Feinmann, A. Glass, J. C. Greenwood, P. G. Griffiths, *E. G. Hall, *Frances A. Hepburn, S. H. Jackson, R. P. Jepson, J. D. Johnson, H. Khazam, M. Levinson, N. A. Lewtas, D. C. Little, J. K. McMyn, F. S. Mooney, A. B. Morrison, T. E. Parry, S. S. Rose, Susanne M. Seligsohn, G. J. Shanklin, H. G. B. Slack, J. Thompson, D. H. M. Titcombe, Vera Waine, F. R. Wilde, L. Wise, B. Wolman, P. B. Woolley. *Pharmacology:* G. Ashe, A. N. Ashworth, Shirley G. Barrett, H. Bolton, D. M. Brierley, W. E. Broughton, P. Cliff, J. G. Coburn, J. A. L. Cooper, D. G. Crawshaw, Betty J. Dakin, Sheila Egan, D. Eglin, C. J. L. Elsdon, Nora F. M. Falk, S. Falk, A. I. Goodman, S. Grace, K. Heap, Mary W. P. Huddart, Esther Jackson, H. Lempert, R. L. Lunt, Elspeth M. McKechnie, C. W. Marsden, R. W. T. Mason, Eileen T. Sloane, H. F. Smith, *S. W. Stanbury, O. C. Sugden, D. Sutton, M. Swerdlow, R. H. Townshend, H. C. Warrington, J. Whewell, J. K. Wright.

* With distinction.

NATIONAL UNIVERSITY OF IRELAND

University College, Cork

The following candidates have been approved at the examinations indicated:

M.Ch.—W. F. Whelton.

M.B., B.Ch., B.A.O.—*J. B. Kearney, *P. J. Pugh, M. Bennett, M. A. Carroll, T. F. Coleman, J. J. Hennessy, J. P. Kenefick, T. McCracken, J. B. McKenna, Kathleen M. McSwiney, Anne M. Madden, J. J. Mockler, P. J. Murphy, W. P. Navin, Mary L. Neville, D. J. O'Callaghan, Nora T. U. O'Callaghan, J. S. O'Dwyer, W. P. O'Neill, D. P. F. O'Sullivan, J. V. O'Sullivan, J. A. A. Ryan. *Part II:* Winifred P. Fielding, W. P. Lee, T. Nunan, I. Tully.

D.P.H.—*Part I:* D. C. Lawton.

* With first-class honours.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh held on December 18, with Dr. H. M. Traquair, President, in the chair, the following candidates, having passed the requisite examinations, were admitted Fellows:

Y. M. E. R. Abeyesundere, T. J. Brownlee, H. Cohen, K. Das, B. K. Das Gupta, J. Dickie, A. A. Douglas, M. P. Embrey, D. Engel, M. R. Ewing, W. L. Fulthorpe, W, C. Gledhill, W. Gray, R. F. H. Hinrichsen, H. G. W. Hoare, Sa'd. Khalil, A. G. R. Lowdon, Rosamund M. J. Mackay, A. Y. Mason, W. Michie, A. C. Miller, N. M. Mody, G. H. Moore, A. Naylor, P. G. Rau, F. H. Robarts, T. F. Rose, F. J. Rutter, C. G. Scorer, J. F. Sheehan, H. A. Thomas, R. N. Traquair, L. J. Woodland.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—E. J. S. Barthorpe, E. Batley, P. S. Clarke, S. J. P. Ras, E. A. Spouse.

MEDICINE.—D. S. Foster, E. G. F. Skinner.

FORENSIC MEDICINE.—D. S. Foster, E. G. F. Skinner.

MIDWIFERY.—R. S. Holtan, C. M. Isherwood, J. Marks.

The diploma of the Society has been granted to E. J. S. Barthorpe, E. A. Spouse, and E. G. F. Skinner.

Medical News

The council of Epsom College will shortly proceed to elect two or more St. Anne's scholars. Candidates must be fully 9 years of age and must be orphan daughters of medical men who have been in independent practice in England or Wales for not less than five years. The value of each scholarship is dependent upon the means of the applicant and the locality and fees of the school selected. Forms of application for the vacant scholarships can be obtained from the secretary at the secretary's office, Epsom College, Epsom, Surrey, and must be completed and returned by January 20, 1940, at latest.

No. 1 of Volume XI of the *Index to the Literature of Food Investigation* is published on behalf of the Department of Scientific and Industrial Research by H.M. Stationery Office at 4s. 6d. This issue deals with papers received between January 1 and December 31, 1939. Henceforth each annual volume will appear in four quarterly numbers.

The issue of *Schweizerische medizinische Wochenschrift* for October 28 is dedicated to Dr. Alfred Vogt, professor of ophthalmology at Zurich and founder of the Swiss Ophthalmological Society, on the occasion of his sixtieth birthday.

The forty-fifth volume of *Uppsala Läkareförenings Förhandlingar* is a *Festschrift* dedicated to Dr. Gustaf Fr. Göthlin, professor of physiology at Uppsala. Of the twenty-nine articles nine are in English and twenty in German.

Dr. Jörgen N. Schaumann, chief physician to the St. Görans Finsen Institute, Stockholm, is to be the recipient of a jubilee number of the *Acta Medica Scandinavica* on the occasion of his sixtieth birthday. His name has been given to a generalized disease of which the skin manifestations are lupus pernio (Besnier) and Boeck's sarcoid.

The thirteenth annual report of the "UFAW" (the Universities Federation for Animal Welfare) has been circulated to members; for reasons of economy it has been drastically reduced in size. Much of the work connected with expansion is hindered by the war, but many activities will be carried on. Sir Peter Chalmers Mitchell, D.Sc., F.R.S., has become president, in succession to the late Sir Frederick Hobday. In March last the offices of the Federation were moved to Gordon House, Gordon Square, W.C.1.

In 1938 New York had the lowest general mortality on record—namely, 10.8 per thousand inhabitants.

An academy of dermatology has recently been founded in New York, with Dr. Howard Fox of New York as president.

The King has granted authority to Dr. Leigh Hunt Henderson to wear the Insignia of Officer of the Order of the Nile conferred upon him by the King of Egypt in recognition of valuable services rendered by him in the employment of the Sudan Government.

A library devoted to the history of medicine has been established at Yale University School of Medicine. Its basis will be formed by the collections of the late Dr. Harvey Cushing and of Dr. John F. Fulton, professor of physiology in the Yale Faculty.

The King of the Belgians has raised Professor Corneille Heymans, the Nobel prizeman, to the rank of Commander of the Order of Leopold.

Queen Elizabeth of Belgium has been made a doctor *honoris causa* of the Medical Faculty of Montpellier.

Announcement is made of the admission by Dr. Barnardo's Homes of the 124,000th child to benefit under their Charter—"No destitute child ever refused admission." The family always numbers about 8,250 boys and girls—a figure that in the near future seems likely to be exceeded by reason of war conditions.

The German Medical Society of New York has had its name changed to the Rudolf Virchow Medical Society of the City of New York.

An Argentine Society of Social Medicine has recently been founded at Buenos Aires.

EPIDEMIOLOGICAL NOTES

Infectious Diseases for the Week

Measles and typhoid fever are the only two important infectious diseases in England and Wales which have increased in prevalence during the week; in the former London has shared to some extent but not in the latter. The expected measles epidemic has been rather slower to appear than usual, but in recent years it has been observed that the biennial epidemics do not enter upon the explosive phase until the latter part of January, reaching the maximum in March, in London in the third week. So far the disease has been widely distributed over England and Wales, affecting rural areas as much as urban centres and avoiding the majority of large towns, including London. Notifications of enteric fever rose from 13 to 29; from eight counties more than one case was reported: Dorset 2 (both in Weymouth and Melcombe Regis M.B.); Hertford 3 (Barnet, St. Albans, and Hemel Hempstead 1 each); Lancaster 3 (Preston, Colne M.B., and Trawden U.D. 1 each); Norfolk 2 (Great Yarmouth 1, Blofield and Flegg R.D. 1); Northumberland 2 (Morpeth 1, Whitley and Monkseaton 1); Nottingham 2 (both in Sutton-in-Ashfield); Warwick 2 (both in Birmingham); Yorks (West Riding) 4 (Harrogate 2, Bradford 1, Denby Dale U.D. 1).

Although the figures for diphtheria have fallen during the week and are less than two-thirds of the level of last year, reports of a disquieting character have arrived from some centres. In Leicester county there were 27 cases, of which 11 were in the City of Leicester, compared with 31 and 13 respectively in the previous week—apparently a highly virulent strain, probably a starch-permeating or "gravis" type, as the response to serum treatment has frequently been unsatisfactory. Despite an intensive immunization campaign for nearly two years in South Shields cases continue, although usually they are mild or are in carriers. Up to December 9 there have been 476 cases in the town this year, making slightly over 100 fewer for the same period last year. In the Don Valley, in the administrative county of Yorks (West Riding), a severe type has appeared, especially in two districts—Ardwick-le-Street and Armthorpe—and 63 cases have recently been admitted to Conisborough Isolation Hospital, of which 4 patients died. In Sheffield there were 18 cases during the week, compared with 6 in Leeds.

No. 49

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended December 9, 1939.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for : (a) England and Wales London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for : (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns n Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases ; a blank space denotes disease not notifiable or no return available.

Disease	1939					1938 (Corresponding Week)

* Includes primary form in figures for England and Wales, London (administrative county), and Northern Ireland.

† Death from puerperal sepsis.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS.—All communications should be addressed to the Advertisement Manager (office hours, 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and communications with reference to subscriptions should be addressed to the Secretary, B.M.A. House.

The Telephone Number of the British Medical Association and the *British Medical Journal* is EUSTON 2111.

The Telegraphic Addresses are

EDITOR OF THE *BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.*

SECRETARY, *Medisecra Westcent, London.*

The address of the B.M.A. Scottish Office is 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh;* telephone 24361 Edinburgh), and of the Office of the Cumann Doctúirí na h-Éireann (I.M.A. and B.M.A.), 95, Merrion Square, W., Dublin (telephone 62550 Dublin).

QUERIES AND ANSWERS

Erythema of Eyelids

Dr. I. **Inman** (Portsmouth) writes: Dr. W. A. Muir (December 16, p. 1214) gives scanty details for a long-range diagnosis upon which scientific treatment might be based, but may I make a suggestion? His treatment with antiseptics points to a belief that infection may be the cause. I invite his consideration of the possibility of a non-infective erythema due to vasomotor disturbance. The condition might then be compared with pathological blushing. If Dr. Muir will refer to the *Journal* of August 19 (p. 396) he will find an article by Mr. T. G. Wynne Parry on ocular reaction to foreign protein which may help him to understand how complicated the mechanism can be. It describes how a young woman developed serious eye disease (irido-cyclitis) usually attributed to septic processes from merely touching egg. The question how the egg operates is not discussed, but, since it is impossible to believe that absorption took place through the skin, the only channel through which it could act was the mind, through association of ideas. I dealt with this aspect of Mr. Wynne Parry's case in a letter to the *Journal* of September 9 (p. 582). If Dr. Muir is interested and will communicate with me I will send him some literature on diseases of the eyelids induced in a similar way.

Dr. **Sydney Tibbles** writes: Dr. Muir might try calamine as a lotion or ointment for his patient's lids, as occasionally mercury is too stimulating. The skin of the lid is very tender, but is liable to the same complaints as that of the rest of the body. A rhubarb and magnesia mixture taken internally might help, as some cases are gastro-intestinal in origin.

Income Tax

Gifts Received from Patients

"M.D., F.R.C.S." has received numerous substantial gifts of money from patients in addition to the ordinary fees charged. Are such receipts assessable? If the authorities inquire by whom they were paid, can "M.D., F.R.C.S." plead professional privilege?

*** Various cases have been before the courts on the question of gifts (mostly in connexion with Schedule E), and the view is that each case must be considered on its own merits to decide whether the payments were made for personal or professional reasons. In the latter case they would in general be regarded as assessable. The fact that in "M.D., F.R.C.S.'s" case such receipts were numerous would suggest that the motive behind them was largely to recognize financially his professional services. The question is one of fact on which the judges are the Local or Special Commissioners—and not, for instance, the inspector of taxes—and "M.D., F.R.C.S." may feel that an appeal to them is justified in view of the amount of tax involved. Professional privilege would not seem to apply, but if "M.D., F.R.C.S." is willing to include a specific gift in hi liability there would be no justification for requiring him t disclose its source.

LETTERS, NOTES, ETC.

Cod-liver Oil and Vitamin D

Mr. K. **MacLennan**, B.Sc., general manager of British Cod Liver Oil Producers (Hull) Limited, writes: I do not wish to s ungenerous in my appreciation of the gesture made by a m with Professor Drummond's scientific reputation when he admits, as he does in your issue of December 2, that so far from cod-liver oil being displaced by any other fish-liver oil it stil provides between three-quarters and five-sixths of the major supplies of this vitamin for human nutrition. But Professor Drummond must go much further than this. The table to which I first drew his attention (page 180 of his book) gives the vitamin D values of cod-liver oil as varying from 50 to 20 units of vitamin D per gramme. Both these figures are in erro to the extent of no less than 70 per cent. in relation to wh the public can possibly or readily obtain by ordinary purchas in fact, the lower limit of 50 is in error to this extent as co pared with the minimum limit, 85 D, imposed by the *Britis Pharmacopoeia* for the legal sale of medicinal cod-liver oil. T method by which Professor Drummond arrives at his drastical reduced estimate, one-quarter to one-sixth contribution by halibu oil, is somewhat obscure, but it obviously arises from the errors in his table and involves some use of the widely advertised fallacy, for which he is apparently responsible, that certain forms of fish-liver oil are some quite unverifiable number of times richer in vitamin D values than cod-liver oil. The plain truth is that, whether from the point of view of actual or potential British or world supplies or use, the amount of vitamin D from cod-liver oil is by comparison so great as to dwarf supplies from all other fish-liver oils into almost total insignificance for the needs of human or animal nutrition.

Test for Albuminuria

"**Board Examiner**" writes: Being No. 1 examiner on a medical board, whose duties include examination of the urine, I find very few men over 50 who know the salicyl-sulphonic acid test for albumin. Most of them either boil the urine or use the nitric acid test, both taking up a good deal of time in the process; whereas just one drop of the salicyl-sulphonic acid solution from a dropper bottle into the urine in a test tube, or the conical glass supplied, gives a cloudy precipitate at once if albumin is present. Of course the other tests could be made afterwards to confirm matters if in doubt. Also for sugar, if the urinometer in the same glass shows a specific gravity of 1015 or less one can give a rough guess that there is no glycosuria, omitting, of course, such cases as that of the diabetic who tried to diddle the doctor by injecting twenty-four units of insulin before coming up for examination.

Rheumatism and Climate

Dr. C. M. **Heanley** (Salisbury, Rhodesia) writes: It is gratifying to see Sir Leonard Hill writing on this subject in the *Journal* o August 5 (p. 276). Why is it that rheumatic fever with card is entirely absent from vast areas of the world which enjo particular type of climate? If we could answer this question should help us in the fight against this disease. The caus mentioned in Sir Leonard Hill's conclusions—namely, dirty, ill-ventilated houses, density of population, and bad diet—are present in superlative degree in South China, but there is no rheumatic fever with carditis. There must be some preventive factor at work. Direct experiment is needed. If the ward was heated to about 85° F. and the humidity kept fairly high, would substances which cause the heart and joint lesions run away in the sweat? 85° F. can be quite pleasant if the humidity and clothing are right.

Disclaimer

Dr. E. J. **Thomson** writes: My attention has been called to a re-hash, in a Sunday newspaper, of the letter you recently published about my light-trap (December 2, p. 1116). I should be grateful if you would make it known that this publicity is not of my seeking. I have made no communication concerning the device except to you and a few personal friends.

The illustrations to Mr. Timbrell Fisher's article on the semilunar cartilages in the *Journal* of December 9 were taken from his book *Treatment by Manipulation*, published by Messrs. H. K. Lewis and Co. Ltd. In our notice of the *Annual Review of Biochemistry* on December 16 "Volume III" was printed in error for "Volume VIII."
